**17.** En las secciones en que la distancia desde el eje neutro hasta la fibra más baja, y el correspondiente módulo de la sección difieren de los (T y X) pertenecientes á la fibra más alta, los correspondientes á la fibra más baja se distinguen con T' y X' respectivamente.

**18.** En cada figura el eje neutro está indicado por una línea horizontal que atraviesa la sección.

**19.** El momento de inercia de cualquier figura, respecto de su eje neutro, es la suma de los momentos de inercia de sus varias partes respecto de ese mismo eje.

**20.** Sea I=al momento de inercia de la figura entera respecto á su eje neutro, *oo*;
$i$=al momento de inercia de cualquier parte respecto del eje neutro de la figura entera;
$m$=al momento de inercia de esa parte respecto de su propio eje neutro;
$a$=al área de esa parte;
$t$=á la distancia de su centro de gravedad al eje neutro, *oo*, de la figura entera.

Entonces $I=\Sigma i$; además, $i=m+at^2$.

**21.** Así, en la fig. 4,

$$i_1 = \frac{BD^3}{12} + BDt_1^2;$$

$$i_2 = \frac{bd^3}{12} + bdt_2^2;$$

$I=i_1+i_2$.

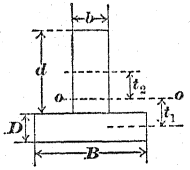

**Fig. 4.**

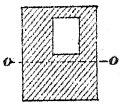

**Fig. 5.**

**22.** En consecuencia, en cualquier sección hueca, como en el rectángulo hueco, fig. 5, sea I'=al momento de inercia de toda la figura (el rectángulo sombreado y el no sombreado), $i$=al del rectángulo que falta ó no sombreado, é I=al de la porción sombreada; todos referidos al eje neutro, *oo*, de la *porción sombreada*. Tendremos : $I=I'-i$.

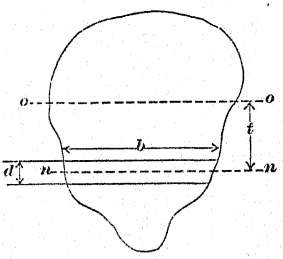

**Fig. 6.**

**23.** En el caso de una sección irregular, como la fig. 6, divídase la sección en numerosas fajas, paralelas al eje neutro y bastante angostas para poderlas considerar como rectángulos; y procédase como en los §§ 19 á 21.

**24.** Mientras más angostas se toman las fajas, más pequeño se hace $m$. Si las fajas se toman tan angostas (relativamente á la altura de la sección), que $m$ pueda despreciarse, entonces $I=\Sigma t^2 a$, como en el § 10. Las fajas no necesitan ser de ancho uniforme.

## El módulo de la sección (ó momento resistente).

**25. Definición.** Si el momento de resistencia, $R = \frac{S}{T}$. $\Sigma t^2 a$, se divide por el esfuerzo por unidad de superficie, S, en las fibras extremas, el cociente, $X = \frac{R}{S} = \frac{\Sigma t^2 a}{T} = \frac{I}{T}$, se llama momento resistente ó módulo de la sección. Éste, como el momento de inercia, §§ 14, etc., es una cantidad puramente *geométrica*, que depende solamente de las dimensiones y de la forma de la sección, y es independiente de la substancia, de la luz y del modo de estar la carga.

**26.** Teniendo el módulo de la sección, X, no tenemos más que multiplicarlo por el esfuerzo por unidad de superficie, S, en las fibras extremas, para obtener el momento de resistencia, R=SX.

**27.** Multiplicando el módulo de la sección, X, por la distancia, T, del eje neutro á las fibras más distantes, obtenemos el momento de inercia, I=TX.

**28.** El módulo de la sección ó momento resistente se da de ordinario en las tablas de vigas laminadas, canales, etc.

## Carga. Resistencia.

**29. El siguiente cuadro ilustrado** da (1) el momento máximo, M, correspondiente á un peso dado; y (2) el peso, W*, correspondiente á un esfuerzo dado, S, por unidad de superficie en diferentes condiciones de apoyo y de carga. En este cuadro,

M = momento máximo de flexión;
R = M = momento de resistencia de la sección transversal;
W = carga total extraña * sobre la viga, ya concentrada en un punto (como se ha mostrado), ya uniformemente distribuída sobre la luz;
$l$ = la abertura ó luz;
S = al esfuerzo por unidad de superficie en las fibras más distantes del eje neutro, debido al peso extraño, W *;
T = á la distancia del eje neutro á las fibras más distantes;
I = al momento de inercia.

En vigas rectangulares,

$b$ = ancho;
$d$ = alto;
I = momento de inercia = $\frac{bd^3}{12}$;
$n = \frac{Wl}{Sbd^2}$.

De los diagramas debajo de cada carga, el primero representa los momentos y el segundo los esfuerzos cortantes en las varias partes de la luz.

**30.** Si S=al esfuerzo permitido por unidad de superficie de la fibra, entonces, en las fórmulas que preceden, W=al peso extraño permitido *.

**31.** Se notará que las resistencias de vigas seme(antes son proporcionales á los valores de $\frac{bd^2}{l}$; esto es: las resistencias de vigas de secciones transversales semejantes son directamente proporcionales á susanchos, a los cuadrados de sus alturas; é inversamente proporcionales á sus luces.

---

* Aquí se supone la viga sin peso. Veanse §§ 42, etc.

| **Para los símbolos,** véase la página que sigue. | M=R **Momento máximo de flexión.** | (Véase final § 10.) **Peso, W, y esfuerzo, S.** S=MT /I=RT /I. **En general.** | **En vigas rectangulares.** | **n** |

| | | $S = \frac{WT}{12I}$ | $S = \frac{WTl}{bd^3}$ <br> $= \frac{Wl}{2bd^2}$ | |

## Símbolos en el cuadro enfrente.

**M**=momento máximo de flexión;
R=M=momento de resistencia de la sección transversal;
S=tensión por unidad de superficie debida á W, en las fibras extremas;
T=distancia del eje neutro á las fibras extremas;
I=momento de inercia; M=momento de flexión máximo;
W=carga; $l$=luz.

En vigas rectangulares $\begin{cases} b=\text{ancho}; \\ d=\text{alto}; \end{cases}$ $n=\dfrac{Wl}{Sbd^2}$; $W=nS\dfrac{bd^2}{l}$.

## Viga de 1 cm cuadrado y 1 decímetro de luz *.

**32.** En una viga, de un cm en cuadro y 1 dcm (10 cm) de abertura ó luz, sostenida en ambos extremos, tenemos, para el peso extraño en el centro ** :

$$W'=S\frac{2bd^2}{3l}=\frac{nSbd^2}{l}=S.\frac{2}{3\times10}=\frac{S}{15};\ \text{de donde } S=15W'.$$

**33.** Para cualquier otra viga rectangular, sea L=á la luz en m. Entonces, el peso extraño W en el centro **, requerido para producir la misma tensión por unidad. S, en las fibras extremas, es

$$W=W'\frac{bd^2}{L}.$$

**34.** Así, para pino amarillo, sea S=á la tensión permitida por unidad de superficie=1,620 lbs por pulg cuad ó sean como 114 kg por cm cuad. Entonces, para una viga de 1 cm en cuadro, 1 dcm de luz, sostenida en ambos extremos y cargada en el centro, el peso ** permitido, W', es

$$W'=\frac{nS}{10}=\frac{2S}{3\times10}=\frac{S}{15}=\frac{114}{15}=7.6\ \text{kg};$$

y para una viga de 8×30 cm y 6 metros de luz (= 60 dcm), la carga extraña** central permitida es

$$W=W'\frac{bd^2}{l}=7.6\frac{8\times(30)^2}{60}=7.6\frac{8\times900}{60}=912\ \text{kg};$$

y la carga extraña uniforme permitida es $2W=2\times912=1{,}824$ kg.

**35.** Si se dan el peso, W, la luz, L, y el coeficiente, W', tenemos $bd^2=\dfrac{WL}{W'}$

Así, en el caso de la viga de pino amarillo, mencionada en el § 34, de 6 m de luz con un peso extraño** uniforme, donde $2W=912\times2$, tenemos

$$bd^2=\frac{WL}{W'}=\frac{912\times60}{7.6}=7{,}200.$$

**36.** Entonces, si se da $b$ ó $d$, el otro se encuentra fácilmente. Si no, asignésele á uno ú otro de ellos un valor arbitrario. Así, si $b=6$, tenemos $d^2=\dfrac{7{,}200}{6}=1{,}200$;

y $d=\sqrt{1{,}200}$=digamos 35.

**37.** Con la regla de cálculo pueden hacerse estas operaciones.

**38.** Si la relación, S=15W' se considera más allá del límite de elasticidad, y si W'=al peso central de ruptura, en una viga de cualquier substancia, de un cm cuadrado y de 1 dcm de luz, sostenida en ambos extremos; entonces, para cualquier otra viga de la misma substancia, y de $b$ cm ancho y $d$ de alto y L dcm de luz, el peso central de ruptura sería $W=W'\dfrac{bd^2}{L}$.

**39.** A pesar de la base defectuosa de este método, aplicado á pesos fuera del límite de elasticidad, su sencillez lo hace muy conveniente y está muy en uso. Véase el siguiente cuadro de valores de W', y el ejemplo, § 40.

---

* *N. del T.* — Hemos cambiado los ejemplos que trae el autor por los análogos en sistema métrico, y con los elementos adecuados, para que resulten también análogas las comparaciones en conexión con la tabla que sigue.

** La viga aquí se supone sin peso; para tomar éste en consideración véanse §§ 42, etc.

**Cargas centrales de ruptura, W', en kilogramos, para vigas de un centímetro cuadrado de sección transversal y de un decímetro de luz, apoyadas en ambos extremos *.**

En las vigas de madera deduzcase en la práctica una tercera parte por nudos, torceduras, etc.

**40. Ejemplo.** En la viga de pino amarillo, §§ 34 á 36, de 8×30 cm y de 6 m de luz, tenemos de la tabla última, W′=42.2 kg. En consecuencia :

Carga central de ruptura * $W = W' \frac{bd^2}{L} = \frac{42.2 \times S \times 900}{60} = 5{,}064$ kg, ó como 5.5 veces el peso permitido encontrado, por medio de la tensión permitida por unidad de superficie, en el § 34.

## Dimensiones.

**41.** Puesto que $W = nS \frac{bd^2}{l} = W' \frac{bd^2}{L}$, y $W' = \frac{nS}{10}$, tenemos *

$$\textbf{Ancho} = b = \frac{Wl}{nSd^2} = \frac{Wl}{W'd^2};$$

$$\textbf{Alto} = d = \sqrt{\frac{Wl}{nSb}} = \sqrt{\frac{WL}{W'b}};$$

donde W=carga extraña* requerida;

W′=carga extraña en vigas de 1 cm cuadrado y 1 dcm de luz;

$n$=coeficiente de la última columna de la tabla $= \frac{Wl}{Sbd^2}$;

S=tensión en la fibra por unidad de superficie;

$l$=luz en cm;

L=luz en dcm.

## Peso de la viga considerado como carga.

**42.** Por simplificar hemos considerado hasta ahora nuestros *cantilevers* y vigas sin peso propio, y, en vigas de dimensiones moderadas como se emplean de ordinario, su propio peso, $w$, es tan pequeño, en comparación con sus cargas, W, que puede casi siempre y sin riesgo ser despreciado; pero en las vigas grandes debe generalmente tomarse en cuenta. Los pesos, encontrados como se ha dicho, con S=la mayor tensión permitida por unidad de superficie, debe entonces comprender no sólo el peso extraño, W, sino también el peso, $w$, de la viga misma, para una longitud=á la luz.

**43.** Si la viga es de sección transversal uniforme, su peso, $w$, obra como uniformemente distribuído, y tenemos, para el peso, ó carga extraña, W, en el caso de un peso central concentrado en una viga, ó de un peso concentrado en el extremo de la longitud, $l$, en *cantilevers*,

$$W = \text{peso ó carga total} — \frac{w}{2};$$

en el caso de un peso uniformemente distribuído,

$$W = \text{peso ó carga total} — w.$$

* Se supone que la viga no tiene peso; para tomar éste en consideración, véanse §§ 42 etc.

**44. Al encontrar el ancho ó el alto** de una viga rectangular, que ha de llevar un peso dado con una luz dada y un esfuerzo dado por unidad de superficie, podemos tener en cuenta el peso con aproximaciones sucesivas. Así,

**45. Para encontrar el ancho,** $b$, requerido para una viga de alto dado, $d$; despréciese el peso, $w$, de la viga y encuéntrese el primer ancho aproximado, $b$, por las fórmulas del § 41, para el peso extraño, W. Luego, calcúlese el peso, $w$, del una viga con ancho, $b$, trátese dicho peso como distribuído uniformemente; y por las mismas fórmulas, encuéntrese el ancho adicional, $b'$, requerido para llevar este peso adicional, $w$. Entonces $b+b'$=un segundo ancho aproximado. Si fuere necesario, encuéntrese el peso, $w'$, de una viga de ancho, $b'$, y, de éste, un segundo ancho adicional, $b''$, requerido para sostenerlo. Entonces, $b+b'+b''$=un tercer ancho aproximado, y así sucesivamente.

**46. Para encontrar el alto,** $d$, que necesita una viga de ancho dado, $b$; encuéntrese un primer alto aproximado, $d$, por la fórmula, § 41, para el peso extraño W. Encuéntrese el peso, $w$, de una viga de ese alto; y aplíquese otra vez la fórmula, usando (en lugar de W) $W+w$, si W es peso uniforme, ó $W+\frac{w}{2}$, si W está concentrado. El alto, $d'$, así encontrado, es una segunda aproximación. Podemos otra vez aplicar la fórmula, como antes, usando el peso, $w'$, de la viga de alto $d'$; ó, más sencillamente, auméntese el ancho, como en el § 45.

**47.** En la práctica, las vigas de sección rectangular son casi siempre de madera; y tales vigas se consiguen á precios económicos solamente con ciertos tamaños comerciales. En consecuencia, basta generalmente la segunda aproximación.

## Fuerzas y pesos de vigas semejantes, de diferentes dimensiones. Comparación entre modelos y formas reales.

**48.** En cualquier viga dada, sea $W_1$=al peso que cause cualquier tensión dada, S, por unidad de superficie. Entonces, $W_1 = \frac{nSbd^2}{l}$ (para $n$, véase cuadro pág. 496); y, en cualquier viga semejante, de $a$ veces el ancho, altura y luz, el peso correspondiente, $W = \frac{nSaba\,d^2}{al}$. En consecuencia, la razón de sus *cargas* es $\frac{W}{W_1} = a^2$; ó $W=a^2W_1$; pero la razón de sus *pesos* es $\frac{w}{w_1} = \frac{abadal}{bdl} = a^3$; ó $w=a^3w_1$.

**49.** En otras palabras, comparando una viga con otra, de $a$ veces su ancho, alto y luz, sus resistencias están como los *cuadrados* de sus respectivas dimensiones; pero sus pesos están como los *cubos* de esas dimensiones.

**50.** En consecuencia, si un modelo de una viga se rompe precisamente bajo una carga uniforme (que incluya su propio peso, $w$)=2, 3 ó 4, etc., veces su propio peso, entonces una viga de semejante sección transversal, pero de 2, 3 ó 4, etc., veces su ancho, alto y luz, se romperá bajo su propio peso solamente.

## Esfuerzo cortante horizontal. Véanse también los §§ 119-122.

**51.** Cuando (figs. 7 y 8) ocurre flexión en un *cantilever* ó una viga compuesta de capas horizontales separadas, como una pila de tablas sueltas, las varias capas resbalan unas sobre otras; pero, si están firmemente unidas entre sí ó por otro

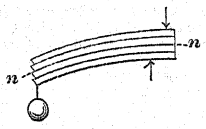

Fig. 7.

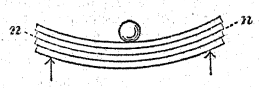

Fig. 8.

medio impedidas de resbalar, ejercen, una sobre otra, un esfuerzo cortante horizontal. En cualquier sección, esta fuerza disminuye desde un máximum en la superficie neutra, $nn$, hasta cero, en la parte superior y en la inferior.

**52.** En cualquier sección de una viga rectangular el esfuerzo cortante horizontal máximo, por unidad de superficie neutra, es

$$H = \frac{3V}{2bd};$$

donde V=al esfuerzo cortante vertical en la sección, y $b$ y $d$=el ancho y el alto de la sección.

Dicho de otro modo, la unidad del esfuerzo cortante horizontal, en cualquier punto, es directamente proporcional al vertical en ese punto. En consecuencia, el diagrama del esfuerzo cortante horizontal es semejante, en la forma, al diagrama del vertical; pero en sentido contrario, correspondiendo el esfuerzo cortante vertical positivo al horizontal negativo.

**53.** Si al esfuerzo cortante horizontal se le opone resistencia por medio de un borde ú obstáculo aplicado á un solo punto, dicho obstáculo debe hacerse suficientemente fuerte para resistir á la *suma de todos* los esfuerzos cortantes horizontales desde dicho punto hasta aquel en donde el esf cort es=0.

**54.** En la fig. 9, los diagramas (*b*) y (*c*) muestran respectivamente los momentos y los esfuerzos cortantes verticales debidos á pesos concentrados y distribuídos en una viga como indica la figura; y, en la fig. (*d*), cada ordenada representa la fuerza que debe aplicarse en dicho punto para resistir á la suma de todos los esfs corts horizontales entre ese punto y el punto en que aquéllos son cero. Las ordenadas por sobre una línea cero indican momentos ó esfs corts positivos y viceversa. En los momentos *positivos*, el segmento á la *izquierda* de una sección tiende á girar

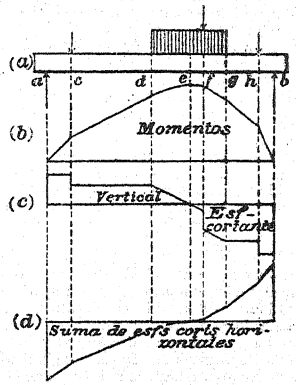

**Fig. 9.**

« como el minutero ». (Véase *N. del T.* pág. 463.) En los esfs corts *positivos*, el segmento de la *izquierda* tiende á *resbalar hacia arriba* ó el segmento *superior* á *resbalar* hacia la *derecha*. Entre *a* y *c*, entre *c* y *d*, entre *g* y *h*, y entre *h* y *b*, todos los diagramas son líneas rectas, siendo las figs. (*b*) y (*d*) inclinadas y la fig. (*c*) horizontal. En *c* y en *h*, las figs. (*b*) y (*d*), cambian su inclinación, y la fig. (*c*) cambia su posición. Entre *d* y *f* y entre *f* y *g* (esto es: bajo el peso distribuído), las figs. (*b*) y (*d*) son curvas parabólicas, y la fig. (*c*) muestra líneas rectas inclinadas. En *f*, las figs. (*b*) y (*d*) cambian de curvatura y la fig. (*c*) cambia su posición. En *e*, punto del momento máximo, las figs. (*c*) y (*d*) cambian de signo. Véase Relación entre el momento y el esfuerzo cortante, §§ 359 á 368 (Estática).

**55.** Atendiendo á que el esfuerzo cortante horizontal es una resistencia á la flexión, al no tomarlo en cuenta, en la teoría común de las vigas, como se ha explicado hasta ahora, contribuye en general á la seguridad. Pero, en vigas compuestas de capas horizontales, deben emplearse medios para transmitirlos de una capa á la inmediata.

**56.** Así, vigas de madera muy altas, fig. 10, se hacen frecuentemente de dos ó más vigas, una sobre otra. Para impedir la flexión, debido al resbalamiento de uno de estos maderos sobre el otro, se insertan bloques entre ellos á intervalos, como indica la figura, ó se ranuran los lados adyacentes de los maderos de modo que se compe-

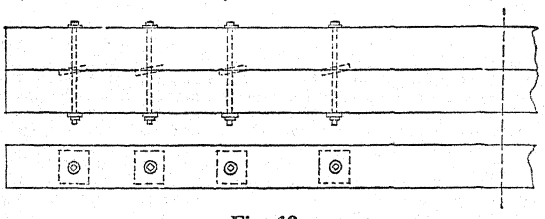

**Fig. 10.**

netren. En uno ú otro caso, los maderos están estrechamente ligados entre sí. Los bloques ó ranuras sirven entonces para transmitir el esf cort horizontal de un madero al otro. En la fig. 10 los bloques son más frecuentes cerca de los extremos, como lo exige el diagrama del esfuerzo cortante horizontal, fig. 9 (*d*).

## Flexiones.

**57. El cuadro del frente** da las **flexiones** dentro del límite de elasticidad de cualquier viga de sección transversal uniforme **bajo diferentes disposiciones de apoyo y de carga**; también da (en la última columna) el **peso** *extraño* **que producirá una flexión dada**, sin ayuda del peso de la viga misma. Todas las fórmulas están basadas en el supuesto de que el aumento de flexión es proporcional al aumento de peso.

Las letras tienen los significados que siguen :

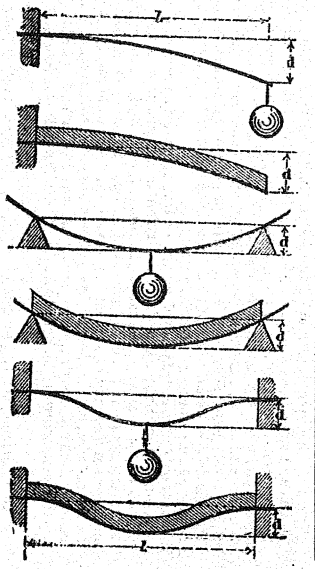
$d$ = flexión de la viga, en cm (véanse las figs.);
**W** = el peso extraño, en kg;
$w$ = peso de la viga en una longitud igual á la abertura ó luz, en kg;
$l$ = longitud de la viga sobre la luz, en cm (véanse las figs.);
**E** = módulo de elasticidad del material de la viga, en kg por cm cuadrado;
**I** = momento de inercia de la sección transversal de la viga, en cm (cuatro dimensiones).

Véase atrás Momento de inercia, § 14.

(*Obs. del T.*— Creemos oportuno advertir que, al hacer uso de estas fórmulas y de sus análogas, es necesario tener cuidado en que resulte homogénea la fórmula empleando las mismas unidades de medida en la valoración de las cantidades que entran en ellas. Si, por ejemplo, se toma á W y $w$ en kg y $l$ en metros, debe tomarse entonces el valor de E en kg por metro cuadrado y el valor de I (de cuatro dimensiones) se formará con el metro por unidad. El valor de la flexión, $d$, vendrá entonces en metros. Se procederá de modo análogo cuando se tome el milímetro por unidad.

También juzgamos oportuno agregar las fórmulas para la flexión cuando la viga (1.°) está *apoyada* en los extremos y cargada con un peso W *en cualquier punto* de su longitud; y (2.°) en las mismas condiciones, *pero empotrada* en ambos extremos. Llamando $m$ y $n$ las distancias de la carga á los apoyos, la flecha $d$, para el primer caso, será $= \frac{1}{3} \times \frac{Wm^2n^2}{EIl}$ ; para el segundo caso, $= \frac{1}{3} \frac{Wm^3n^3}{EIl}$).

**Flexión de vigas de sección transversal uniforme.** (Para el significado de las letras, véase pág. 502.)



| Si la viga está : | Flexión $d$, en cm, causada : por pesos extraños. | por peso de la viga. | por peso de la viga y carga. | Peso extraño para una flexión dada (se desprecia el peso de la viga). |
|---|---|---|---|---|
| Fija en un extremo y cargada en el otro. | $\frac{1}{3}\ \frac{l^3\ W}{E\ I}$ | $\frac{1}{8}\ \frac{l^3\ w}{E\ I}$ | $\frac{1}{3}\ \frac{l^3\ (W + \frac{3}{8}\ w)}{E\ I}$ | $3\ \frac{d\ E\ I}{l^3}$ |
| Fija en un extremo y cargada uniformemente. | $\frac{1}{8}$ " | $\frac{1}{8}$ " | $\frac{1}{8}\ \frac{l^3\ (W + w)}{E\ I}$ | 8 " |
| Apoyada en ambos extremos y cargada en el centro. | $\frac{1}{48}$ " | $\frac{5}{384}$ " | $\frac{1}{48}\ \frac{l^3\ (W + \frac{5}{8}\ w)}{E\ I}$ | 48 " |
| Apoyada en ambos extremos y cargada uniformemente. | $\frac{5}{384}$ " | $\frac{5}{384}$ " | $\frac{5}{384}\ \frac{l^3\ (W + w)}{E\ I}$ | $\frac{384}{5}$ " |
| Fija en ambos extremos y cargada en el centro. | $\frac{1}{192}$ " | $\frac{1}{384}$ " | $\frac{1}{192}\ \frac{l^3\ (W + \frac{1}{2}\ w)}{E\ I}$ | 192 " |
| Fija en ambos extremos y cargada uniformemente. | $\frac{1}{384}$ " | $\frac{1}{384}$ " | $\frac{1}{384}\ \frac{l^3\ (W + w)}{E\ I}$ | 384 " |

De los principios comprendidos en el cuadro anterior encontramos que en vigas de sección semejante y de la misma substancia y dentro del límite de elasticidad, el peso y las flexiones (despreciando el peso de la viga misma) están como sigue :

| Con igual | Las flexiones bajo un peso extraño dado varían en razón |
|---|---|
| luz | inversa á los anchos y como los cubos de los altos |
| — y ancho | — á los cubos de los altos |
| — y alto | — á los anchos |
| ancho y alto | directa de los cubos de las luces. |

| Con igual | Los pesos extraños para una flexión dada varían en razón |
|---|---|
| luz | directa á los anchos y como los cubos de los altos |
| — y ancho | — á los cubos de los altos |
| — y alto | — á los anchos |
| ancho y alto | inversa á los cubos de las luces. |

**Flexión en función de la tensión por unidad de superficie en la fibra extrema.** En el cuadro, pág. 496, el peso $W = kS\frac{I}{Tl}$; donde $k$=á un coeficiente, como se indica abajo; S=á la tensión por unidad de superficie en las fibras extremas; I=momento de inercia; T=distancia del eje neutro á la fibra extrema y $l$=á la luz. Del cuadro último, tenemos ·

$W = m\frac{dEI}{l^3}$; donde $m$ = un coeficiente, como se indica abajo; $d$ = flexión, y E=módulo de elasticidad. En consecuencia, $Sk\frac{I}{Tl} = m\frac{dEI}{l^3}$; y $d = \frac{k}{m}\cdot\frac{l^2S}{ET} = \frac{l^2S}{ETc}$

donde $c = \frac{m}{k}$.

| | | | |
|---|---|---|---|
| En un *cantilever*, cargado en el extremo, | $m=$ 3; | $k=$ 1; | $c=$ 3. |
| — — — uniformemente, | $m=$ 8; | $k=$ 2; | $c=$ 4. |
| En una viga apoyada, y cargada en el centro, | $m=$ 48; | $k=$ 4; | $c=$12. |
| — — — — uniformemente, | $m=$ 76.8; | $k=$ 8; | $c=$ 9.6. |
| — — empotrada, — en el centro, | $m=$192; | $k=$ 8; | $c=$24. |
| — — — — uniformemente, | $m=$384; | $k=$12; | $c=$32. |

## Límite de elasticidad.

**58.** Bajo cargas moderadas, las flexiones son prácticamente proporcionales al peso. Cuando ellas empiezan á aumentar perceptiblemente con más rapidez que el peso, se dice que el último ha llegado al límite elástico ó límite de elasticidad. Es generalmente en este punto donde la « **deformación permanente** » se hace por primera vez perceptible; esto es : después de removido el peso, la viga no vuelve á su estado original y permanece más ó menos cimbrada. Las flexiones empiezan entonces también á aumentar *irregularmente*, y continúan indefinidamente sin aumentos de peso. En breve, la viga está en peligro. En consecuencia el peso efectivo nunca *debe exceder* al límite de elasticidad; no debe pasar de un tercio á dos tercios de su valor, según las circunstancias.

**El límite de elasticidad de una viga** de cualquier forma ó material especial, **se determina experimentalmente** con una viga semejante, como en el caso de las constantes de cargas de ruptura, etc., de la manera siguiente : Cárguese una viga en el centro, por la cuidadosa adición gradual de pesos pequeños iguales; anótese cuidadosamente la flexión que ocurre dentro de algunos minutos (mientras más, mejor) después de haberse aplicado cada peso, á fin de averiguar cuándo empiezan las flexiones á aumentar más rápidamente que los pesos, porque, cuando esto ocurre, se ha llegado á la carga del límite de elasticidad *.

* Naturalmente, en la práctica es difícil con frecuencia averiguar con precisión

No son las flexiones de *toda* la viga las que han de anotarse, sino las de la luz solamente. Deben ensayarse varias vigas, á fin de obtener una constante *media*, pues aun en vigas de hierro laminadas del mismo modelo y del mismo hierro, hay diferencias muy apreciables de resistencias y flexiones.

Entonces, para obtener las constantes, usando el *peso total* aplicado durante las flexiones iguales, incluyendo la mitad del peso de la viga misma, tenemos :

$$\textbf{Constante para el límite de elasticidad} = \frac{\text{luz en m} \times \text{peso total en kg}}{\text{ancho en cm} \times \text{cuadrado del alto en cm}}.$$

**La constante, para vigas de madera,** puede obtenerse, con bastante aproximación para la práctica común, tomando un *tercio* de las constantes de *ruptura* en el cuadro del § 39.

(*Obs. del T.* — Creemos oportuno aclarar un poco más este punto. Esta constante experimental se encuentra cargando una viga en las condiciones dichas con el peso máximo que la lleva á su límite de elasticidad; luego, de acuerdo con la fórmula $\frac{bd^2}{l}$ ($b$=ancho en cm; $d$=alto en cm; $l$=luz en m), se encuentra que una viga de *un metro* de luz resistirá (llamando $c$ la carga dicha en kg), $l$ veces más carga, ó sea $c \times l$, y para un cm de ancho y uno de altura $\frac{c \times l}{bd^2}$, que es la fórmula dada en lenguaje vulgar. Si se la quiere para una viga de un decímetro de largo, el multiplicador de la carga en el numerador será el número de decímetros que tenga la viga.)

Dicha constante, así calculada, es pues el límite de elasticidad de una viga de la forma y material dados de 1 cm de ancho, 1 cm de alto y un m de luz sostenida, en ambos extremos y cargada en el centro. Para obtener ahora el límite de elasticidad de cualquier otra viga de la misma forma ‡ y del mismo material, sostenida y cargada de modo análogo, pero de otras dimensiones, tendremos :

$$\textbf{Límite de elasticidad} = \text{constante} \times \frac{\text{ancho en cm} \times \text{cuadrado del alto en cm}}{\text{luz en m.}}$$

| Si la viga está | | | | Multiplíquese el resultado por |
|---|---|---|---|---|
| sostenida en ambos extremos y cargada | | | en el centro, | 1 |
| — | — | — | — uniformemente, | 2 |
| empotrada † | — | — | — en el centro, | 2 |
| — | — | — | — uniformemente, | 3 |
| — | un extremo | | — en el otro extremo, | 1/4 |
| — | — | | — uniformemente, | 1/2 |

---

cuándo ó bajo qué peso empiezan efectivamente las flexiones á aumentar más rápidamente que los pesos sucesivos. Pues, aunque *por la teoría* las flexiones son prácticamente iguales para pesos iguales, hasta que se llega al límite de elasticidad, sinembargo, *de hecho*, están sujetas á más ó menos irregularidades; pues nunca el material de que se compone una viga es perfectamente uniforme en toda su extensión, en contextura y fuerza. En consecuencia, no siempre habrá aumentos regulares de flexión, sino que tendremos variaciones á veces más grandes y otras más pequeñas. Por consiguiente, se requiere un buen criterio para determinar el punto final. Es mejor, en caso de duda, inclinarse hacia el dato de más *seguridad*. Supónese siempre que el peso no está sujeto á movimientos ni vibraciones. Estos aumentarían las flexiones.

† Dícese que una viga está « empotrada » (bien fijada) en uno ú otro extremo cuando la tangente al eje longitudinal de la viga flexada en ese extremo permanece siempre horizontal.

‡ Las formas de las dos vigas no necesitan ser *semejantes*. Por ejemplo, la constante deducida de experimentos en cualquier viga rectangular es aplicable á cualquier otra viga rectangular, sea cuadrada ú oblonga.

## La curva de elasticidad.

**59.** Cuando un *cantilever*, fig. 1, ó una viga, fig. 2, sostenida ó empotrada de cualquier manera se flexa bajo la acción de cualquier peso, la superficie neutra, *nn*, forma una curva tal, que, en cualquier sección,

$$R = \frac{EI}{M} = \frac{IS}{Mk};$$

donde R = al radio de curvatura, en la sección;
M = el momento de flexión, en la sección;
I = el momento de inercia de la sección;
E = el coeficiente de elasticidad del material $= \frac{S}{k}$;
S = cualquier esfuerzo por unidad de superficie dentro del límite de elasticidad.
*k* = á la unidad de alargamiento ó acortamiento producido en el material por S como fuerza de tensión ó compresión.

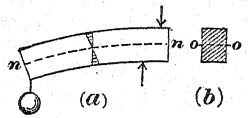


**Fig. 1 (repetida).**

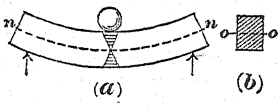

**Fig. 2 (repetida).**

## El coeficiente de flexión.

**60. Definición.** El coeficiente de flexión, para cualquier material dado, es la flexión, en cm, de una viga, de ese material, de un cm en cuadro y de 1 m de luz**, sostenida en cada extremo, y llevando en su centro un peso extraño de 1 kg — $^5/_8\,w'$, donde $w'$ = peso de la parte de viga que ocupa la luz en kg.

**61.** Sea *y* = el coeficiente de flexión para cualquier material dado. Entonces, en cualquier viga rectangular del mismo material, con peso central ó peso uniforme, sean

*b* = el ancho, en cm;
*d* = el alto, en cm;
L = la luz, en metros;
*w* = el peso, en kgs, de la parte de la viga misma que ocupa la luz;
W = peso central $+ \,^5/_8\,w$;
$= \,^5/_8$ (peso uniforme $+ w$).

Entonces, en la viga dada, tendremos:

$$\textbf{Flexión} = Y = y\,\frac{W.L^3}{b.d^3}; \quad \textbf{Ancho}\,* = b = W.\frac{L^3.y}{d^3.Y};$$

$$\textbf{Carga} = W = Y.\frac{b.d^3}{L^3.y}; \quad \textbf{Alto}\,* = d = L\sqrt[3]{\frac{Wy}{bY}}.$$

**62.** El coeficiente de flexión, *y*, para cualquier material dado, se obtiene experimentalmente, así: En el centro de cualquier viga rectangular, del material dado, colocada horizontalmente sobre dos apoyos, separados por cualquier distancia conveniente y conocida, colóquese cualquier peso que esté dentro del límite de elasticidad y mídase la flexión resultante, Y. Sea W = al peso central extraño $+ \,^5/_8\,w$, donde *w* = al peso de la luz de la viga. Entonces el coeficiente de flexión es

$$y = Y.\frac{b.d^3}{W.L^3};$$

---

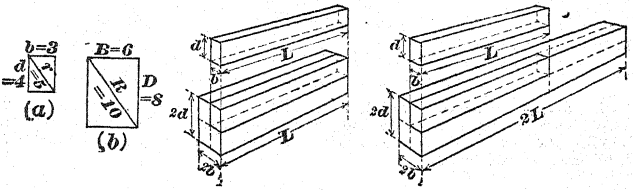
* Al calcular el ancho ó el alto, si es necesario contar con el peso de la viga misma, hacemos primero W = al peso extraño solamente, y luego procedemos por aproximaciones sucesivas, como en los §§ 45 y 46, recordando, sin embargo, que en el caso de flexiones 5/8 del peso de cada sección adicional ha de tomarse como peso central equivalente, y no 1/2 como en el caso de resistencias.

** *N. del T.*— Puede tomarse, para la luz, el decímetro como unidad; pero recuérdese entonces que, suponiendo iguales las otras condiciones, las flexiones son proporcionales á los cubos de las luces; ó bien las cargas que producen una misma flexión, están en razón inversa de los cubos de las luces. (Véase comienzo pág. 504.)

donde $b$ y $d$ = al ancho y el alto, en centímetros, y L = á la luz, en metros, de la viga con que se hace la experiencia.

**63.** La relación entre cualesquiera dos líneas homólogas, en cualesquiera dos figuras ó cuerpos semejantes, es constante. En consecuencia, al determinar ó usar coeficientes, ya para resistencia, ya para flexión, comparando vigas de secciones semejantes pero de tamaños diferentes, podemos usar cualesquiera dos líneas homólogas en lugar de los dos anchos, ó en lugar de los dos altos.

Así, en las figs. 11, B/$b$ = D/$d$ = R/$r$ = 2.



**Figs. 11.** **Fig. X.** **Fig. Y.**

Por tanto,

$$\frac{BD^2}{bd^2} = \frac{384}{48} = 8 = 2^3 = \frac{RR^2}{rr^2}; = \frac{1,000}{125} = 8 = 2^3;$$

También,

$$\frac{BR^2}{br^2} = \frac{6\times100}{3\times25} = \frac{600}{75} = 8 = 2^3.$$

También,

$$\frac{B^3D}{b^3d} = \frac{1,728}{108} = 16 = 2^4 = \frac{R^3R}{r^3r} = \frac{10,000}{625} = 16 = 2^4.$$

**63 a.** De lo precedente y del § 31, pág. 495, se sigue que, con *secciones transversales semejantes* pero *aberturas ó luces iguales*, fig. X, las resistencias son proporcionales á los *cubos* de cualesquiera líneas homólogas en las dos secciones; pero, con vigas semejantes *en todos respectos, inclusive la luz*, fig. Y, las resistencias están como los *cuadrados* de cualesquiera líneas homólogas en las dos secciones; esto es : como las *áreas* de las dos secciones.

**64. Coeficiente de flexión** para vigas de sección transversal rectangular. Véanse §§ 60, 61. Viga de 1 cm en cuadro y 1 metro = 100 cm de luz. W (= peso central + $^5/_8$ × peso de la luz) = 1 kg. Del cuadro pág. 503, tenemos :

$$\text{Coef de flex} = \text{flex, } y, \text{ en cm, en el centro} = \frac{L^3W}{48EI} = \frac{100^3\times12}{48E} = \frac{250,000*}{E}$$

**65. Advertencia.** Las flexiones de maderas de la misma clase varían mucho con el grado de sazón, la edad del árbol, la parte de donde se corta la viga, etc. En nuestros propios experimentos sobre buenas piezas, bien sazonadas, en las cuales se dejaron obrar los pesos durante meses, menos del 2 por ciento del peso de ruptura produjo deformaciones permanentes en pocos meses. Varios de los maderos soportaron sus pesos de ruptura durante meses antes de ceder efectivamente. Las

---

* *N. del T.* — Ayudará al lector la siguiente ampliación : el caso tercero del cuadro de la pág. 503 (que es el actual) da para flexión la fórmula $\frac{1}{48} \times \frac{L^3W}{EI}$. El valor de I tomado de cuadro pág. 491, para una sección cuadrada es $\frac{bd^3}{12}$; pero como aquí $b = d = 1$ cm; el valor $\frac{bd^3}{12}$ queda reducido á $\frac{1}{12}$ y como L = en nuestro caso á 100 cm, la fórmula $\frac{1}{48}\frac{L^3W}{EI}$ se convertirá recordando que W = 1 kg en $\frac{1}{48} \times \frac{100^3\times1}{E\times1/12} = \frac{100^3\times12}{48E} = \frac{250,000}{E}$. (Véase además *N. del T.* **, pág. 506.)

vibraciones y trepidaciones á que están expuestas todas las construcciones aumentan las flexiones.

**66. Pesos excéntricos concentrados.** Sea Y, fig. 12 (*a*), la flexión, en el centro de la luz (esto es : en el punto de aplicación del peso) de una viga sostenida en cada extremo, y debida á un peso central W (dentro del límite de elasticidad). Entonces, si el mismo peso, W, se coloca excéntricamente en la misma viga, como en la fig. 12 (*b*), la flexión, Y′, en el punto, *c*, de aplicación del peso, y debida al peso, W, es

$$Y' = Y \frac{16\, m^2 n^2}{l^4} ; *$$

donde

$l$ =á la luz ó abertura;
$m$ y $n$ =los segmentos en que el peso divide la luz.

**67. Cargas uniformes.** Sea Y la flexión, debida á cualquier peso central extraño (dentro del límite de elasticidad), sobre una viga sostenida en cada extremo. Entonces, la flexión, Y′, de la misma viga, debida al mismo peso uniformemente distribuído sobre la luz, es :

$$Y' = \frac{5}{8} Y.$$

**68. Vigas inclinadas.** Si la viga es inclinada, úsese la proyección horizontal de su luz, en lugar de $l$, al determinar sus flexiones.

**69. Vigas cilíndricas.** Sea Y la flexión de una viga cuadrada bajo cualquier peso dado. Entonces, para una viga cilíndrica cuyo diámetro = al lado del cuadrado, la flexión, bajo el mismo peso es = 1.698 Y.

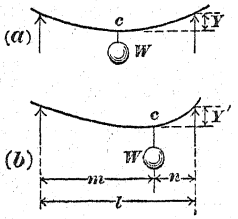


Fig. 12.

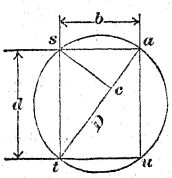
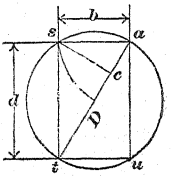


Fuerte. (*a*)



Rígida. (*b*)

Fig. 13.

**70.** Las figs. 13 (*a*) y (*b*) muestran, respectivamente, las más fuertes y más rígidas secciones rectangulares que pueden cortarse de un madero cilíndrico de diámetro D. En la sección más fuerte, fig. (*a*), $ac = \frac{D}{3}$, y $b = \sqrt{\frac{1}{3} D^2}$. En la sección más rígida, fig. (*b*), $ac = \frac{D}{4}$ y $d = \sqrt{\frac{3}{4} D^2}$.

**71. Flexión máxima permitida.** Bajo un peso aun perfectamente seguro, puede una viga tener demasiada flexión para ciertos fines. Así, para impedir que

---

* *N. del T.*—Esta fórmula de la flexión para carga excéntrica en función de la flexión para carga central se deduce así: el tercer caso del cuadro, pág. 503 (que es este caso), da para la flexión con carga central, que la llamaremos Y como el autor: $Y = \frac{1}{48} \times \frac{l^3 W}{EI}$; y la fórmula que dimos al final de nuestra observación, pág. 502, para carga en cualquier punto, da, llamando Y′ la flexión excéntrica: $Y' = \frac{1}{3} \times \frac{W m^2 n^2}{EIl}$. Dividiendo ésta por aquélla, resulta $\frac{Y'}{Y} = \frac{\frac{1}{3} \times \frac{W m^2 n^2}{EIl}}{\frac{1}{48} \times \frac{l^3 W}{EI}} = \frac{16\, m^2 n^2}{l^4}$.

se agriete el enyesado de los cielos rasos, es usual limitar la flexión de las vigas á $\frac{\text{luz}}{360}$. En líneas largas de transmisiones, para maquinarias, la flexión se limita de ordinario á $\frac{\text{luz}}{1{,}200}$; en puentes de camino real á $\frac{\text{luz}}{640}$; en puentes de ferrocarril á $\frac{\text{luz}}{1{,}600}$.

**72.** Sea Y = á la flexión máxima permitida, en cm por metro de luz, en cualquier caso dado;
$y$ = al coeficiente de flexión, §§ 60, etc.;
L = la luz neta de la viga, en metros;
$w$ = al peso de la luz neta de la viga, en kg;
W = al peso central + $^5/_8$ $w$;
= $^5/_8$ (peso uniforme + $w$).

Entonces, YL = la flexión, en cm, para toda la luz, L, y tenemos, para el peso permitido, W, el ancho, $b$, y el alto, $d$, requeridos para una viga rectangular (véase 61)

$$\textbf{Peso} \quad = \mathrm{W} = \frac{\mathrm{YL}bd^3}{\mathrm{L}^3y} = \frac{\mathrm{Y}bd^3}{\mathrm{L}^2y};$$

$$\textbf{Ancho}^* \quad = b = \mathrm{W}.\frac{\mathrm{L}^2y}{d^3\mathrm{Y}};$$

$$\textbf{Alto}^* \quad = d = \sqrt[3]{\mathrm{W}.\frac{\mathrm{L}^2y}{b\mathrm{Y}}}.$$

## Cargas aplicadas repentinamente.

**73.** Supóngase una carga aplicada repentinamente á una viga flexible, sin golpe ni trepidación, como, por ejemplo, sostenida por una cuerda que la deja precisamente tocar la viga sin descansar sobre ella, y cortando luego la cuerda. La flexión de la viga, en tal caso, es teóricamente doble que cuando el mismo peso se aplica gradualmente, como, por ejemplo, aflojando la cuerda lentamente, ó dividiendo el peso en fragmentos pequeños y aplicándolos á intervalos, uno por uno. Véanse §§ 35, etc. (Resistencia de Materiales.) En consecuencia, la resistencia de la viga (dentro del límite de elasticidad) es mucho más intensamente atacada en el primer caso que en el último. Un tren pesado que pasa muy rápidamente por un puente es un caso intermedio entre los dos citados.

## « Cantilevers » y vigas de resistencia uniforme.

**74.** Para el equilibrio, el momento de resistencia, R, de cualquier sección, debe contrarrestar el momento de flexión, M, en esa sección. Es decir,

$$\frac{\mathrm{S}}{\mathrm{T}}.\mathrm{I} = \mathrm{M};\ \mathrm{S} = \mathrm{M}.\frac{\mathrm{T}}{\mathrm{I}};$$

donde S = esfuerzo por unidad de superficie en las fibras extremas;
T = distancia del eje neutro á las fibras extremas;
I = momento de inercia de la sección.

**75.** En una viga de sección transversal uniforme, puesto que T ó I son uniformes en toda la luz, la unidad de esfuerzo, S, en las fibras extremas, varía con el momento de flexión, M. Para resistencia uniforme contra los momentos de flexión, la sección transversal debe variar de modo que $\frac{\mathrm{T}}{\mathrm{I}}$ sea inversamente proporcional á M, á fin de que S permanezca constante.

**76.** El cuadro siguiente muestra, en elevación y en plano, las formas teóricas de *cantilevers* y vigas rectangulares, de resistencia uniforme contra los momentos de flexión, bajo pesos concentrados y uniformes. En la práctica, algunas de estas formas deberían hacerse más fuertes cerca de sus extremos, para que tengan una sección suficiente para resistir al esfuerzo cortante.

---

* Véase nota al pie del § 61.

**77.** No obstante la reducción del material empleando vigas de resistencia uniforme, resulta su uso raras veces económico, excepto en el caso del hierro fundido. Con la madera, el material suprimido no se ahorra todo; y con el acero la economía del material queda con frecuencia compensada por el costo del trabajo adicional.

Además, las *flexiones* de vigas de resistencia uniforme, bajo un peso dado, son considerablemente mayores que las de vigas de sección transversal uniforme.

En el cuadro pág. 511.

W=carga concentrada;
$w$=carga uniforme por unidad de luz;
$l$=luz;
$x$=distancia desde un apoyo á cualquier sección dada;
$d$=alto de la viga en esa sección;
$b$=ancho de la viga en esa sección;
D=alto máximo de la viga;
B=ancho máximo de la viga;
S=esfuerzo por unidad de superficie en las fibras extremas
E=coeficiente de elasticidad;
Y'=flexión, debida al peso extraño, en vigas de resistencia uniforme;
Y=flexión, debida al peso extraño, en vigas de sección transversal uniforme= sección transversal máxima de vigas de resistencia uniforme.

**Símbolos** en el cuadro pág. 512:

W=carga concentrada; $w$=carga uniforme por unidad de luz;
$l$=luz; $x$=dist de un apoyo á una sec dada;
$d$=alto de la viga en esa sección; $b$=ancho de la viga en esa sec;
D=alto máximo de la viga; B=ancho máximo de la viga;
S=unidad del esfuerzo en las fibras extremas;

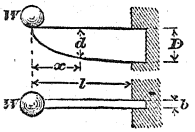
$$\text{E=coeficiente de elasticidad} = \frac{\text{tensión por unidad de superficie}}{\text{alargamiento por unidad de longitud}};$$

Y'=flexión, debida al peso extraño, en vigas de resistencia uniforme;
Y=flexión, debida al peso extraño, en vigas de *sección* transversal uniforme= sección transversal máxima de vigas de *resistencia* uniforme.

## « Cantilevers » de sección transversal rectangular y de resistencia uniforme. Perfiles, planos y flexiones.

**Para símbolos**, véase § 77.

### Carga concentrada en el extremo=W.

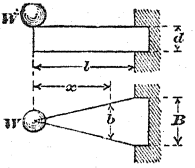


Ancho, $b$, constante.

Perfil, parábola, con vértice en la carga.

$$d = \sqrt{\frac{6Wx}{Sb}}; \quad Y' = \frac{8Wl^3}{EbD^3} = 2Y;$$

D = altura máxima.

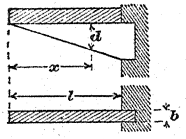


Alto $d$, constante.

Proyección, triángulo.

$$b = \frac{6Wx}{Sd^2}; \quad Y' = \frac{6Wl^3}{EBd^3} = \frac{3}{2}\,Y.$$

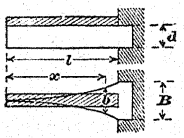
### Carga uniforme por unidad de luz=$w$.



Ancho, $b$, constante.

Perfil, triángulo.

$$d = x\sqrt{\frac{3w}{Sb}}.$$



Alto, $d$, constante.

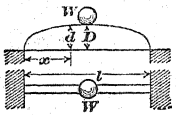
Proyección, dos curvas parabólicas con vértices en el extremo libre.

$$b = \frac{3wx^2}{Sd^2}, \quad Y' = \frac{3Wl^3}{EBd^3} = 2Y.$$

## Vigas de sección transversal rectangular, y resistencia uniforme
## Perfiles, planos y flexiones.

**Para símbolos**, véase § 77, al final.

### Carga concentrada en el centro=W.

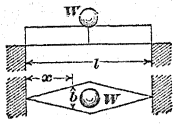


Ancho, $b$, constante.

Perfil, dos curvas parabólicas con vértice en los apoyos.

$$d = \sqrt{\frac{3Wx}{Sb}} \qquad D, \text{ en el centro de la luz.}$$

$$Y' = \frac{Wl^3}{2EbD^3} = 2Y.$$

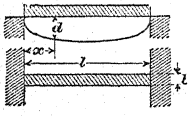


Alto, $d$, constante. B = ancho máximo.

Proyección, dos triángulos.

$$b = \frac{3Wx}{Sd^2}; \quad Y' = \frac{3Wl^3}{8EBd^3} = \frac{3}{2}\,Y.$$

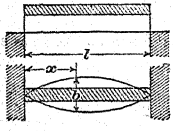
### Carga uniforme por unidad de luz=$w$.



Ancho, $b$, constante.

Perfil, elipse ó semielipse.

$$d = \sqrt{\frac{3w}{Sb}\,(lx - x^2)}.$$



Alto, $d$, constante.

Proyección, parábolas con vértices en el centro de la luz.

$$b = \frac{3w}{Sd^2}\,(lx - x^2).$$

**Vigas continuas.** Véanse también §§ 134-6.

**78.** Una viga continua es la que descansa sobre más de dos apoyos.

**79.** Las resistencias y flexiones de las vigas continuas, como las de vigas empotradas, se determinan por medio de la curva de elasticidad usando el cálculo. Los hechos más importantes, así deducidos, se indican en la fig. 14 y en el cuadro ilustrado, pág. 514.

**80.** La fig. 14 representa el carácter general de las flexiones y las variaciones de los momentos y de los esfuerzos cortantes en vigas continuas uniformemente cargadas.

**81. Momentos**, fig. 14 (*b*). Ordenadas trazadas *por encima* de la línea cero, *a'b'*, representan momentos *positivos*, ó aquellos en que el segmento de la viga, á la izquierda de cualquier sección, tiende á girar *como el minutero* *, y viceversa.

**82.** En cada extremo de la viga, en un punto, *i* (llamado punto de inflexión ó de flexión contraria), en cada tramo de los extremos, y en dos puntos semejantes en cada tramo ó luz restante, el momento es cero.

**83.** En otro punto, *m*, en cada tramo ó luz, el momento positivo llega á un máximo para ese tramo, mientras que los momentos negativos llegan á sus máximos en los apoyos. Tanto los momentos positivos como los negativos varían con aberturas ó luces diferentes; pero, si las luces son iguales, entonces los momentos, en cualesquiera dos puntos equidistantes del centro de la viga entera, son iguales.

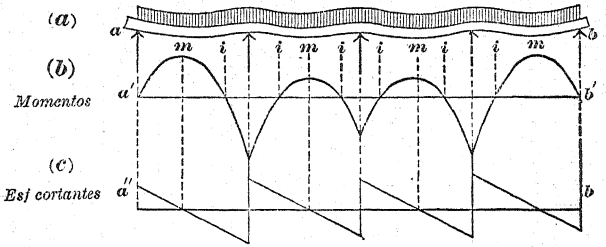


**Fig. 14.**

**84.** El diagrama de los momentos, entre cada apoyo y el punto, *m*, del momento positivo máximo, á uno ú otro lado de él, es una semiparábola, con su vértice en *m*.

**85. Esfuerzos cortantes**, fig. 14 (*c*). Las ordenadas trazadas *por encima* de la línea cero, *a''b''*, representan *esfuerzos cortantes positivos* ó aquellos en que el segmento *izquierdo*, en cualquier sección, tiende á resbalar *hacia arriba*, más allá del segmento *derecho*, y viceversa.

**86.** En el punto, *m*, del momento máximo, en cada luz, el esfuerzo cortante es cero. Entre cada uno de dichos puntos y el próximo apoyo á la izquierda, el esfuerzo cortante es positivo y viceversa.

**87.** En cada apoyo el esfuerzo cortante cambia de súbito con una intensidad=á la reacción del soporte.

**88.** El diagrama del esfuerzo cortante es una serie de líneas rectas.

**89. El cuadro ilustrado**, pág. 514, representa las condiciones teóricamente existentes en vigas continuas uniformemente cargadas desde dos hasta cinco luces iguales. Sólo se ve en la figura la mitad izquierda de cada una de tales vigas, siendo la mitad derecha simétrica con la izquierda.

**90.** Los números indican la intensidad del momento positivo máximo en cada luz, la del momento negativo en cada apoyo y el esfuerzo cortante en cada lado de cada apoyo.

**91.** Los números muestran también el coeficiente, *a*, para la distancia, *al*, desde el apoyo izquierdo de cada luz hasta el punto del momento máximo en esa luz; y el coeficiente, *x*, para la distancia ó distancias, *xl*, desde el mismo apoyo hasta el punto ó puntos de inflexión en esa luz. En cada luz central, la suma de los dos valores de $x=1$. En cada luz extrema, $x=2a$.

---

* *N. del T.* — Veáse nuestra nota pág. 463.

$m\,w\,l^2$ = Momento.

$v\,w\,l$ = Esfuerzo cortante.

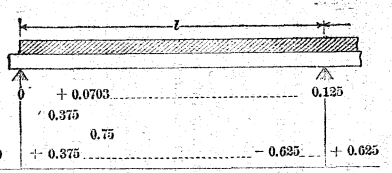
$al$ = Distancia del apoyo izquierdo de cualquier luz, al punto máximo de momento positivo de esa luz.

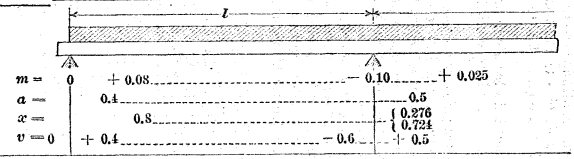
$xl$ = Distancia de cualquier apoyo izquierdo al punto de inflexión.

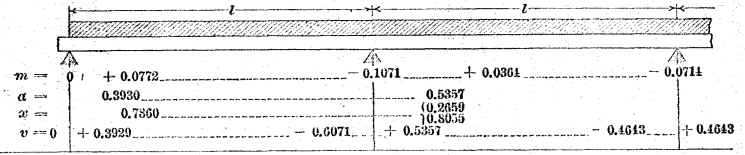
$w$ = Carga por unidad de luz.

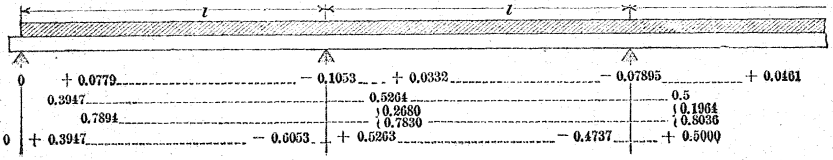
$l$ = Luz.

| Número de | |
|---|---|
| Luces. | Apoyos. |
| 2 | 3 |
| 3 | 4 |
| 4 | 5 |
| 5 | 6 |









**92.** En cada luz central, el punto del momento positivo máximo está en el centro de la luz. En otros términos, la flexión en esa luz es simétrica, ó bien $a = .5$.

**93.** La suma numérica de los dos esfuerzos cortantes, uno en cada lado de un apoyo, es=á la reacción de ese apoyo. En cada apoyo central, los esfuerzos cortantes, en sus dos lados, son iguales.

En el cuadro :

$w$=peso por unidad de luz;
$l$=luz;
$m$=el coeficiente para el momento;
$mwl^2$=momento;
$v$=el coeficiente para el esfuerzo cortante;
$vwl$=esfuerzo cortante;
$a$=el coeficiente para la distancia al punto del momento máximo;
$al$=distancia desde el apoyo izquierdo de cualquier luz al punto del momento positivo máximo en esa luz;
$x$=el coeficiente para la distancia al punto de inflexión;
$xl$=distancia del apoyo izquierdo de cualquier luz á uno ú otro punto de inflexión en esa luz.

**94.** La fig. 15 muestra los valores de $m$ y de $v$ en una viga no continua, uniformemente cargada. Comparando éstos con los correspondientes valores en vigas continuas, como se ven en el cuadro ilustrado último, se observa que la viga continua tiene considerable ventaja teórica. Pero véase § 95.

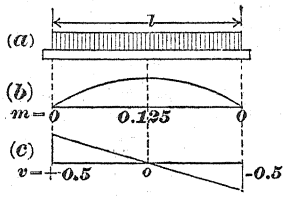


**Fig. 15.**

**95.** Ciertas consideraciones prácticas, empero, reducen considerablemente estas ventajas en muchos casos. Así, en un puente continuo de ferrocarril de 30 m, por ejemplo, de luz, de tal modo calculado que la flexión máxima no exceda de 2 cm, una bajada ó hundimiento de 2 cm en un pilar intermedio privaría al puente del apoyo de tal pilar y prácticamente pondría así dos luces adyacentes en una sola, haciendo obrar sobre sus miembros fuerzas muy superiores á aquellas para las cuales fueron calculadas y destinadas. Además, con cargas móviles, la ventaja teórica es á veces mucho menor que la debida á una carga fija.

## Vigas en forma de cruz *.

**96.** En una viga en forma de cruz, fig. 16, de material homogéneo, cargada en el centro, sean :

W = á la carga;

E=al coeficiente de elasticidad = $\frac{\text{esfuerzo por unidad de superficie}}{\text{alargamiento por unidad de longitud}}$;

Y=á la flexión en el centro;
L, $l$=á la luz ó abertura de
D, $d$=á los altos de
T, $t$=á las semi-alturas de
I, $i$=á los momentos de inercia de
S, $s$=esfuerzo por unidad de superficie en las fibras extremas de
P, $p$=las porciones de W sostenidos por

} los dos brazos respectivamente.

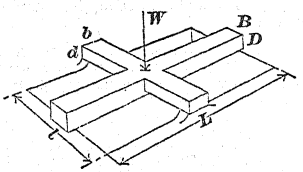

**Fig. 16.**

Entonces (véase cuadro ilustrado pág. 503), puesto que la flexión es necesariamente la misma para ambos brazos,

$$\frac{L^3P}{EI} = \frac{l^3p}{Ei}; \text{ ó}$$

$$\frac{P}{p} = \frac{I.l^3}{i.L^3}$$

y, puesto que $P = 4.\frac{S.I}{T.L}$, y $p=4.\frac{s.i}{t.l}$ (véase cuadro pág. 496), tenemos (despejando S y $s$, dividiendo sus valores, reemplazando $\frac{P}{p}$ por su valor y á $\frac{T}{t}$ por su equivalente $\frac{D}{d}$), $\frac{S}{s} = \frac{D}{d}\left(\frac{l}{L}\right)^2$.

**97.** En otros términos, á fin de que ambos brazos sean igualmente fuertes, sus altos (independientemente de sus anchos) deben estar en razón inversa de los cuadrados de sus luces, ó sus luces en razón inversa de las raíces cuadradas de sus altos.

## Resistencia transversal de planchas planas.

Para Planchas ondeadas, convexas, véase pág. 1212.

**98.** Las leyes que rigen la resistencia de las planchas, á presiones perpendiculares á sus superficies, no están bien comprendidas, y las fórmulas que las expresan deben usarse con cautela y sólo como aproximaciones probables.

**99.** En el siguiente cuadro, los momentos son los dados, como suficientemente aproximados, por Rankine, Ingeniería Civil, pág. 544, para planchas apoyadas en sus bordes. Los esfuerzos se deducen de estos momentos por medio de la fórmula, $S=M\frac{6}{Ld^2}$. Véanse Símbolos, § 101. Véanse las fórmulas para pesos, en las vigas rectangulares (cuadro pág. 496). Para planchas con los extremos *fijos, empotrados*, véase § 100.

Una plancha oblonga homogénea tiende á henderse á lo largo de su eje mayor.

* F. Reuleaux, « Der Konstrukteur ». Braunschweig, 1889. « The Constructor », traducido por H. H. Suplee, Filadelfia, 1893.

**100. Extremos fijos ó empotrados.** Si M es el momento, y S el esfuerzo de la fibra máxima, para una plancha apoyada en sus bordes, y si $Mf$ y $Sf$ son los valores correspondientes para el mismo peso en la misma plancha con los extremos *fijos* (empotrados), podemos suponer :

para carga central, $Mf = {}^1/_2 M$; $Sf = {}^1/_2 S$;
para carga uniforme, $Mf = {}^1/_3 M$; $Sf = {}^2/_3 S$.

Véanse fórmulas para vigas ordinarias, cuadro pág. 496.

**101.** En una plancha apoyada en sus bordes, sean :

$d$ = espesor de la plancha;
$w$ = peso por unidad de superficie;
W = peso total;
M = momento máx de flexión;
S = esfuerzo máximo de la fibra.

En una plancha oblonga, sean :
L = la luz más larga;
$b$ = la luz más corta;
en una plancha cuadrada ó circular, $L = b$;
en una plancha circular, $r$ = radio.

**Momento máximo de flexión**, M, y **esfuerzo máximo**, S, de la fibra en planchas apoyadas en los bordes. Para bordes empotrados, véase § 100.

### Peso ó carga central.

| Plancha. | Momento, M. | Esfuerzo, S. |
|---|---|---|
| Oblonga | $\frac{1}{4}\,W b$ | $\frac{3}{2}\,\frac{b}{L}\,\frac{W}{d^2}$ |
| $L < 1.19\,b$ | | |
| $L < 1.19\,b$ | $\frac{3}{8}\,W\,\frac{L^4 b}{L^4+b^4}$ | $\frac{9}{4}\cdot\frac{L^3 b}{L^4+b^4}\cdot\frac{W}{d^2}$ |
| Cuadrada | $\frac{3}{16}\,WL$ | $\frac{9}{8}\,\frac{W}{d^2}$ * |
| Circular | $W\,\frac{r}{\pi}$ | $\frac{3}{\pi}\,\frac{W}{d^2}$ * |

### Carga uniforme.

| Plancha. | Momento, M. | Esfuerzo, S. |
|---|---|---|
| Oblonga | $\frac{1}{8}\,W\,\frac{L^4 b}{L^4+b^4} = \frac{1}{8}\,w\,\frac{L^5 b^2}{L^4+b^4}$ | $\frac{3}{4}\cdot\frac{L^4 b}{L^4+b^4}\cdot\frac{W}{d^2} = \frac{3}{4}\cdot\frac{L^4 b^2}{L^4+b^4}\cdot\frac{w}{d^2}$ |
| Cuadrada | $\frac{1}{16}\,WL = \frac{1}{16}\,wL^2$ | $\frac{3}{8}\cdot\frac{W}{d^2}$ * $= \frac{3}{8}\cdot L^2\cdot\frac{w}{d^2}$ |
| Circular | $\frac{1}{3}\,W\,\frac{r}{\pi} = \frac{1}{3}\,wr^3$ | $\frac{1}{\pi}\cdot\frac{W}{d^2}$ * $= r^2\,\frac{w}{d^2}$ |

**102. En una plancha circular,** uniformemente cargada, la **flexión** en el centro $= c\,\frac{wr^4}{Ed^3}$ donde $c = \frac{2}{3}$ para planchas *apoyadas* en sus bordes ; $c = \frac{1}{6}$ para planchas *empotradas;* E = módulo de elasticidad.

---

* Puesto que el esfuerzo $\left(S = M\,\frac{6}{Ld^2}\right)$ es proporcional á $\frac{WL}{Ld^2}$, la tensión, S, bajo un peso *total* dado, W, en planchas *cuadradas* ó *circulares*, y en planchas rectangulares donde $L/b$ es constante, es independiente de las dimensiones de la superficie.

## ESFUERZOS TRANSVERSAL Y LONGITUDINAL COMBINADOS

**103.** Aunque es censurable la combinación de los esfuerzos longitudinal y transversal en la misma pieza, es á menudo inevitable. Así, en un techo de madera, los contrapares obran por lo general como columnas y como vigas.

En tales casos, el esfuerzo total por unidad de superficie, S, en las fibras extremas, es la suma del esfuerzo uniforme, $S_c$, debido á compresión ó tensión directa, y el esfuerzo de las fibras extremas, $S_b$, debido á los momentos de flexión solamente, bajo la acción de las cargas transversales y longitudinales combinadas. Es decir, $S = S_c + S_b$.

Sea $M_b$ = al momento de flexión debido al peso transversal; $M_c$ = al momento de flexión debido al peso longitudinal, P; y M = al momento de flexión resultante total, $= M_b - M_c$, cuando la carga longitudinal ejerce tensión; $= M_b + M_c$ cuando ejerce compresión.

Pero $M_c = Pd$, donde P = al peso ó carga longitudinal, y $d$ = su brazo palanca, = la flexión de la viga, debida á todas las causas; y (véase § 57) $d = \frac{l^2 S_b}{ETc}$; donde $l$ = luz, $S_b$ = esfuerzo por unidad de sup en las fibras extremas, debido á la flexión; E = módulo de elasticidad; T = distancia del eje neutro á las fibras extremas, y $c$ = un coeficiente, cuyos valores, para diferentes casos, se dan en el § 57.

En consecuencia, $M_c = P\frac{l^2 S_b}{ETc}$, y el momento resultante $M = M_b \pm P\frac{l^2 S_b}{ETc}$. El momento de resistencia, R (véase § 10), es $= S_b \frac{I}{T}$; y, para el equilibrio, R = M.

Por tanto, $S_b \cdot \frac{I}{T} = M_b \pm P\frac{l^2 S_b}{ETc}$; de donde deducimos, para el esfuerzo de la fibra extrema, S, debido á la flexión solamente, bajo la acción de las cargas ó peso transversal y longitudinal combinados,

$$S_b = \frac{M_b T}{I + \frac{Pl^2}{Ec}}$$ donde el esfuerzo longitudinal es de tensión

$$S_b = \frac{M_b T}{I - \frac{Pl^2}{Ec}}$$ donde el esfuerzo longitudinal es de compresión

Además de esto, tenemos el esfuerzo por unidad de sup (esfuerzo unitario), $S_c$, debido directamente al peso longitudinal, P, que es $= \frac{P}{A}$, donde A es el área de la sección transversal de la viga. Por consiguiente, para la unidad total del esfuerzo, S en las fibras extremas, tenemos

$$S = S_c + S_b = \frac{P}{A} + \frac{M_b T}{I \pm \frac{Pl^2}{Ec}}.$$

Cuando la flexión, $d$, es despreciable, $M_c = 0$; $M = M_b = S_b \frac{I}{T}$; y $S_b = \frac{M_b T}{I} = \frac{MT}{I}$ como en el § 10; y $S = \frac{P}{A} + \frac{MT}{I}$. En la práctica, $d$ es frecuentemente despreciable y se usa esta fórmula.

## ESFUERZOS DIAGONALES EN LAS VIGAS

### Unidad máxima del esfuerzo.

**104.** Cuando un cuerpo (como un perno) está **sometido á fuerza de tensión (ó compresión) solamente**, la tendencia del cuerpo, *considerando las secciones perpendiculares á los esfuerzos*, es á separarse, rajarse (ó aplastarse) en la dirección del esfuerzo, ó perpendicularmente á la sección, y todo el esfuerzo obra perpendicularmente sobre la sección; pero, en los *planos oblicuos al esfuerzo*, éste se resuelve en dos componentes, una (*n*) de tensión (ó comp) perpendicular al plano, y una (*t*) tangencial al plano (esfuerzo cortante).

**105. Bajo el esfuerzo cortante solamente**, el efecto, sobre un plano paralelo á las dos fuerzas, y entre ellas, resulta de exclusivo esfuerzo cortante; pero en planos *oblicuos* á las fuerzas que producen el esfuerzo cortante, aquéllas se resuelven en (*t*) fuerzas tangenciales ó de esfuerzo cortante, y (*n*) fuerzas perpendiculares (de tensión ó comp).

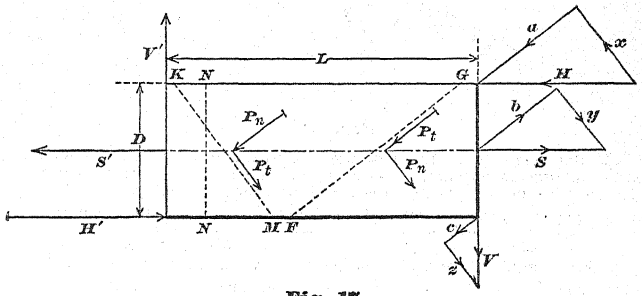

**Fig. 17.**

**106.** Así, fig. 17, sea una barra, de largo, L, y alto, D, sometida á una tensión S=S', en línea con su eje horizontal, y dos pares de fuerzas=V=V' y H=H', como se indican; constituyendo V y V' un esfuerzo cortante vertical *á la derecha*, mientras que H y H' forman un esfuerzo cortante horizontal *á la izquierda*.

Supóngase dividida la barra por una sección, como NN, FG ó KM, y considérese que las fuerzas obran, en uno ú otro caso, sobre el segmento á la derecha de la barra según se haya dividido.

Sobre la sección *perpendicular*, NN, la tensión, S, y el esfuerzo cortante horizontal, H, obran perpendicularmente (S como tensión, H como compresión), y el esfuerzo cortante vertical, V, tangencialmente (como esfuerzo cortante); pero, para una sección *oblicua*, FG ó KM, resolvemos primero cada fuerza, S, V y H, en dos componentes, *b* é *y*, *c* y *z*, *a* y *x*, respectivamente perpendiculares y paralelas á la sección, como se demuestra por los triángulos de las fuerzas á la derecha *. Entonces, sumando estas compresiones algebraicamente, obtenemos las fuerzas resultantes, $P_n$ (perpendicular) y $P_t$ (tangencial ó de esfuerzo cortante) que obran sobre la sección de que se trata. Con las fuerzas, S, V y H, como se indica en la fig. 17, tenemos:

En la sección FG, $P_n$, tensión, $=y+z-x$;

$P_t$, esfuerzo cortante *derecho*, $=a+c-b$;

En la sección KM, $P_n$, compresión, $=a+c-b$;

$P_t$, esfuerzo cortante *derecho*, $=y+z-x$.

**107.** Si ahora examinamos *todos los planos posibles* cortando el cuerpo en un punto dado, encontraremos (1) uno de tales planos en que la unidad de fuerza de *tensión* resultante llega á su máximum; (2) otro, perpendicular al (1), en el cual la unidad de fuerza *compresiva* resultante llega á su máximum, y (3) dos planos, perpendiculares entre sí y que dividen en dos partes iguales los ángulos rectos

* A fin de que, para una ú otra fuerza, S, V ó H, los dos triángulos de fuerzas (para las dos secciones, FG y KM) sean idénticos, simplificando así la figura, tomamos las dos secciones, FG y KM, perpendiculares entre sí.

entre los planos (1) y (2). Sobre los dos planos últimamente nombrados, (3), la unidad resultante de las fuerzas que producen el esfuerzo cortante llega á su máximo,

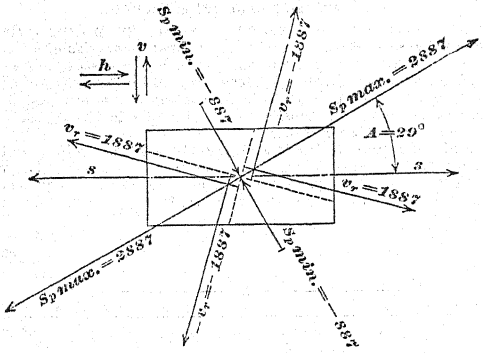

**Fig. 18.**

**108.** Represente la fig. 18 un **pequeño elemento** en una barra sometida á tensión y esfuerzo cortante; y trátese de determinar las **posiciones de estos planos y las correspondientes tensiones máximas.** Sean

$s$ = esfuerzo normal original por unidad de superf (de tens ó comp);
$v$ = — vertical — — — (esfuerzo cortante);
$h$ = — horizontal — — — (esfuerzo cortante);
$s_p$ = la resultante normal de la unidad máx ó mín del esfuerzo;
$v_r$ = — — — máxima del esf cortante;
A = ángulo formado por $s$ con $s_p$.

$$\text{Entonces } \tan 2A = \frac{v}{s/2} \quad \ldots\ldots (1)$$

$$v_r = \sqrt{(s/2)^2 + v^2} \quad \ldots\ldots (2)$$

$$s_p \text{ máx} = s/2 + v_r = s/2 + \sqrt{(s/2)^2 + v^2} \quad \ldots\ldots (3)$$

$$s_p \text{ mín} = s/2 - v_r = s/2 - \sqrt{(s/2)^2 + v^2} \quad \ldots\ldots (4)$$

Si $s$ es { tensión { signo + da tensión máx; — — — comp — = tensión mín. / comp { — + — comp —; — — — tensión — = comp mín.

**109. Ejemplo** : Sean

$s$ = 2,000 kg/cm cuad, tensión (no trazada en escala);
$v = h$ = 1,600 — — esf cortante ( — — ).

Aquí $v$ es izquierdo, $h$ derecho. Si esto se invierte, el ángulo, A, entre la tensión resultante, $s_p$, y la horizontal, estará *por debajo* del eje neutro.

**110.** Entonces $\tan 2A = \dfrac{v}{s/2} = \dfrac{1{,}600}{1{,}000} = 1.6$; $2A = 58°$; $A = 29°$;

$$v_r = \sqrt{(s/2)^2 + v^2} = \sqrt{1{,}000^2 + 1{,}600^2} = 1{,}887;$$
$$s_p \text{ máx} = s/2 + v_r = 1{,}000 + 1{,}887 = 2{,}887 \text{ (tensión)};$$
$$s_p \text{ mín} = s/2 - v_r = 1{,}000 - 1{,}887 = -887 \text{ (comp)}.$$

**111.** En otras palabras, **tenemos, como resultantes,** (1) una unidad máx de tensión, $s_p$ máx = 2,887 kg/cm cuad formando un ángulo, A = 29°, con el eje de la barra ó con la dirección de $s$; (2) una unidad mín de tensión ó máx de compresión, $s_p$ mín = — 887 kg/cm cuad, perpendicular á $s_p$ máx; (3) una unidad de esfuerzo cortante derecha, $v_r$ ‖ 1,887 kg/cm cuad; y una unidad de esfuerzo

cortante izquierdo $-v_r = -1{,}887$ kg/cm cuad. Las direcciones de los esfuerzos cortantes dividen en dos partes iguales los ángulos rectos entre los esfuerzos normales máx.

**112.** La tensión y compresión máx, en cualquier punto, se llaman los « **esfuerzos principales** » para ese punto.

## Esfuerzo cortante horizontal y vertical en las vigas.

Véanse también los §§ 301, etc., 325, etc., 348, etc., en Estática, y los §§ 51 á 56 en Resistencia de Materiales.

**113.** Supongamos que la fig. 19 representa la mitad izquierda de una **viga homogénea**, de sección rectangular; ancho, $b_1=1$ cm; alto, $d_1=10$ cm; luz, $L_1=100$ cm; con carga cent, W *, de 200 kg; reacción izquierda, $R=W/2=100$ kgs. Despréciase el peso de la viga. El mom de flexión, en el cent de la luz, es $M=RL/2=WL/4$ *$=5{,}000$ kg-cm; y el mom disminuye uniformemente *, desde su máx, en el cent de la luz, hasta cero en los apoyos. En las fibras extremas, superiores é inferiores, la unidad de fuerza longitudinal (§ 10), $s_1=MT/I$, donde $T=d/2$=dist del eje neut á las fibras extremas$=5$ cm; I=mom de inercia de la sección transversal$=bd^3/12=1{,}000/12$. En consecuencia, en la fig. 19, $s=12\times 5M/1{,}000=.06M$. Ahora $s$, siendo así proporcional á M, también disminuye uniformemente *, desde su máx, en el cent de la luz, hasta cero en los apoyos. Los valores de M y de $s$, para las secciones 0, $a$, $b$, $c$, $d$, $e$, están indicados con números en el diagrama.

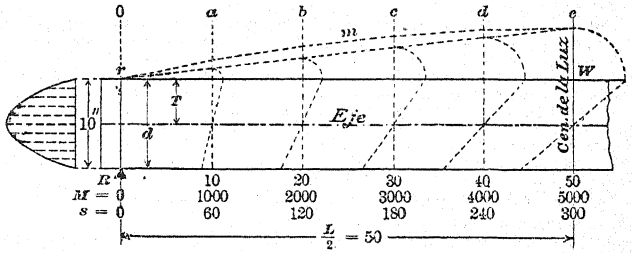

**Fig. 19.**

**114.** Las unidades de **fuerzas** horizontales de **tensión y compresión**, $s$, en los varios puntos en cualquier sección vert, son **proporcionales á las dists** de esos puntos **al eje neutro**, como lo indica el diagrama en cada sección vert, fig. 19.

**115.** En la fig. 20, sean $n$ y $g$ dos sécciones vert de esta viga, tales que, en $n$ y en $g$, las unidades de las fuerzas de las fibras extremas sean : $mn=15$, y $ug=25$, respectivamente. Entonces sobre la **parte rectangular**, $nf$, de la viga, entre las secciones $n$ y $g$, obran una serie de fuerzas que varían de compresión, $eg=ug-mn=-25-(-15)=-10$, en el borde superior, á tensión, $=+10$, en el inferior, como lo indica el diagrama en $ek$.

**116.** Supóngase la pieza $gf$ dividida en 10 fajas horiz de igual altura, $=1$ cm. Entonces las unidades de fuerza neta, $s$, que obran en estas fajas, respectivamente, son las $(-10, -8, -6, \ldots. 6, 8, 10)$ numeradas de $e$ á $k$, y la fuerza media, ó (puesto que el alto de cada faja$=b=1$) **la fuerza, que obra sobre cada faja**, es la $(-9, -7, -5, \ldots. 5, 7, 9)$ numeradas entre $g$ y $f$.

**117. Estas fuerzas son transmitidas**, de faja á faja, por sus superficies de contacto; y, al determinar el esfuerzo cortante, que obra en el plano horizontal

* Bajo un peso *uniformemente distribuido*, el mom de flex, en el cent de la luz, es $WL/8$; y los moms de flex, M, y la unidad del esfuerzo longitudinal resultante, $s$, varían como las ordenadas de una parábola, como lo indica la parábola de puntos, $rmc$, en la parte superior de la fig. 19, que corresponde á un peso uniforme $=400\,\text{kg}=2W$. La unidad de esfuerzos cortantes $v$, en una sección horiz dada, disminuye entonces uniformemente, desde un máx, en los apoyos, hasta cero en el cent de la luz. Compárense 3.ª y 4.ª figs, en el cuadro de la pág. 496.

entre cualesquiera dos fajas, consideramos la faja superior (ó inferior) como movida por su propio empuje ó impulso positivo *más* (suma algebraica) de los de todas las fajas por encima (ó por debajo si se tomó ésta) de ella.

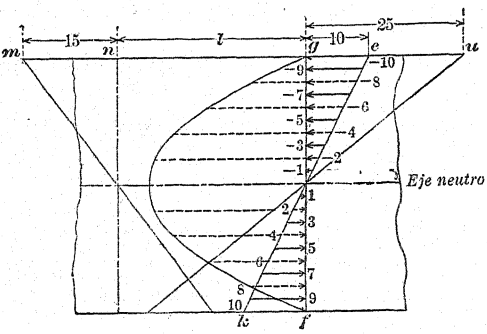

**Fig. 20.**

**118.** Así, la 3.ª faja, á partir de arriba, es empujada hacia la izquierda por una fuerza de — 9 — 7 — 5 = — 21, mientras la 4.ª faja, precisamente por debajo de ella, es impulsada hacia la derecha por una fuerza de 9+7+5+3+1 — 1 — 3=21. En consecuencia, la superficie entre la 3.ª y 4.ª fajas, sostiene un **esfuerzo cortante** « contra el del minutero »* de 21; que, dividido por el área, $bl=l$, de esa superficie, da el **esfuerzo cortante** por unidad de superficie en el plano entre la 3.ª y la 4.ª fajas. Con peso central **, esta unidad de esfuerzo cortante es uniforme desde cada apoyo al centro de la luz, donde cambia de sentido (de más á menos, ó vice versa), pero es de la misma intensidad en la otra media luz. Véase 3.ª figura del cuadro, pág. 496.

**119. En cualquier sección vertical de la viga**, sean

V = al esfuerzo cortante total
  = á la reacción de uno ú otro apoyo, menos la suma de todos los pesos entre ese apoyo y la sección;
I = al momento de inercia con respecto al eje neut;
$b$ = ancho; $d$ = alto;
$a$ = al área por encima (ó por debajo) de cualquier punto en la sección;
$c$ = la distancia del eje neut, al cent de grav de $a$;
$M_s = ac$ = al mom estático de $a$, con respecto al eje neut;
$v$ = al esfuerzo cortante por unidad de superf vert = esfuerzo cortante por unidad de superficie horizontal en un punto dado.

**120.** Entonces

$$v = \mathrm{V}\frac{\mathrm{M}_s}{\mathrm{I}} \div b = \mathrm{V}.\frac{ac}{\mathrm{I}b}$$

$$\text{En el eje neut, } \mathrm{M}_s\ (=ac) = \frac{db}{2}\cdot\frac{d}{4} = \frac{d^2b}{8}$$

En consecuencia, **en el eje neutro :**

$$v = \mathrm{V}\frac{d^2}{8\mathrm{I}} = \mathrm{V}\frac{12d^2}{8bd^3} = \frac{3}{2}\cdot\frac{\mathrm{V}}{bd}$$

$$= \frac{3}{2} \times \text{el esfuerzo cortante vert medio en la sección transversal.}$$

Véanse también §§ 51, etc.

---

* Véase *N. del T.* pág. 463.
** Véase nota pág. 521.

En el § 115 hemos tomado dif en $s$, entre $n$ y $g$, fig. 20, $=10=V/bd$.

En consecuencia, $v = \frac{3}{2} \cdot \frac{V}{bd} = \frac{3}{2} \cdot \frac{100}{10} = 15 = \frac{3}{2} \times$ dif en $s$.

En el eje neut, fig. 20, tenemos esfuerzo cortante horiz total $=9+7+5+3+1=25$; y dist $ng=l=bl=$esfuerzo cortante horiz total $\div$ unidad del esfuerzo cortante $=25/15=1.666\ldots$; y $s$ máx $\times \frac{l}{L/2} = (300 \times 1.666\ldots)/50=10=$dif en los esfuerzos, $s$, de las fibras horiz, entre $n$ y $g$.

**121.** A la izquierda de la fig. 19 hay un **diagrama que indica las unidades de los esfuerzos cortantes** en las varias secciones horizontales.

**122.** Representemos por la fig. 21 un pequeño elemento de un cuerpo, de unidad de espesor, perpendicular al papel, sobre el que obra un esfuerzo cortante vert derecho, $V=vD$ (donde $v=$á la unidad del esfuerzo cortante vert, y $D=$la altura del elemento) y por un esfuerzo cortante horiz izquierdo, $H=hL$ (donde $h=$á la unidad del esfuerzo cortante horiz, y $L=$el largo del elemento). Para el equilibrio de los momentos debemos tener

$$VL = HD; \quad \text{ó } vDL = hLD; \quad \text{ó sea } v = h.$$

En otros términos,

**la unidad del esfuerzo cortante vert = la unidad del esfuerzo cortante horiz.**

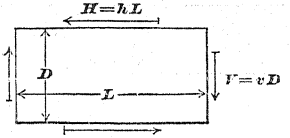

**Fig. 21.**

## Esfuerzos máximos por unidad de superficie en las vigas.

**123. La teoría común de las vigas** (§§ 1-103, págs. 488 á 518) considera solamente las **fuerzas longitudinales, tensión y compresión** y los **esfuerzos cortantes** vert y horiz, debidos directamente á la carga y á las reacciones ascendentes de los apoyos, y que obran, en cualquier punto, sobre *planos verts y horizs* que pasan por determinado punto; pero, excepto en ciertas porciones limitadas de la viga, estos esfuerzos no son **los esfuerzos máximos** que obran en dicho punto; pues ellos se combinan para formar esfuerzos **diagonales** resultantes, que obran sobre planos **diagonales** (que pasan por el mismo punto); y, sobre algunos de estos planos diag, los esfuerzos resultantes normales y tangenciales son mayores que los esfuerzos originales.

**124. La teoría común** se **adapta** bastante bien á vigas de muchas clases, y especialmente á **vigas de acero**, donde las alas de la viga resisten á las fuerzas longitudinales, y los esfuerzos cortantes los resiste el alma de la viga; pero, en ciertas porciones de vigas altas y fuertemente cargadas, especialmente las de **cemento armado**, las resultantes diagonales ó **esfuerzos máximos** son los esfuerzos *predominantes*, y no deben desatenderse.

**125.** En una viga, en la parte alta y baja, tenemos, respectivamente, sólo esfuerzos de tensión y compresión horiz, y, en el eje neut, esfuerzos cortantes (vert y horiz) solamente; pero en todos los otros puntos, tenemos esfuerzo cortante (vert y horiz), **obrando conjuntamente con esfuerzos horiz**, ya de tensión, ya compresivos. En todos los puntos, estos esfuerzos cortantes y las fuerzas longitudinales pueden **resolverse en componentes**, normales y tangenciales á cualquier plano, como en el caso de la barra ó del perno, fig. 17.

**126.** Así, sobre cada elemento de la viga, figs. 22, 23, 24, actúan fuerzas horiz y verts (unidades de esfuerzos), que, obrando sobre planos diagonales, se resuelven en componentes diagonales, y estas componentes algebraicamente **sumadas forman resultantes**; pero las fuerzas originales varían en intensidad, y las fuerzas resultantes tanto en intensidad como en dirección, de un punto á otro.

Para las **direcciones y valores** de estos esfuerzos resultantes en sus máximums, tenemos la ecuación (1), § 108, pág. 520.

$$\text{Tang } 2A = \frac{v}{s/2} \quad \ldots\ldots (1)$$

$$v_r = \sqrt{(s/2)^2 + v^2} \quad \ldots\ldots (2)$$

$$s_p = s/2 \pm v_r = s/2 \pm \sqrt{(s/2)^2 + v^2} \quad \ldots\ldots (3)\ (4)$$

donde

$s$ = al esfuerzo original por unidad de superf (tens ó comp) en el punto;
$v$ = esfuerzo cortante original (vert ú horiz) por unidad de superf, en el punto.

Los esfuerzos perpendiculares máx, $s_p$, se llaman **esfuerzos principales**.

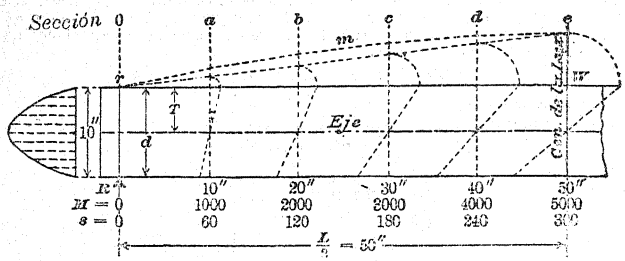

**Fig. 22.**

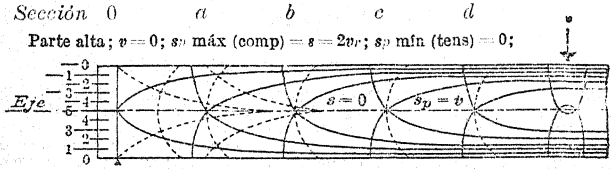

Parte alta; $v = 0$; $s_p$ máx (comp) $= s = 2v_r$; $s_p$ mín (tens) $= 0$;

Parte baja; $v = 0$; $s_p$ máx (tens) $= s = 2v_r$; $s_p$ mín (comp) $= 0$;

**Fig. 23.**

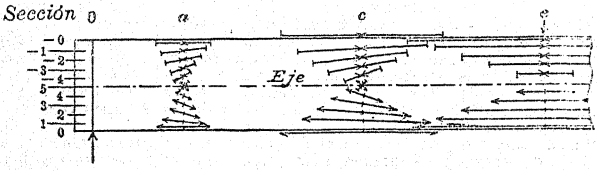

**Fig. 24.**

**127.** Aplicando estas fórmulas en numerosos puntos del perfil de la viga, fig. 22, se llega á construir **curvas**, fig. 23, que muestran las **direcciones** de los esfuerzos, y á trazar, como en la fig. 24, para puntos dados, las **direcciones é intensidades** de los esfuerzos que allí obran. En cualquier punto, fig. 24, tenemos esfuerzos resultantes normales y esfuerzos cortantes análogos á los de la fig. 18, pág. 520; pero, en esta fig. 24, debido á la falta de espacio, sólo se muestra para cada punto elegido el esfuerzo **principal máx**, $s_p$.

**128.** En la fig. 23, las direcciones de los **esfuerzos principales**, $s_p$, están representadas por las curvas continuas; las de los **esfuerzos cortantes resultantes**, $v_r$, por las de puntos.

| De las curvas continuas (esfuerzos principales) | cóncavas | horizontal en el cent de la luz | á 45° con | á 90° con |
|---|---|---|---|---|
| Las curvas de tensión son | hacia arriba | por debajo del eje neut | eje neut | borde sup de viga |
| Las curvas de compresión son | hacia abajo | por encima del eje neut | eje neut | borde inf de viga |

Las curvas de tens y comp son perpendiculares entre sí en sus intersecciones.

**129.** Siguiendo cualquier curva (cóncava hacia arriba) de tensión normal *, encontramos que :

(1) para su punto de **tangencia con la horiz** (esto es : en el cent de la luz) $s_p$ máx=tensión=$s$; $s_p$ mín=comp=0;

(2) para el punto **donde la curva cruza el eje neut** (á 45°) $s_p$ máx (tensión) $=s_p$ mín (comp)$=v_r=\pm v$ (esfuerzo cortante);

(3) **Por sobre el eje neut**, la tensión se hace $s_p$ mín, y continúa disminuyendo, á medida que la dirección se acerca á la vert, haciéndose cero en el borde sup, donde A=90°. Por encima del eje neut, para puntos de la misma curva, la *compresión* (*normal* á la curva) es ahora $s_p$ máx, y aumenta desde $s_p=v_r=\pm v$, en el eje neut, hasta $s_p$ máx (comp)$=s$, en el borde sup.

**130. Donde v=cero** (esto es : en cualquier punto de la sección transversal vert en el cent de la luz, y á lo largo de las fibras extremas superiores é inferiores) tenemos (§ 126) :

$$v_r=s/2$$
$$s_p \text{ máx}=s/2+v_r=s; \quad \text{tang } 2A=0;$$
$$s_p \text{ mín}=s/2-v_r=0; \quad \text{tang } 2A=0.$$

**131.** La ecuación, tang 2A=0, da ó 2A=0°, ó 2A=180°; esto es : A=0°, ó A=90°; pero sabemos que, en el cent de la luz y á lo largo de las fibras extremas (superiores é inferiores), $s_p$ máx es horiz, ó A=0°; y $s_p$ mín es vert, ó A=90°.

**132. Donde s=cero** (como en la superf neut y donde el momento de flexión= cero), tenemos (§ 126) : $v_r=\pm v$; $s_p$ máx$=s_p$ mín$=\sqrt{v^2}=\pm v$; tang 2A$=\infty$; 2A= 90°; y A=45°.

**133.** De las **curvas** (de puntos) **del esfuerzo cortante**, fig. 23, unas son tangenciales al eje neut y llegan al borde sup é inf de la viga en ángulos de 45°, tendiendo á separarse del cent de la luz; mientras que las otras son perpendiculares á éstas y al eje neut en sus intersecciones, llegando al borde sup é inf de la viga en áng de 45°, tendiendo hacia el cent de la luz.

* *Al contrario* para curvas (cóncavas hacia abajo) de compresión normal.

## MOMENTOS EN LAS VIGAS CONTINUAS

Véanse también §§ 78, etc.

**134.** Las figs. 25 y 26 muestran **momentos de flexión** positivos y negativos **en dos vigas continuas**; la fig. 25 de dos luces iguales, y la fig. 26 de tres luces iguales, descansan libremente sobre sus apoyos. Cada luz=1. La fig. 26 (tres luces) puede usarse, con bastante aproximación, para casos de mayor número de luces.

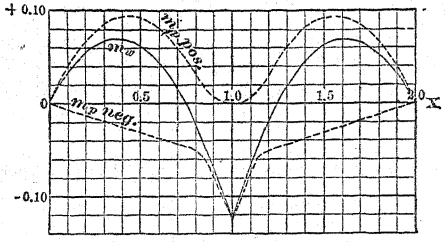

**Fig. 25.**

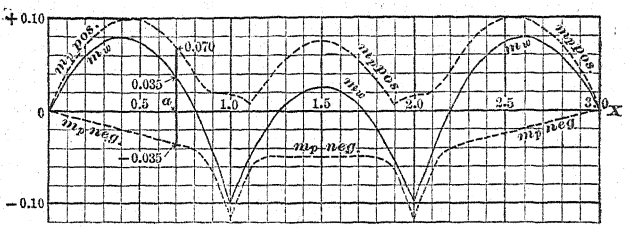

**Fig. 26.**

**135.** En cualquier sección transversal, la ordenada, entre el eje, 0X, de las abscisas, y la curva (1) $m_w$, (2) $m_p$ *pos*, ó (3) $m_p$ *neg*, representa, respectivamente, por la escala de las ordenadas, á la izquierda, (1) el momento de la carga muerta, $m_w$, (2) el mom máx positivo de la carga viva, $m_p$ *pos*, ó (3) el mom máx negativo de la carga viva, $m_p$ *neg*, en esa sección, estando la carga muerta (1 por unidad de luz) uniformemente distribuída sobre toda la longitud (dos ó tres luces, como se indica) de la viga, y estando el peso vivo (1 por unidad de luz) uniformemente distribuído alternativamente sobre dos porciones del largo de la viga, y siendo dichas porciones, para cada sección transversal, tales, que la carga viva uniformemente distribuída, puesta sobre aquéllas, produzca, alternativamente, el mom pos máx y el mom neg máx en dicha sección.

**136. En una viga real**, en cualquier punto, tenemos, para mom de flexión

$$M = m_w w L^2 + m_p p L^2;$$

donde

$m_w$=la ordenada, en el punto, desde 0X hasta la curva $m_w$;

$m_p$= — — — 0X — — $m_p$ *pos* ó $m_p$ *neg*;

$w$=carga muerta uniforme, por unidad de luz;

$p$= — viva — — — situada como se explica en el § 135.

L=la luz efectiva.

Así, en el punto, *a*, fig. 26 (distante .7 L de 0), tenemos, por la escala, $m_w$=.035; $m_p$ *pos*=.070 $m_p$ *neg*= — .035.

En consecuencia, en el punto *a*,

mom pos máx = $.035\, wL^2 + .070 pL^2$;

mom neg máx = $.035\, wL^2 - .035 pL^2$.

Si $p=w$, el mom neg máx, en $a$, es cero, y no hay momento neg resultante á la izquierda de $a$; pero, si $p=2w$, tendremos $w=p/2=(w+p)/3$; y, en $a$, con $p=2w$:

mom neg máx $= .035\,wL^2 - .035\times 2\,wL^2$;

$= .035\,wL^2 - .070\,wL^2 = - .035\,wL^2$

$= - .035\,(w+p)L^2/3$.

## COLUMNAS EN GENERAL

### Resistencia de las columnas, pilares, postes, de sección transversal uniforme.

Para Columnas de hierro y acero, véanse págs. 1236, etc., y para Columnas de madera, véanse págs. 1190, etc.)

**1. El eje** de una columna es una línea que pasa por los centros de gravedad de todas sus secciones transversales.

**2.** Si la línea de acción de la carga coincide con el eje de la columna en las secciones extremas, se dice que la columna está **cargada según el eje**; de otro modo, **excéntricamente cargada.**

**3.** Bajo una carga en el eje, si éste queda matemáticamente recto, coincide con la línea de presión en todo el largo de la columna, y el esfuerzo está uniformemente distribuído sobre cada sección transversal, como se indica por el paralelogramo, *ab*, fig. 2; pero la excentricidad de la carga, fig. 1 *a*, ó falta de rectitud en el eje, fig. 1 *b*, ó de homogeneidad en el material, hará que el eje diverja de la línea de presión.

**4.** Cuando el eje y la línea de presión dejan de coincidir, en cualquier sección, su divergencia establece, en esa sección, un « par » (véanse §§ 148, pág. 420, etc., y §§ 155, etc., pág. 423) representado por los dos triángulos, *bcd* y *ecf*, fig. 2, § 6 abajo.

**5.** En todos los casos, por tanto, **el diagrama** de los esfuerzos en la sección transversal consiste en el **paralelogramo**, *ab*, modificado ó no (según el caso) por los **dos triángulos**, *bcd* y *ecf*. En la fig. 2, los esfuerzos de las fibras extremas son : $s=af\ (=ae+ef)$ y $gd\ (=gd-bd)$.

**6. En columnas muy cortas**, cargadas en el eje, el paralelogramo está poco (si está algo) afectado por los triángulos; esto es : la presión está casi ó toda uniformemente distribuída sobre la sección transversal; mientras que, en **columnas muy delgadas**, por el contrario, la presión está desigualmente distribuída; y los efectos perturbadores, representados por los dos triángulos, pueden llegar á ser factores principales; de modo que la unidad máxima del esfuerzo del lado cóncavo, puede exceder considerablemente al esfuerzo medio, *ae* ó *gb*, fig. 2; mientras que la unidad del esfuerzo, *gd*, sobre el lado convexo, puede bajar á cero y aun llegar á ser tensión.

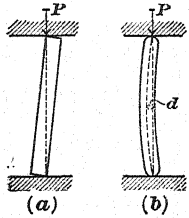

Fig. 1.

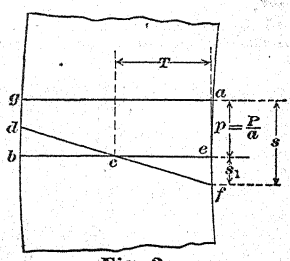

Fig. 2.

**7. En columnas muy delgadas, bajo flexiones moderadas**, los cambios de longitud en las fibras extremas, y por tanto los esfuerzos ejercidos por ellas, son relativamente pequeños. En consecuencia, la columna puede dejar de sostener su carga mucho tiempo antes de que estos esfuerzos lleguen á la última resistencia, ó al límite de elasticidad del material; como cuando una barba de ballena es comprimida por sus extremos entre el pulgar y otro dedo y salta lateralmente.

**8.** Pero, á medida que la flexión, *d*, fig. 1 *b*, aumenta, el momento, $Pd$, del peso

ó carga, P, aumenta también. Los cambios de longitud de las fibras, y por tanto las fuerzas ejercidas por ellas, aumentan también á causa del aumento de curvaturas de modo que es eventual poder impedir el movimiento ulterior de la carga, y si ésta es suficiente, puede la columna romperse ó quedar encorvada.

**9.** Una oblicuidad muy ligera, fig. 1 *a*, ó flexión, fig. 1 *b*, puede reducir su resistencia en un 50 por ciento; y pueden encontrarse diferencias de 10 por ciento ó más, en las cargas, entre dos pilares que, según todas las apariencias, y probados en las mismas condiciones, son perfectamente semejantes. En consecuencia, el modo de conducirse las columnas es mucho menos cierto que el de las piezas en tensión y aun que el de las vigas; y **hay que emplear factores muy liberales de seguridad** al usar fórmulas ó tablas para columnas.

**10.** Esta falta de certeza, con respecto á las resistencias de las columnas, es especialmente lamentable en el uso necesario, tan generalizado, **de las columnas como piezas de compresión en las armaduras de puentes y de techos.** (Véase Puente de Quebec en Columnas de hierro y de acero, pág. 1246.)

**11. El eje neutro** de cualquier sección es una línea, de esa sección, que pasa por su centro de gravedad, y perpendicular al plano en que se supone ó se efectúa la flexión. Una sección transversal puede en consecuencia tener uno ó varios ejes neuts, pues la col puede cimbrarse en uno ó varios planos. De ordinario, sin embargo, cuando una col de material homogéneo, se deja que cimbre libremente en cualquier plano, el plano de flexión se determina por la forma de su sección transversal y es el de su menor radio de giro. Así, si la sección es circular, sea sólida ó hueca, la flexión puede ocurrir igualmente en cualquier plano; pero, en una sec cuadrada, la flexión ocurre en un plano paralelo á uno ú otro lado; en un rectángulo, en un plano paralelo á los lados más cortos, etc., etc.

**12. Cuando el plano de flexión está predeterminado** por algún motivo, como por las espigas ó pernos en la fig. 3 *c*, **la economía de material** requiere que la sección esté de tal modo dispuesta, en lo que se refiere á la espiga, etc., que el **menor radio de giro** (véanse págs. 371 y 372) sea perpendicular al plano de flexión ya determinado. Cuando el plano de flexión no está determinado, la economía de material requiere que la sección esté trazada de tal modo, que los varios radios de giro sean tan próximamente iguales como sea posible.

**13.** Puesto que una construcción está en peligro cuando cualquier porción de ella sostiene una fuerza mayor que el **límite de elasticidad**, ese límite debe tomarse como valor del esfuerzo máximo.

**14. Fatiga.** En las consideraciones siguientes sobre este asunto, suponemos que los pilares sostienen una carga *constante;* y la carga última ó de ruptura á que se hace referencia es aquella que, durante su primera aplicación, dañaría ó rompería el pilar en corto tiempo. Pero los puntales en puentes, etc., tienen á menudo que soportar esfuerzos que varían considerablemente en intensidad de tiempo en tiempo. Su carga máxima ó de ruptura es entonces menor. Véanse págs. 486 y 487.

**15.** La resistencia de una columna está considerablemente afectada por la disposición que se dé á sus extremos; véase fig. 3. Así:

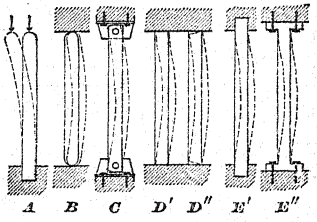

**Fig. 3.**

**A. Extremo libre.** Columna libre para flexarse en cualquier dirección, respectos al otro extremo (fijo).

En los siguientes casos, se supone que los extremos permanecen estacionarios aunque el eje esté más o menos libre para doblarse.

**B. Extremos redondeados.** Eje libre para doblarse en cualquier plano vertical.

**C. Extremos con pernos ó espigas.** Flexión limitada á un plano vertical.

**D. Extremos planos ó cuadrados.** Tangentes al eje de la columna, en los extremos, fijos en posición (véase D') hasta que haya rotación en los extremos, como en D".

**E. Extremos fijos.** Tangentes al eje de la columna, en los extremos, fijos en posición. Los dos extremos de una columna pueden estar diferentemente dispuestos. Así, puede uno estar fijo y el otro redondo, ó uno plano y el otro fijo con pernos ó espigas, etc.

## Cargadas según el eje (carga axil).

**16.** Se desprecia **el peso de la columna misma.**

**17.** Exprésense todas las dimensiones en una sola y misma unidad, como el centímetro, y todas las fuerzas en una sola y misma unidad, como el kg; y sean:

$a$ = área de la sección transversal;
$r$ = radio menor de giro;
$I = ar^2$ = su menor momento de inercia;
T = distancia desde el eje neutro de la sección á la fibra extrema en el lado cóncavo de la col flexada;
L = largo de la parte no apoyada de la col (véase § 41);
$K = \frac{L}{r}$ = coeficiente de delgadez de la col;
$b$ $m$, $c$ = coeficientes, como se explican abajo;
P* = carga de la columna;
$p^* = \frac{P}{a}$ = carga por unidad de superficie en la columna;
$s^*$ = unidad máxima del esfuerzo en la sección transversal;
$s_e$ = límite de elasticidad del material;
E = coeficiente de elasticidad del material;
$e$ = excentricidad de la carga, P; fig. 5;
$d$ = flexión bajo la carga, P; fig. 1$b$
= dist máx de la línea de pres al eje de la col.

**18. Fórmula de Euler.** Véase fig. 4 **. Supongamos que la columna sea ligeramente flexada por una fuerza lateral. Entonces el peso medio $p$, por unidad de superf, que bastará precisamente para tener en equilibrio la columna flexada, es:

$$p = \frac{P}{a} = b.\frac{\pi^2 E}{K^2}; \quad K = \pi\sqrt{\frac{bE}{p}} \ldots\ldots\ldots\ldots\ldots (1)$$

Para extremos redondos, $b=1$; para extremos fijos $=b=4$. Para un extremo redondo y un extremo fijo, $b$ se toma ordinariamente entre 2 y 2¼.

Bajo cualquier carga menor, ó K menor, volverá la columna á las mismas condiciones que cuando estaba derecha. Bajo cualquier peso mayor, la flexión aumentará. Véase § 8.

**19.** Para columnas muy largas, la **fórmula de Euler**, § 18, da resultados que concuerdan bien con la experiencia; pero, para longitudes usuales, da pesos excesivos. Véanse líneas *Ee*, *E'e'*, fig. 4. Para longitudes usuales (si la columna pudiera quedar derecha y cargada según el eje) y hasta para bloques cortos, recomendaríamos, para resistencia máxima, $p = P/a = s_e$ = límite de elasticidad, y el diagrama sería *Jbe* ó *Jb'e'*, fig. 4. Véase § 13.

**20.** Pero, por imperfecciones inevitables, las columnas de longitudes usuales, son susceptibles de flexión lateral, y el diagrama por tanto pasa más abajo de la línea *Jbb'*. Véase « Fórmula parabólica », § 28.

**21. Fórmula de Rankine** *** para columnas de longitudes usuales cargadas según el eje, fig. 2.

Como en el § 17, sean

---

* Bajo cualesquiera condiciones dadas, P y $p$ son la carga total y la carga media por unidad de superficie respectivamente, correspondientes al esfuerzo, $s$, de la fibra extrema bajo esas mismas condiciones. Así, P, $p$ y $s$ pueden corresponder á la carga de ruptura ó de seguridad, ó á cualquiera otra.

** *N. del T.* — Como el autor trae toda esta teoría con el diagrama (fig. 4) y las presiones, coeficientes, etc., en sistema inglés, hemos tenido que transformarlo todo al sistema métrico.

*** W. J. M. Rankine, « Ingeniería Civil », pág. 523. « La fórmula de Gordon », atribuída al prof. Lewis Gordon, de Glasgow, usa el *diámetro* menor, en vez del menor *radio de giro*, de la sección transversal.

**p**=carga media por unidad de superficie en la columna;
**s**=unidad máx del esfuerzo en la sección transversal;
**K**=L/*r*=longitud parte no apoyada ÷ radio menor de giro;
**m**=un coeficiente.

**22.** En una columna cargada según el eje (§ 2), mientras no está flexada, tenemos:

$$s=p=\mathrm{P}/a;$$

**23.** Pero, cuando la columna se *dobla*, obra por ese hecho un esfuerzo *adicional*, $s_1$, en su lado cóncavo (véase § 6), y tenemos, para el esfuerzo total por unidad de sup, *s*, en dicho lado :

$$s=p+s_1=(\mathrm{P}/a)+s_1$$

**24.** El momento de flexión, debido á la flexión, *d*, fig. 1 *b*, de la columna, $\mathrm{M}=\mathrm{P}d$.

**25.** Como en las vigas, págs. 489 y 490, tenemos, para equilibrio entre el momento de flexión, M, y el de resistencia, R,

$$\mathrm{M}=\mathrm{R};\quad \text{ó } \mathrm{P}d=\frac{s_1}{\mathrm{T}}\,\mathrm{I}.$$

En consecuencia,

$$s_1=\frac{\mathrm{MT}}{\mathrm{I}}=\frac{\mathrm{P}d\mathrm{T}}{ar^2}=p\,\frac{d\mathrm{T}}{r^2}$$

$$s=p+s_1=p+p\,\frac{d\mathrm{T}}{r^2}=p\left(1+\frac{d\mathrm{T}}{r^2}\right).$$

**26.** En una viga, pág. 504, para esfuerzo de una fibra dada, la flexión, *d*, es proporcional al cociente $\mathrm{L}^2/\mathrm{T}$. Suponiendo que esto es también verdad respecto á las columnas, tenemos :

$$d=m\ (\mathrm{L}^2/\mathrm{T}).$$

En consecuencia,

$$s_1=p\,.\,\frac{d\mathrm{T}}{r^2}=p\,.\,m\,\frac{\mathrm{L}^2}{\mathrm{T}}\,.\,\frac{\mathrm{T}}{r^2}=pm\mathrm{K}^2;\ \text{y}$$

$$s=p\ (1+m\mathrm{K}^2) \qquad (2)$$

Por tanto, la **fórmula de Rankine** ·

$$p=\frac{\mathrm{P}}{a}=\frac{s}{1+m\mathrm{K}^2}=s\,\frac{1}{1+m\mathrm{K}^2} \qquad (3)$$

$$\mathrm{K}=\sqrt{\frac{\frac{s}{p}-1}{m}} \qquad (3a)$$

**27.** Ritter * da $m=s_e/(b\pi^2\mathrm{E})$; y Crehore ** da $m=s/(b\pi^2\mathrm{E})$. Para valores de *b*, correspondientes á diferentes disposiciones de los extremos de la columna, véase § 18 §.

(*Obs. del T.* — Para valores de *s* y de $1/m$, usados en la práctica, en columnas de hierro y acero, véase pág. 1242. Allí están los valores de *s* en libras por pulg cuad, y debajo de cada uno, entre paréntesis, su equivalente en kg por cm cuad (véase *Obs. del T.*, pág. 1241, § 19). Para obtener el valor de $1/m$, divídase simplemente á la unidad por el correspondiente valor de B en la misma pág. 1241, etc. Para las columnas de madera, véanse fórmulas y tablas prácticas, págs. 1190, etc.)

**28. Fórmula parabólica. J. B. Johnson** ‖ .

$s_e$=límite de elasticidad del material; **q**=un coeficiente.

$$\text{Resistencia máx en kg por cm cuad}=p=\frac{\mathrm{P}}{a}=s_e-\frac{s_e^2}{q\pi^2\mathrm{E}}\,\mathrm{K}^2 \qquad (4)$$

$$\mathrm{K}=\sqrt{\frac{(s_e-p)\pi^2\mathrm{E}q}{s_e^2}} \qquad (4a)$$

---

* Construcciones de Techos y Puentes, 1873.
** Van Nostrand's Magazine, 1879.
Véase *N. del T.*, § 18.
‖ Estructuras armadas modernas, Nueva York, John Wiley and Sons, 1873, pág. 150.

Para extremos de espiga ó articulados $q=6.4$; para extremos chatos $=10$. Para columnas de madera, véanse fórmulas y tablas prácticas, págs. 1190, etc.

**29 *. Fórmula (línea recta). Thos. H. Johnson**.** En vista de la sencillez, propone el Sr. Thos. H. Johnson, para columnas de longitudes prácticas, la fórmula siguiente :

$$\text{Resistencia máx en kg por cm cuad} = p = P/a = s_s - Kc \quad \ldots\ldots (5)$$

$$K = (s_s - p)/c \quad \ldots\ldots (5a)$$

**Valores de $s_s$ y de c, para columnas de hierro y acero. Cargas de ruptura** (kg/cm cuad).

| | | Extremos | | | | | |
|---|---|---|---|---|---|---|---|
| | | chatos. | | espigados ó articulados. | | redondeados. | |
| | $s_s$ | $c$ | K | $c$ | K | $c$ | K |
| Hierro forjado..... | 2,950 | 12.96 | 218 | 10.99 | 178 | 14.21 | 138 |
| Acero blando; carbón=.12%. | 3,700 | 12.43 | 195 | 15.40 | 159 | 19.88 | 123 |
| — duro; — =.36%.. | 5,600 | 23.59 | 158 | 28.98 | 129 | 37.38 | 100 |
| Hierro colado..... | 5,600 | 30.66 | 122 | 37.59 | 99 | 48.51 | 7 |

(Para columnas de madera, véanse fórmulas y tablas prácticas, págs. 1190, etc.)

El error, debido al uso de esta fórmula, es probablemente mucho menor que los inevitables provenientes de la naturaleza de las columnas.

**30.** La fig. 4 muestra una **comparación de los resultados de experimentos y fórmulas para columnas de acero soldable, de extremos redondos**, como sigue : Para la fórmula de Euler, $p$ es la carga, en kg/cm cuad, que sostendrá, ligeramente cimbrada, una columna de los E y K dados. **Para las otras fórmulas** y para los experimentos de Tetmajer, $p$ es el peso *flexor.* en kg/cm cuad.

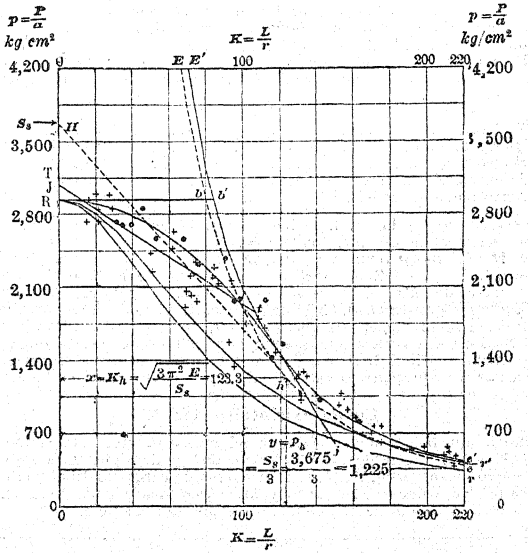

**Fig. 4.**

* Véase *N. del T.*, § 18.

** Trans. Am. Soc. Civ. Engrs, julio, 1886, vol. 15, pág. 547.

## Ensayos.

(De Tetmajer *: dimensiones aproximadas.)

16 barras redonds, de $^3/_4$ á $1\ ^3/_4$ pulgadas (19 á 44 mm) de diámetro.

102 experimentos, que comprenden ángulos, $4\times4$ pulgs ($102\times102$ mm) formas en **T** $5\times2\frac{1}{2}$ pulgs ($127\times63$ mm), canales, $5\frac{1}{2}\times2\ ^1/_4$ pulgs ($140\times57$ mm), vigas I, $7\times3\ ^3/_4$ pulgs ($178\times82$ mm), columnas remachadas como sigue : — 2 ángulos, $3\ ^1/_4$ pulgs (82 mm); 4 ángulos, $2\frac{1}{2}$ pulgs (57 mm); 2 formas en **T**, $3\frac{1}{2}\times1\ ^3/_4$ de pulg ($89\times44$ mm); 2 canales, $3\ ^1/_4\times1\frac{1}{2}$ pulgs ($82\times38$ mm). Cada punto representa el término medio de dos experimentos.

**31. T. H. Johnson** encuentra que, **para todas las tangentes á la curva de Euler**, las coordenadas del punto (como *h*, fig. 4) de tangencia son :

$$\text{Abscisa, } x=K=\sqrt{3zE/s_s}; \qquad \text{Ordenada, } y=ps=s_s/3;$$

donde $z=\pi^2=9.87$; para extremos redondos; $z=(5/3)\pi^2=16.45$, para extremos con goznes, y $z=(5/2)\pi^2=24.67$, para extremos planos; y $s_s$=la ordenada de ese punto, H, donde la tangente encuentra el eje de las ordenadas.

El Sr. Johnson toma $E=1{,}890{,}000$ kg por cm cuad, y $s_s=3{,}690$.

En consecuencia, en la fig. 4, $x=123.3$; $y=1{,}230$.

**32. Tetmajer** da los siguientes valores, $x'$, para la abscisa del punto donde su línea recta encuentra la curva de Euler (E, está dado en kg/cm cuad) :

| | E | $x'$ |
|---|---|---|
| Madera | 98,420 | 100 |
| Hierro fundido | 984,200 | 80 |
| Hierro forjado | 1,968,400 | 112 |
| Acero blando de construcción | 2,100,000 | 105 |
| Acero medio de construcción | 2,249,000 | 105 |

En consecuencia, en la fig. 4, su línea recta, *Tt*, encuentra la curva de Euler, *E'e'* (no tangencialmente) en *t*, donde $K=105$.

**33. J. B. Johnson** toma $E=2{,}100{,}000$ kg por cm cuad; y su curva, *Jj*, es tangente á la curva de Euler, *E'e'*, en el punto donde $K=120$. Para columnas de acero suave con extremos de espigas, él limita el valor de K á un máx de 150.

**34. Fórmula gradual. J. R. Worcester.** En vista de la amplia divergencia encontrada en la resistencia de las columnas, por las varias fórmulas y coeficientes en uso, y de la variación igualmente amplia en los resultados experimentales, considera inútil el Sr. J. R. Worcester ‖ darle á *p* un valor diferente para cada valor de K; y propone un valor *fijo* de *p* para cierta *serie* de valores de K.

## Carga excéntrica. Fig. 5.

**35.** Hasta aquí hemos supuesto que la columna está axilmente cargada (según el eje) (véase § 2) y, considerando la desigualdad de distribución de los esfuerzos en una sección transversal, fig. 2, con su exceso de carga resultante en las fibras extremas del lado cóncavo, hemos tomado en cuenta solamente aquel exceso, $s_1$, que se debe á la *flexión* de una columna cargada según su eje.

---

* Comunicaciones del Instituto de Examen de Materiales á la Politécnica Suiza en Zurich. Entrega VIII, 1896.

** $0.105=s^2/\pi^2bE=2{,}953^2/(9.87\times2{,}100{,}000\ b)$. Para extremos redondos, $b=4$.

‖ Trans. Am. Soc. Civ. Engrs., vol. 54, p. 417, junio 1905.

**36.** Pero muy comúnmente sucede que las columnas están (accidental ó intencionalmente) cargadas excéntricamente; y esta excentricidad, *e*, trae sobre las fibras extremas del lado más próximo á la línea de presión, un exceso *adicional* de la unidad del esfuerzo, fig. 5. Si la columna quedase perfectamente recta, tendríamos (véanse págs. 489-90) $s_2 = TM/I = TPe/ar^2 = (P/a)(Te/r^2) = pTe/r^2$; y en consecuencia, en una columna cimbrada (véase ecuación (2), donde $s_1 = pmK^2$),

$$s = p + s_1 + s_2 = p\left(1 + mK^2 + \frac{Te}{r^2}\right) \qquad (6)$$

$$p = \frac{P}{a} = \frac{s}{1 + mK^2 + \frac{Te}{r^2}} \qquad (7)$$

$$K = \sqrt{\frac{\frac{s}{p} - 1 - \frac{Te}{r^2}}{m}} \qquad (7a)$$

donde, como en el § 17 :

**p** = carga media de la columna;
**e** = excentricidad, fig. 5;
**s** = unidad máxima del esfuerzo en la sección transversal;
**K** = $L/r$ = longitud entre soportes ÷ radio menor de giro;
**r** = dist del eje neutro de la sección hasta la fibra extrema en el lado cóncavo,

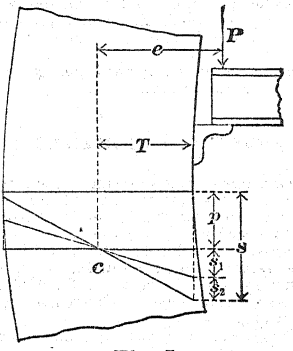

**Fig. 5.**

**37.** Como asunto de hecho, la flexión de la columna, establecida en el término, $mK^2$ (Ecuaciones 6 y 7), aumenta ligeramente la excentricidad, *e*, del peso (véase fig. 5) y esto se desprecia en el término $Te/r^2$. En consecuencia, el esfuerzo de la fibra, *s*, dada por la ecuación (6) es un poco pequeño, y el peso, *p*, dado por la ecuación (7), es un poco grande; pero la discrepancia de ordinario se desprecia en la práctica.

**38.** Para columnas de extremo redondo, da **J. M. Moncrieff** ★:

$$p = \frac{P}{a} = \frac{s}{1 + \frac{Te}{r^2}\left(\frac{48E + pK^2}{48E - 5pK^2}\right)} \qquad (8)$$

$$K = \sqrt{\frac{48E}{5s + p(Te/r^2 - 5)}\left(\frac{s}{p} - 1 - \frac{Te}{r^2}\right)} \qquad (8a)$$

★ Trans. Am. Soc. Civ. Engrs., vol. 45, pág. 349, junio 1901.

**39.** Sean

M = P*e*, fig. 5 = momento de un peso excéntrico, P, respecto de *c*;
I = momento de inercia de la sección transversal;
T = distancia del eje neutro á la fibra más distante;
X = I/T = módulo de sección transversal en la dirección de la flexión;
$s_2$ = esfuerzo máximo de la fibra debido solamente á la excentricidad.

Entonces, $s_2 = MT/I = M/X$ ..... (9)

**40.** Con columnas que se suponen axilmente cargadas, la carga es, en realidad y muy comúnmente, más ó menos excéntrica, y el tamaño de la excentricidad se desconoce; pero cuando una carga se aplica en un punto del borde de la columna ó más allá de él, como en la fig. 5, la excentricidad es tan grande, que ocurren incertidumbres, inevitables en cuanto á su exacto valor, y éste se hace relativamente despreciable; las Ecuaciones (7 y (7 *a*) pueden usarse con más ó menos confianza.

**41.** Si una columna muy larga fuere de tal modo **reforzada á intervalos** que se impida su flexión en esos puntos, entonces su longitud disminuye virtualmente, y se aumenta su fuerza. Así, si una columna de 30 m de largo fuere suficientemente reforzada á intervalos de 10 m, entonces puede sostener la carga de una columna de sólo 10 m de largo.

### Advertencias.

**42.** Las columnas de hierro fundido están sujetas á tener huecos y otros defectos ocultos y se rompen fácilmente por golpes laterales. Las columnas de todas clases están sujetas á trepidaciones y vibraciones provenientes de cargas movibles. Muy raras veces sucede que la presión esté igualmente distribuída sobre toda el área del pilar; ó que los extremos estén igualmente apoyados y sostenidos en todas sus partes.

**43.** En ensayos de columnas pueden lograrse por excepción buenos resultados cuando sus condiciones se acercan al ideal.

## ESFUERZO CORTANTE

**Esfuerzo cortante ocurre** cuando sobre un cuerpo obran dos fuerzas opuestas en planos paralelos y adyacentes, que tienden á hacer deslizar unas partículas sobre las otras. En la fig. 1, las dos fuerzas son (1) la presión descendente del peso, W, y (2) la reacción ascendente del soporte A.

En el **esfuerzo cortante simple**, fig. 1, el área del esfuerzo cortante, $a$ = á la sección *gg*. En el **esfuerzo cortante doble**, fig. 2, $a = gg + oo = 2 \times gg$. En la fig. 3, $a$ = 6 × sección transversal de la pieza. En la fig. 4 (esfuerzo cortante simple), $a$ = sección *cc*. Al horadar agujeros para remaches, $a$ = circunferencia del agujero × espesor de la plancha.

En cualquier caso, si S = al esfuerzo cortante por unidad de superficie, el esfuerzo cortante total será = S*a*.

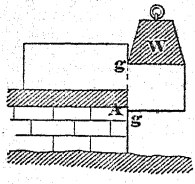

Fig. 1

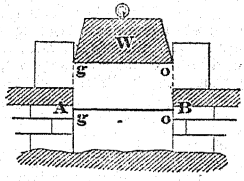

Fig. 2

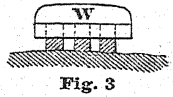

Fig. 3

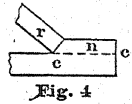

Fig. 4

**El esfuerzo cortante, S,** por unidad de superficie, en kg por cm cuadrado, en los metales y en las maderas, está indicado por las cifras siguientes:

Metales: Hierro forjado, 2,500 á 3,800; hierro fundido, 1,400 á 2,100; acero, 3,200 á 5,300; cobre, 2,300.

| | Abeto del Canadá | » | » |
| | Pino amarillo | ..... | 300 á 400 |
| | Roble | 30 á 50 | ..... |
| | Roble blanco | ..... | 300 |

## TORSIÓN

**La torsión** ocurre cuando sobre un cuerpo obran dos pares ó momentos de sentido contrario y en planos diferentes. Por ejemplo: en el eje de un freno cuando lo hacemos girar mientras su extremo inferior está sujeto por la cadena del freno; y en los ejes transmisores de fuerza motriz cuando transmiten ésta de la máquina á los aparatos. Supóngase que el cuerpo sometido á torsión se divida en capas, por medio de secciones transversales. Entonces cada capa tiende á ejercer un esfuerzo cortante desde la próxima capa. En consecuencia, para mantener el equilibrio, cada dos capas adyacentes deben ejercer, en la sección transversal entre ellas, un momento de resistencia interno igual á uno de los dos momentos de torsión externos y contrarios.

**Momento de resistencia,** en una sección transversal circular de un árbol cilíndrico. Sean:

$P$ = la fuerza de torsión de uno de los dos momentos externos;
$l$ = su palanca = su distancia al eje del árbol;
$M = Pl$ = momento externo ó de torsión;
$T$ = distancia del eje á las fibras más distantes = radio del árbol;
$D$ = diámetro del árbol, $= 2T$;
$S$ = esfuerzo cortante por unidad de superficie en las fibras más remotas;
$t$ = distancia del eje á cualquier fibra dada;
$s$ = esfuerzo cortante por unidad de superficie en dicha fibra dada;
$a$ = área de dicha fibra dada;
$F$ = esfuerzo cort total en dicha fibra;
$r$ = momento de resistencia de dicha fibra respecto al eje;
$R$ = momento interno de resistencia de la sección transversal entera
$= \Sigma r$ = suma de los momentos de resistencia de todas las fibras;
$I_p$ = momento polar de inercia* de la sección transversal;
= momento de inercia de la sección transversal respecto del eje del árbol;
$= \Sigma t^2 a$, = la suma, para todas las fibras, de $t^2 a$.

(*Obs. del T.* — Hay que tener mucho cuidado en la elección de estas unidades para que resulte la homogeneidad de las fórmulas al aplicarlas. Por ejemplo, si P son kilogramos y $l$ y $D$ son centímetros, han de calcularse los esfuerzos S, $s$ en kg por cm cuad y las áreas, como $a$, en cm cuad. Es claro que M vendrá en kg-centímetro y el momento de inercia I será una unidad de cuatro dimensiones, cuya base es el centímetro. Estas unidades serán las que adoptaremos en los ejemplos que van después. Todos los que trae el autor en medidas inglesas los hemos transformado para adaptarlos al sistema métrico.)

Entonces el esfuerzo por unidad de superficie en cualquier fibra dada, es $s = St \div T$; su esfuerzo total, F, es $= as = Sat \div T$; y su momento de resistencia, $r$, es $= Ft = Sat^2 \div T$. Para el equilibrio, el momento interno de resistencia, R, de la sección entera, debe ser = al momento externo de torsión, M.

En consecuencia, para el **momento interno de resistencia,** R, tenemos

$$R = M = \Sigma r = \Sigma Sat^2 \div T = (S \div T)\, \Sigma t^2 a = (S \div T)\, I_p.$$

De donde, también, $S = MT \div I_p$; $M = SI_p \div T$; y $P = M \div l = SI_p \div (Tl)$.

**En un círculo sólido,** $I_p = \pi T^4 \div 2$. Por tanto, $S = 2MT \div (\pi T^4) = 2M \div (\pi T^3)$; $M = S\pi T^3 \div 2$; $P = S\pi T^3 \div (2l)$; y $T = \sqrt[3]{\frac{2lP}{\pi S}}$; de donde

---

* En cualquier figura, el momento polar de inercia, $I_p$, es = á la suma de los momentos de inercia más grandes y más pequeños de la misma figura, respecto á dos ejes que estén en la figura y que se intersecten en su centro. En un círculo sólido, cada uno de éstos es un momento de inercia respecto de un diámetro, y es $= \pi T^4 \div 4$. Por tanto, dicho círculo, $I_p = \pi T^4 \div 2$.

**Diámetro,** $D, = 2\,T = 2 \times \sqrt[3]{\frac{2Pl}{\pi S}} = \sqrt[3]{\frac{5.1\,M}{S}} = 1.72 \sqrt[3]{\frac{M}{S}}$.

(*Obs. del T.* — Pongamos un ejemplo: supongamos el momento M=86,400 kg-cm y $s$=422 kg por cm cuad; tendremos $1.72 \sqrt[3]{\frac{86,400}{422}} = 1.72 \times 5.85 = 10.06$, digamos 10 cm.)

**Para valores aproximados de S, para la torsión,** úsense los valores para el esfuerzo cortante, pág. 528*f*, con **factores de seguridad** de 5 á 10.

**Fuerza en caballos de un eje de transmisión.** En una revolución, la fuerza, P kg, que describe una circunferencia con radio=$l$ cm, efectúa un trabajo=$2\pi lP$ kg-cm, y, en $n$ revoluciones, trabajo=$2\pi lPn$ kg-cm. Si $n$ es el número de revoluciones *por minuto,* el caballo de fuerza es:

$H = 2\pi lPn \div (100 \times 75 \times 60)$ * $= 2\pi Mn \div (100 \times 75 \times 60) = \pi Mn \div (50 \times 75 \times 60)$ ó puesto que $Pl = M = R = SI_p \div T$, tenemos:

$H = S\pi nI_p \div (50 \times 75 \times 60\ T)$; de donde $S = 50 \times 75 \times 60\ TH \div (\pi nI_p)$.

**En un árbol cilíndrico sólido** (véase nota pág. 528*g*): $I_p = \pi T^4 \div 2$. Por tanto, $H = S\pi n\pi T^4 \div (100 \times 75 \times 60\ T) = S\pi^2 nT^3 \div (100 \times 75 \times 60)$; de donde

$S = H\,(100 \times 75 \times 60) \div \pi^2 nT^3 = 100 \times 456.4\ H \div nT^3$;

$n = 45,640H \div S\,\frac{D^3}{8} = 365,120\ H \div D^3S$; y

$$D = \sqrt[3]{\frac{365,120\ H}{Sn}} = 71 \sqrt[3]{\frac{H}{Sn}}.$$

**Mientras mayor es la velocidad, menor es la fuerza,** y por tanto menor es la fuerza del eje de transmisión para transmitir un *caballo;* pero si se aumenta la velocidad aumentando la fuerza de torsión, se aumenta así la fuerza transmitida.

**Ejemplo.** Dado un árbol de hierro forjado; sea S=422 kg por cm cuad; P=3,456 k; $l$=25 cm; M será=86,400 kg-cm. Tendremos para el diámetro (véase ejemplo del traductor al comienzo de esta página) D=10.06 cm.

Supongamos que la potencia en caballos sea H=25. Entonces $n = 365,120 \times 25 \div (D^3S) = 9,128,000 \div (10.06^3 \times 422) =$ digamos 21.

Comprobemos ahora: $D = 71 = \sqrt[3]{H \div Sn} = 71 \times \sqrt[3]{25 \div (422 \times 21)} = 71 \times .14 =$ digamos 10 cm.

**Secciones rectangulares.** Las ecuaciones que preceden se basan en el supuesto de que la fuerza aumenta uniformemente desde el eje del árbol hacia afuera. Se ha demostrado (especialmente por St. Venant) ** que esta hipótesis no es aplicable á secciones cuadradas y rectangulares. En un rectángulo, sea B=lado más largo, $b$=más corto, y $c = b \div B$. Entonces $S = M\,(3 + 1.8\ c) \div (Bb^2)$; y $P = SBb^2 \div [(3 + 1.8\ c)l]$. En un cuadrado, de lado=$b$, resulta $S = 4.8\ M \div b^3$; $M = Sb^3 \div 4.8$. $P = Sb^3 \div (4.8\ l)$.

**El ángulo de torsión** es el descrito por uno de los momentos externos de torsión respecto al otro. Dentro del límite de elasticidad este ángulo es proporcional al momento de torsión, M, y (suponiendo constante á $l$) proporcional á la fuerza, P. En igualdad de las otras circunstancias, el ángulo es proporcional á la distancia entre los planos de los dos momentos opuestos externos, y, en un árbol sólido cilíndrico, es inversamente proporcional á $D^4$. No es bueno que el ángulo de torsión exceda de 1° en una longitud=á 20 diámetros, en árboles que giran en una sola dirección. En árboles alternativos concédase aún menos. Véase Fatiga, pág. 486, etc.

**Consideraciones prácticas.** En muchos casos el diámetro del árbol debe hacerse más grande que el requerido por las fórmulas que preceden; como, por ejemplo, en un árbol largo, á fin de mantener el ángulo de torsión dentro de los límites permitidos, en las ruedas volantes y otros árboles que llevan considerables pesos de flexión además de las fuerzas de torsión; y, en los más de los casos, para prever los momentos adicionales debidos á alternativas aceleraciones y retardaciones.

---

* *N. del T.* — *Como* $2\pi lPn$ son kg-cm *por minuto,* para tener kg-metro, se divide por 100; ahora, como un caballo = 75 kgm por seg, se divide aún por 75 y por 60.

** Véase Tratado de Física, por Sir William Thomson y Peter Guthrie, parte II, nueva edición, Cambridge, 1890, págs. 236, etc.

# HIDROSTÁTICA

**Art. 1. La hidrostática trata de** la presión del agua y de otros líquidos en reposo.

En cualquier punto dado dentro de un fluido **la presión es igual en todas direcciones**, y la presión contra cualquier punto de cualquier superficie, plana ó curva, es **perpendicular á la superficie comprimida** (ó á un plano tangente á esa superficie) en ese punto.

**La intensidad de la presión** es proporcional á la profundidad del punto bajo la superficie del agua.

**Presión contra cualquier superficie plana.**

Sean

$a$=el área de la superficie comprimida;
$h$=la profundidad vertical del centro de gravedad de la superficie comprimida por debajo de la superficie libre del fluido;
H=la profundidad total del fluido;
$w$=el peso de una unidad de volumen del fluido *;
$p$=la presión media por unidad de la superficie comprimida;
P=la presión total sobre la superficie comprimida.

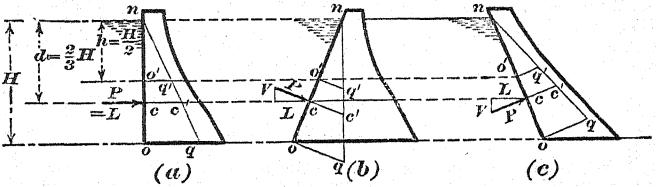

**Fig. 1.**

Entonces la **unidad media de presión**, $p$, es igual al peso de un prisma del fluido, cuya base es=1, y cuyo largo es=$h$; ó

$$p=hw;$$

y la **presión total**, P, es igual al peso de un prisma del fluido, cuya base es=$a$ y cuyo largo es=$h$. O bien

$$P=ahw=ap.$$

**En los diagramas** de las figs. 1 y 2, las *ordenadas* (que se suponen trazadas desde las superficies comprimidas y perpendicularmente á ellas, respectivamente) representan las *unidades* de presión (como en lbs por pulgada cuad, kilogramos por centímetro cuad, etc.) y el *área*, enfrente de cualquier superficie dada, representa la presión *total* sobre esa superficie. Así, en la fig. 1 (*a*), las unidades de presión en *n*, en *o'*, en *c* y en *o* están representadas por *n* (=0), por *o'q'*, por *cc'* y por *oq* respectivamente; y la presión total sobre *no* está representada por el área *no'q*, la sobre *no'* por el área *no'q'*, la sobre *o'o* por el área *oq'*, y la sobre *o'c* por el área *cq'*.

**El centro de presión** sobre cualquier superficie está enfrente del centro de gravedad del área que representa la presión total sobre esa superficie. Así, en las figs. 1, el centro de presión sobre *no*, está enfrente del centro de gravedad del triángulo, *noq*, ó á una profundidad, $d$, $=\frac{2}{3}$H, por debajo de la superficie de agua. Véase « El Centro de Presión », arts. 8, etc., y también §§ 133, etc., de « Estática ».

* Para agua, $w$ = cosa de 62.5 lbs por pie cúbico = 1 kg por decímetro cúbico.

**La paradoja hidrostática.** Para una profundidad dada, *h*, tanto la unidad de presión media, *p*, como (para un área dada *a*) la presión, P, son independientes de la cantidad de agua. Así, en las figs. 1, las paredes sostienen una presión tan grande, ya provenga de una lámina vertical de agua de sólo un cm de espesor ó de una masa de agua que se extendiese kilómetros detrás del muro.

En la fig. 2 (*b*), el exceso de peso de agua sobre el de la fig. 2 (*a*), es soportado por la pared inferior inclinada de la vasija. Las presiones totales, P, sobre las bases iguales, *ab* y *a'b'*, figs. 2 (*c*) y (*d*), son iguales. En la fig. 2 (*c*), la presión total sobre la base es mayor, y en la fig. 2 (*d*), menor que el peso del agua; pero, en uno ú otro caso, la suma algebraica de todas las presiones verticales en la vasija (tomadas como negativas las presiones ascendentes) es=al peso de todo el agua de la vasija, y la suma algebraica de todas las presiones horizontales es=0.

Así, supongamos que la parte inferior de la fig. 2 (*c*) representa una caja cúbica, de 2.40 m por lado, llena de agua. Ahora, llénese de agua el tubo *no*, de 11 m de alto y de 7 mm de diámetro. El agua en el tubo solo, aunque pesa solamente cosa de 450 gramos, causará una presión adicional (que tiende á reventar la vasija) de 1.1 kg por cm cuad, ó digamos 384 toneladas totales, que se ejercerá sobre la parte superior, el fondo y los lados de la caja.

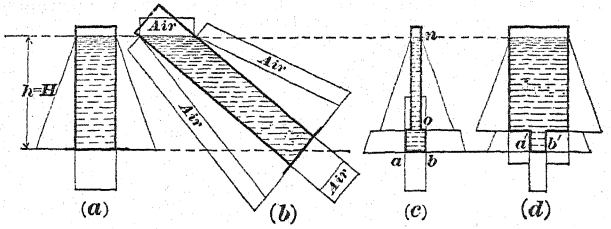

**Fig. 2.**

**Presión del aire en la superficie del agua.** Además de la presión del agua, la superficie libre de cualquier masa de agua sostiene también la presión del aire, =cosa de 1 kg/cm cuad. Esta presión (transmitida por el agua á las paredes de la vasija) está indicada por los paralelogramos marcados « aire » en la fig. 2 (*b*). En los más de los casos, la presión debida al aire contra una superficie de agua, es contrarrestada por una presión igual del aire en la dirección opuesta, como contra los lados externos de las paredes de las vasijas en las figs. 2, y contra los lados de las presas en las figs. 1.

Estrictamente hablando, la presión del aire, ejercida directamente contra las paredes, figs. 2, ó contra las presas, figs. 1, siendo ejercida prácticamente en los centros de gravedad de esas superficies, y por tanto á más profundidad que la presión opuesta debida al aire sobre la superficie libre del agua, es muy poco mayor que la última. En una presa de 30 m de profundidad, esta diferencia es más ó menos de .0018 kg **por** cm cuad=.0018 atmósfera.

**Refuerzos para presas.** Siendo la presión del agua perpendicular á la superficie comprimida, los postes, fig. 3, deben también ser perpendiculares á la super-

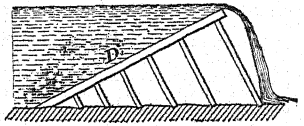

**Fig. 3.**

ficie D, para que reciban la presión longitudinalmente y evitar así momentos de flexión; pero otras consideraciones pueden prohibir que se coloquen de esa manera. Así, si la cara, D, de la presa, es casi vertical, los postes tendrían que hacerse

extraordinariamente largos; y por consiguiente muy débiles, como pilares, á no ser que se hagan exageradamente gruesos. Así puede quedar más que compensada la ventaja debida á la acción longitudinal de la presión. Además, los pies de los postes más largos se proyectarían más allá del borde de la presa y podrían dañarse con el hielo, troncos, etc., que cayeran por el vertedero de la presa. Como la presión aumenta uniformemente desde la superficie del agua hacia abajo, los postes se colocan de ordinario más próximos cerca del fondo que cerca del tope, aunque lo corto de los más bajos los hace más fuertes como pilares. De modo semejante, los aros de las tinas, si son de la misma fuerza, se colocan más próximos unos á otros cerca del fondo.

**Componentes horizontales y verticales.** En las figs. 1 (*b*) y (*c*) el triángulo de fuerza (Estática, §§ 46, etc.) nos da los componentes horizontales y verticales, L y V, de la presión perpendicular total, P. O bien, si *n o* se toma, en cada caso, para representar la presión perpendicular total, P, por escala, entonces H=la presión horizontal total. En la fig. 1 (*a*), tratándose de una presión contra una superficie vertical, L=P, y V=0.

En la fig. (*b*), la componente vertical, V, comprime la pared hacia abajo contra su base; pero en la fig. (*c*) tiende á levantarla y volcarla.

Siendo la profundidad, H, la misma en cada una de las tres figuras, figs. 1 *a*, *b* y *c*, las proyecciones *verticales* de las tres superficies sumergidas son iguales, y en consecuencia las presiones *horizontales* totales son iguales en los tres casos; pero la proyección *horizontal* y en consecuencia la presión *vertical* total, varían con la inclinación de la superficie. Así, en la fig. 1 (*a*), la proyección horizontal y la presión vertical son cada una=0.

**Presiones en vasijas cúbicas de otras formas, llenas de agua.** Sean F=el peso de agua contenida en una vasija prismática; y $f = \frac{F}{3}$ = el peso de la que contiene una vasija cónica ó piramidal de las mismas base y altura.

En una vasija cúbica, la presión sobre la base=F; presión sobre un lado $= \frac{F}{2}$;

presión sobre la base y cuatro lados juntos $= F + 4\,\frac{F}{2} = 3F$.

En una vasija cónica ó piramidal, presión sobre la base $= 3f = F$.

En una vasija esférica, presión total = 3 × peso del agua.

**Art. 2. Presión desigual en direcciones opuestas.** En las figs. 4, represente *n o* el lado de un paralelogramo, cuyo lado superior coincide con la superficie del agua, y cuyo fondo sea paralelo á esa superficie; sea *a*=el área de la porción,

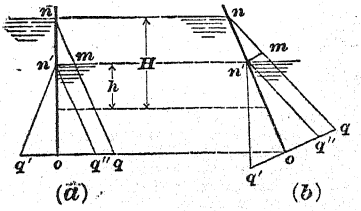

Fig. 4.

*n'o*, que está sometida á presión en ambos lados; y sean H y *h*=las profundidades verticales del centro de gravedad de *n'o* por debajo de las dos superficies de agua *n*, y *n'*, respectivamente. Entonces, en cada fig., el triángulo grande, *noq*, representa la suma de las presiones del agua más honda á la izquierda contra todo el muro, *no;* el trapezoide *mo*, representa la suma=*a*H*w* de las presiones del agua á la izquierda contra *n'o;* y el triángulo más pequeño, *n'oq'*=*n'oq''*, representa la suma, =*ahw*, de las presiones del agua más baja á la derecha contra la porción, *n'o*. Entonces el paralelogramo, *mq''*, representa el *exceso* de presión, del lado izquierdo, contra la porción, *n'o*. Este exceso, debido á la diferencia, H — *h*, entre los dos niveles, está uniformemente distribuído sobre *n'o*, estando representada la *unidad* de exceso de presión uniforme por la ordenada *n'm*=*q''q*. El exceso *total* de pre-

sión, representado por el paralelogramo, $mq'' = aHw - ahw = (H - h)\ aw$, es por tanto proporcional á $(H - h)$.

La presión procedente de la derecha contra la porción *n'o*, y representada por el triángulo *n oq'* está equilibrada por una porción igual (representada por el triángulo *n'oq''*) de la presión total, *mo*, desde la izquierda contra la porción *n'o;* y los centros de estas dos presiones, estando cada uno á una profundidad$=\frac{1}{3}$ *n'o* por debajo de *n* , son opuestos y estas dos presiones están en equilibrio. Pero el centro del exceso de presión, *n'q*, de la izquierda, está frente al centro de gravedad del paralelogramo, *n'q*, ó en el centro de gravedad de *n'o*. En consecuencia, la porción *n'o*, considerada independientemente de *n'n*, es impulsada por la fuerza no contrarrestada *n'q*, procedente de la izquierda, obrando por su centro de gravedad y tendiendo á moverla hacia la derecha, sin rotación.

Esto se comprenderá por medio de la fig. 5 *, que representa cinco tablones 1, 2, 3, 4 y 5, formando un dique visto de canto. Cada taldón tiene 1 pie de alto y 20 pies de largo, horizontalmente, formando, por tanto, una superficie comprimida de 20 pies cuadrados. La presión en libras contra cada 20 pies cuad de superficie separadamente, calculada por la regla del art. 1, se indica en la figura. Ahora bien, la presión hacia afuera contra los 20 pies cuad del primer tablón *sumergido* superior n.º 3, es de 3,125 lbs, mientras que la presión contraria que obra del otro lado es de 625 lbs, produciendo un *exceso* de presión hacia afuera de 3,125 — 625 = 2,500 lbs. Ahora bien, en el tablón más bajo n.º 5, la presión hacia afuera excede de la que obra hacia adentro en 5,625 — 3,125 = 2,500 lbs lo mismo que en el de arriba; y así en cualquiera superficie igual sumergida á cualquiera profundidad; dependiendo el exceso de la altura vertical *mn*, se distribuirá igualmente sobre *ab*. Falta sólo demostrar que el exceso total de la presión hacia afuera ejercida contra *ab* es igual en intensidad al peso de una columna de agua con una base igual en superficie á *ab* y una altura igual á *mn*. Así hemos visto que en el ejemplo presente el exceso asciende á 3 veces 2,500 lbs ó sean 7,500 lbs. Ahora el peso de la columna de agua es 60 (área de *ab*) × *mn* (ó 2 pies) × 62.5 lbs = 7,500 lbs, que es lo mismo que el *exceso* de presión sobre *ab*. El exceso de presión entre la cara entera *sb*, y la cara *n o*, es evidentemente la diferencia de las dos presiones calculadas respectivamente según la regla del art. 1.

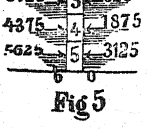

Fig 5

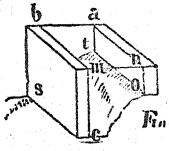

Fig 6

**Art. 3. Las superficies verticales como** *bmcs, anot*, **fig. 6, ó de otra manera, de iguales anchos** *bm, an*, **que comienzan al nivel** *banm* **del agua, pero que se prolongan á diferentes profundidades,** *mc, no*, **medidas verticalmente, con la misma inclinación hacia la superficie del agua, sufren presiones totales proporcionales á los cuadrados de aquellas profundidades.**

En la fig. 6, supongamos que las dos caras verticales *anot* y *bmcs* de un envase, tengan el mismo ancho *an* y *bm*. Si la profundidad *mc* es de 2, 3, 4, 5, etc., veces mayor que la profundidad *no*, la presión contra la superficie *bmcs* será 4, 9, 16, 25, etc., veces mayor que la que obra contra *anot*. Esto se verá observando las presiones indicadas del lado izquierdo de la fig. 5, donde, como se ha dicho en el art. 2, la superficie del tablón 1, expuesta á la presión que obra contra la cara izquierda, es de 20 pies cuad; la de los tablones 1 y 2, de 40 pies cuad; la de los 1, 2 y 3, de 60 pies cuad., etc. Todas estas superficies principian al nivel del agua, y siendo todas ellas verticales, tienen, por supuesto, la misma inclinación con la superficie del agua; pero sus profundidades son de 1, 2 y 3 pies respectivamente.

* *N. del T.* — Dejamos el ejemplo en medidas inglesas, porque para la teoría no tiene importancia la unidad elegida.

La presión contra la superficie 1 es de 625 lbs; la que se ejerce contra la superficie 1 y 2, es de 625+1,875=2,500; y la que obra contra las superficies 1, 2 y 3 es de 625+1,875+3,125=5,625. Pero 2,500 es *cuatro* veces 625, y 5,625 es *nueve* veces 625. Y la presión total contra la superficie entera *sb* (que tiene una profundidad 5 veces mayor que el tablón 1), es 25 veces mayor que la que actúa contra el tablón 1, ó 625×25=15,625 lbs, suma de todas las presiones marcadas en el lado izquierdo de la fig. 5. (*N. del T.* — Véase nuestra nota al pie de la página anterior.)

Se sigue de la regla del art. 1, que para una superficie de área doble, multiplicada por el doble de la altura vertical del centro de gravedad á la superficie del agua, se obtendrá una presión cuádrupla; para una área triple multiplicada por profundidad triple debe dar una presión nueve veces mayor, etc. Se sigue también que para cualquier *punto* ó contra cualquier área *dada* situados á diferentes profundidades, la presión aumentará simplemente como la profundidad vertical; de manera que si hay tres áreas, cada una de 1 p cuad colocadas en las mismas posiciones, pero con sus centros de gravedad respectivamente á 8, 16 y 24 p debajo de la superficie, la presión que obrará contra ellas será respectivamente *como* 8, 16 y 24, ó *como* 1, 2 y 3.

**Art. 4. La presión del agua en equilibrio en cualquiera dirección dada** contra cualquiera superficie dada, vertical, horizontal, inclinada, plana ó curva, es igual al peso de una columna de agua, con una base igual al área de la proyección *de la superficie comprimida tomada perpendicularmente á la dirección dada;* y una altura igual á la profundidad vertical del centro de gravedad de dicha superficie bajo el nivel superior del agua.

*Regla.* **Para encontrar la presión en** *kg*, multiplíquense entre sí el área en decímetros cuad de la proyección perpendicular á la dirección de la presión, por la profundidad vertical en decímetros del centro de gravedad de la superficie comprimida bajo el nivel del agua. Sea *mcsn*, fig. 7, una superficie inclinada que soporta la presión del agua, cuyo nivel superior está en *mc*. La presión total sufrida por *mcsn*, normal á ella, es por la regla del art. 1 un caso particular de la presente regla; porque la proyección de *mcsn*, tomada perpendicularmente á la dirección dada, ó paralela á *mcsn*, es de hecho igual á *mcsn*. Por lo tanto, la regla del art. 1 es meramente una simple modificación de la presente, aplicable al caso de la presión *total* contra cualquier superficie.

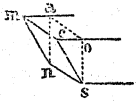

Fig 7

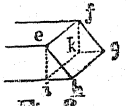

Fig 8

Fig. 9.

**Pero si se quiere solamente encontrar la presión vertical ó la presión hacia abajo contra** *mcsn* en kg, multiplíquense entre sí el área de la proyección horizontal *aocm*, en decímetros cuad, por la profundidad vertical en decímetros del centro de gravedad de *mcsn* á la superficie del agua. O si solamente se busca la componente horizontal de la presión sobre *mcsn*, multiplíquense entre sí el área de la proyección vertical *aosn*, la dist vertical del centro de gravedad de la superf *mcsn* á la superf del agua.

En la figura 8, la presión *total* contra *efgh* se halla también por la regla del art. 1, y las presiones horizontales y verticales se hallan como en la fig. 7, usando las proyecciones *efki* y *kygh*. En la fig. 7, la presión vertical es hacia abajo, mientras en la fig. 8, es hacia arriba; pero esta circunstancia no altera la regla por ningún respecto.

*Nota* 1. A cualquier profundidad dada, la presión perpendicular á una superficie cualquiera es la misma en todas direcciones; pero las figuras 7 y 8 demuestran que la presión total, *oblicua* á una superficie dada, es menor que la presión normal á la misma profundidad; porque la proyección oblicua de una superficie es siempre menor que la superficie misma, mientras que en el cálculo de la presión entra toda la superficie cuando la presión es perpendicular á ella. De modo que, en un estanque, la total presión perpendicular á una pared inclinada como *mnsc*, fig. 7, es mayor que la presión vertical ú horizontal ejercida sobre ella.

Sea la fig. 9, **un envase cónico lleno de agua,** cuya base *bc* es de 2 decímetros

de diámetro y su altura vertical *an* de 3 dcm. La circunferencia de la base será entonces de 6.2832 dcm; el área de la base, 3.1416 dcm cuad; el largo del lado oblicuo *ab* ó *ae*, 3.16 dcm; el área de la superficie curva lateral será $\frac{6.2832 \times 3.16}{2} = 9.93$ dcm cuad, y el centro de gravedad de los lados oblicuos estará á dos terceras partes de la altura vertical *an* á partir del vértice *a*, es decir, á 2 dcm de dicho vértice.

Para hallar aquí la presión total contra la base, tenemos, por la regla del art. 1, $3.1416 \times 3 = 9.425$ kg (porque un decím cúb de agua pesa un kilogramo). Para obtener la presión total contra la superficie oblicua lateral, la misma regla nos dará: $9.93 \times 2 = 19.86$ kg. Para la presión vertical hacia arriba ejercida contra el área total de la superficie oblicua lateral mencionada, tenemos el área de la base (que representa aquí la proyección horizontal de dicha superficie oblicua) = 3.1416, y la altura vertical 2 dcm del centro de gravedad de la superficie oblicua, *y*, por lo tanto, tenemos: $3.1416 \times 2 = 6.2832$ kg, presión vertical hacia arriba.

Finalmente, para la presión horizontal en cualquier dirección dada contra la superficie lateral oblicua de la *mitad* del cono, tenemos la proyección vertical de esta mitad, representada por el triángulo *abc;* su base de 2 dcm y su altura de 3; y, por consiguiente, con un área de 3 dcm cuad: Su centro de gravedad se encuentra á 2 dcm de *a*, de consiguiente tenemos: $3 \times 2 = 6$ kg, la presión horizontal buscada *.

En la fig. 10, que representa un envase lleno de agua, la presión *total* normal á la superficie semicilíndrica *avemdk*, debe ser horizontal, porque la superficie es vertical; pero puesto que la superficie es curva, la presión total, por la regla del art. 1, obra sobre ella en muchas direcciones, representadas por un número infinito de radios tirados desde *o* como centro. Pero si se solicita la presión horizontal en una dirección solamente, por ejemplo, paralela á *oe*, ó perpendicular á *ad*, que sería la fuerza que tendería á separar la superficie curva de las caras planas *abnv* y *desk*, produciendo fracturas á lo largo de *av* y *dk*, ó la tendente á reventar un tubo ú otro cilindro. En este caso, multipliquense entre sí el área de la proyección vertical *adkv* en decímetros cuad por la altura vertical desde la superficie libre del líquido al centro de gravedad de la superficie curva en decims (el cual, en un semicilindro, estará en la mitad de *em* ó de *oi*). Desde que á la resultante de las presiones se opone la resistencia del envase á lo largo de las líneas *av* y *dk*, es claro que es suficiente que el espesor del envase resista la mitad de la presión solamente, y así respecto de los tubos ú otros cilindros, tales como estanques, tinas, etc. (Véase art. 17.)

Para buscar la presión ejercida solamente contra la mitad de la superficie curva *edmk* y en una dirección paralela á *od*, tendiendo la presión á producir fracturas á lo largo de las líneas *em* y *dk*, se toma la proyección vertical *oemi*, la misma altura vertical y se multiplican entre sí como anteriormente.

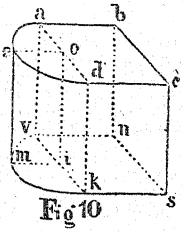

Fig 10

Fig. 10 1/2.

Se sigue de esto que si la base de un émbolo metálico es cóncava ó convexa, no se necesitaría más presión, para introducirlo á cualquiera distancia, que la que se necesitaría si fuera plana, porque la presión que obra contra la base del émbolo en la dirección en que éste se mueve, debe ser medida por el área de una proyección de aquella cara, tomada perpendicularmente á dicha dirección, y el área de la proyección será la misma en todos los casos.

* En una esfera llena de un fluido, la presión total interior es igual á 3 veces en peso del fluido.

*Nota* 2. **Si la pila de un puente ú otra construcción, fig. 10½, tiene sus cimientos sobre arena ó granzón,** ó sobre cualquier substancia, á través de la cual el agua puede filtrar por debajo, aunque sea en una capa muy delgada, entonces habrá una presión de abajo hacia arriba que tiende á levantar la pila con una fuerza igual al peso del agua desalojada por la pila. (Véanse arts. 18, 19.) En otras palabras, el peso real de la porción de pila *sumergida* será disminuído á razón de 1 kg por decímetro cúbico, que es próximamente la mitad del peso de la mampostería.

**Pero si los cimientos están sobre roca,** cubiertos con una capa de cemento para evitar la filtración del agua por debajo de la mampostería, no se producirá este efecto, sino que, al contrario, la presión vertical de arriba abajo, producida sobre las caras oblícuas de la pila y sobre el cimiento saliente, se agregará á su peso y aumentará su estabilidad, la cual, en agua tranquila, será mayor en este caso que en tierra.

**Art. 5. Para dividir una superficie rectangular, sea vertical como** *abcd*, **ó inclinada como** *mnop*, **fig. 11, cuya parte superior** *ab* **ó** *mn* **está**

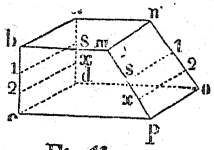

Fig 11

**al nivel de la superficie del agua, por medio de una línea horizontal** *x*2 **tal, que la presión total contra la parte superior de dicha línea horizontal sea igual á la de la parte que está debajo, se observará la siguiente regla:**

*Regla.* Multiplíquese la mitad de la longitud *bc* ó de *mp*, según el caso, por el número constante 1.4142, y el producto será *b*2 ó *mx*.

Ej. Sea *bc*=12 m; entonces tendremos 6×1.4142=8.4852 m ó *b*2.

Sea *mp*=16 m; entonces 8×1.4142=11.3136 m ó *mx*.

*Nota.* La línea *x*2, hallada así, no debe confundirse con el *centro de presión*, que es del todo diferente. (Véase art. 8.)

**Art. 6. En una superficie rectangular, sea vertical como** *abcd*, **ó inclinada como** *mnop*, **fig. 11, cuya parte superior** *ab* **ó** *mn* **coincide con la superficie del agua, encontrar cualquier número de puntos como 1, 2, etc., por los cuales, si se tiran líneas horizontales, 1*s*, 2*x*, etc., éstas dividan la superficie dada en rectángulos más pequeños, que sufran iguales presiones.**

*Regla.* Fíjese primero el número de rectángulos pequeños que se desea. Luego, para fijar el punto 1 de la parte superior, multiplíquese el número 1 por el número de los rectángulos; tómese la raíz cuadrada del producto; multiplíquese esta raíz cuadrada por el largo entero de *bc* ó *mp*, según el caso; divídase el producto por el número de rectángulos, y el cociente será la distancia *b*1 ó *n*1, según el caso.

Para la distancia *b*2 ó *n*2, procédase exactamente de la misma manera, solamente que en lugar del número 1, úsese el número 2 para multiplicarlo por el número de rectángulos, y así empléense sucesivamente los números 3, 4, 5, etc., si se necesitan estos números de puntos.

Ej. Sea *bc*=10 m, y que se requiera hallar 2 puntos, 1 y 2, para dividir la superficie rectángular *abcd* en tres partes rectangulares, que soporten iguales presiones. Tendremos para el punto 1:

$$1 \times 3 = 3.$$ La raíz cuad de 3=1.732; y $1.732 \times 10$; ó $(bc) = 17.32$

y $$\frac{17.32}{3 \text{ rectáng}} = 5.773 \text{ m} = b1.$$

Para el punto 2 tenemos:

$$2 \times 3 = 6.$$ La raíz cuad de 6 = 2.449; y $2.449 \times 10$; ó $(bc) = 24.49$

y $$\frac{24.49}{3 \text{ rectáng}} = 8.163 \text{ m} = \text{ó } b2,$$

Y así para cualquier número de puntos.

*Nota* 1. **Esta regla será útil en la determinación de los espacios á que deben colocarse los atravesaños de las puertas de canales, los aros de los envases cilíndricos y los puntales de una construcción como la fig. 3.**

*Nota* 2. **Para dividir de la misma manera cualquier superficie** *obed.* **fig. 12, que no sea rectangular,** con la exactitud suficiente para la mayor parte de los usos prácticos, quizás la siguiente regla sea la más conveniente.

*Regla.* Primeramente, divídase la superficie como en la fig. 12, en varias partes pequeñas horizontales, iguales ó no, como se quiera. Luego, por la regla del art. 1, búsquese la presión contra cada parte por separado, como se supone hecho, é indicado por los números situados del lado izquierdo de la figura. La suma de éstos (en este caso = 15,510) es la presión total ejercida contra la superficie entera *obed.* Ahora, suponiendo que deseamos dividir esta superficie en cuatro partes que soporten la misma presión; divídase primeramente á 15,510 por 4 = 3,878. Luego, principiando en la parte superior, súmese un número de presiones suficiente para producir la suma de 3,878; por este medio se busca el punto 1. Después procédase á la adición hasta que la suma ascienda al doble de 3,878 ó 7,756, que indicará el punto 2, y de esta misma manera búsquese el punto 3, sumando hasta obtener el triple de 3.878 ú 11,634, entonces las líneas horizontales de puntos, tiradas por 1, 2, 3, darán las divisiones buscadas aproximadamente. De este modo encontramos las separaciones que deben darse á los aros de los envases cónicos, ó de otras formas, con exactitud suficiente para las aplicaciones prácticas.

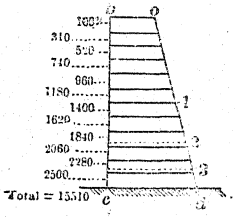

Fig. 12.

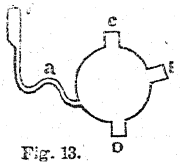

Fig. 13.

**Art. 7. Transmisión de presión por el agua. El agua y los otros fluidos poseen la propiedad importante de transmitir presiones iguales en todas direcciones.** Así, suponiendo que el envase, fig. 13, está enteramente cerrado y lleno de agua, y suponiendo las áreas transversales de T, *c*, D, E, iguales á un cm cuad cada una. Entonces, si por medio de un émbolo ó de otro modo se aplica la presión de un kg, de una tonelada ó de cualquier otro peso al área de un cm cuad de T, *c*, D ó E, cada cm cuad de la superficie interior del envase recibirá instantánea y normalmente una presión igual de 1 kg, 1 ton., etc., además de la presión producida por el agua misma; y esto sucede aunque el envase tenga varios km de largo, como por ejemplo si T distara varios km de E y estuvieran unidos por una larga tubería. Si este envase fuese una fuerte caldera de vapor llena de agua, una simple presión de pocos quintales aplicada en T, *c*, etc., podría hacerlo reventar. Véase también fig. 2 (*c*) y el párrafo anterior.

**La prensa hidrostática* está basada en este principio.** Cualquier cuerpo que se halle en el interior del envase recibirá también igual presión adicional en cada cm cuad de su superficie.

Si la parte superior de T está abierta, el aire ejercerá una presión como

---

* *N. del T.* — El autor, como todos los que hablan inglés, llama esta prensa *hidrostatic press*, es decir, *prensa hidrostática*. En español se llama *prensa hidráulica*, pero nos parece más adecuado el nombre de *prensa hidrostática*, toda vez que esta máquina se funda en el principio de la transmisión de presiones en una masa líquida, que es principio exclusivamente *hidrostático*, y á la hidráulica sólo pertenecen las aplicaciones de la hidrodinámica que estudia exclusivamente el movimiento de los líquidos. Podría rebuscarse en defensa del nombre español, que el agua de la prensa se mueve alterando su nivel al transmitir la presión; pero éste es un movimiento insignificante y no esencial para la transmisión de la fuerza ni tan importante en el aparato, como la multiplicación de la fuerza transmitida por entre el líquido, que es *principio de hidrostática*.

de 1.033 kg sobre cada cm cuad de la superficie libre del agua y una presión de igual intensidad será transmitida también á cada cm cuad de la superficie interior del envase y de los tubos que los conectan; pero no hay peligro de que reviente á consecuencia de esta presión atmosférica, porque el aire también ejerce una presión igual sobre cada cm cuad en la superficie exterior del envase.

**El aire y otros fluidos gaseosos transmiten la presión igualmente en todas direcciones**, como los líquidos; pero no con tanta rapidez.

**Art. 8. Centro de presión.** Sea la fig. 14, un envase lleno de agua, y supongamos que la cara P está perfectamente floja, de manera que con la menor presión que se ejerza sobre el agua contenida, sea empujada ó botada hacia afuera. Ahora bien, sólo existe un punto único, P, en toda superficie comprimida de este modo, cualquiera que sea su forma, al cual, si se aplica una fuerza igual á la presión del agua, y en dirección opuesta á aquélla, impedirá que la cara P ceda al empuje antes citado. Este punto se llama *centro de presión*.

Pero no debe entenderse por esto que la intensidad total de la presión efectiva del agua contra la parte de superficie que está encima de la línea horizontal de puntos que pasa por P, sea igual á la del agua que está debajo de dicha línea; sino que la suma de los productos de las diversas presiones que se ejercen de dicha línea hacia arriba, multiplicada por sus diversos brazos de palanca respecto á P, es igual á la suma de los productos de las diferentes presiones que obran de la línea hacia abajo, multiplicada por sus brazos de palanca respecto al mismo punto; ó, en otras palabras, que la suma de los *momentos* referidos al punto P, de las presiones que obran de la línea hacia arriba, es igual á la suma de los *momentos* de las que actúan de ella hacia abajo; de manera que si pasamos una barra de hierro, *bb*, por toda la cara P al nivel de la línea de puntos para que sirva como de eje á cuyo alrededor pueda girar, esta cara se mantendrá en equilibrio.

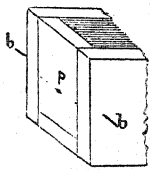

Fig. 14.

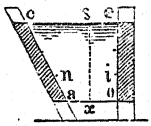

Fig. 15.

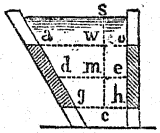

Fig. 16.

**Art. 9. Encontrar el centro de presión de un fluido en reposo contra una superficie plana**, fig. 15.

1. El centro de presión de un fluido en reposo contra cualquiera superficie plana, de anchura uniforme en toda su profundidad, sea que dicha superficie esté vertical, como *eo*, ó inclinada, como *ca* (ó inclinada en la dirección opuesta), y cuya parte superior *e* ó *ce* coincida con la superficie horizontal del agua, se halla á una distancia vertical bajo la superficie del agua, igual á dos terceras partes de la profundidad *sx* de dicha superficie del agua, como en *n* é *i*. Puesto que una línea horizontal situada á $^2/_3$ de la profundidad *sx*, corta á *ca* y á *eo* á $^2/_3$ de sus longitudes, respectivamente, podíamos decir de una vez, que el centro de presión contra una superficie plana de ancho uniforme se encuentra á dos tercios de su longitud á partir de la superficie del agua.

A todo lo aludido en el art. 9 puede aplicársele la **unidad de medida** que se desee.

2. Pero si el extremo horizontal *a* ú *o*, fig. 16, del plano rectangular *ag* ú *oh*, está cubierto de agua hasta alguna altura, entonces la dist vertical *sm* del centro de presión *d* ó *e* á la superficie del agua será igual á

$$\frac{2}{3} \text{ de } \frac{\text{cubo de } sc - \text{cubo de } sw}{\text{cuad de } sc - \text{cuad de } sw}.$$

en que *sc* es la profundidad vertical del fondo y *sw* la profundidad de la parte superior de la superficie comprimida de que se trata; ó, en otras palabras, del cubo de *sc* réstese el cubo de *sw* y llámese el residuo *a*. Luego, del cuadrado de *sc* réstese el cuad de *sw;* y llámese el residuo *b*. Divídese á *a* por *b* y tómese $^2/_3$ del cociente para obtener á *sm*.

3. Cuando una superficie plana de cualquier forma, ya sea rectangular, triangular ó circular, etc., sea vertical como *op*, fig. 17, ó inclinada como *nm*, se halla *enteramente sumergida*, de manera que la presión se ejerza sobre toda el área de *ambas caras*, pero por *diferentes alturas* de agua en dichas dos caras, el centro de presión coincidirá con *el centro de gravedad* de la superficie comprimida. En las tres figuras que anteceden, las superficies supuestas se ven de canto, de modo que no se ven sus anchos.

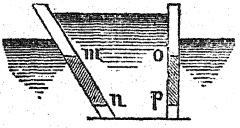

Fig. 17.

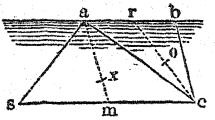

Fig. 18.

4. En cualquiera superficie plana triangular, en ángulo recto ó situada de otro modo, como *abc*, fig. 18, vertical ó inclinada, cuya *base ab* coincida con la superficie horizontal del agua, el centro de presión *o*, estará en el centro de la línea *cr*, que divide la base *ab* en dos partes iguales.

5. Pero si el triángulo *asc*, vertical ó inclinado, tiene su *vértice a* en la superficie del agua, y su base *sc* horizontal, entonces el centro de presión *x* estará también en la línea *am*, que divide la base en dos partes iguales; pero *ax* será $^3/_4$ de *am*.

6. Si cualquier triángulo plano, *abc*, fig. 19, con la base hacia arriba, y horizontal, tiene su base *ab*, á una profundidad *nd*, del líquido, el centro de presión *o*, estará en la línea *cs*, que divide la base en dos partes iguales, y *no* será igual á

$$\frac{mx^2 + (2mx \times ma) + 3ma^2}{(mx + 2ma) \times 2}.$$

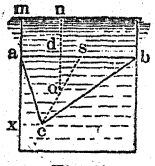

Fig. 19.

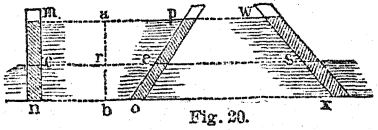

Fig. 20.

7. El centro de presión contra cualquier superficie plana *rectangular*, fig. 20, vertical como *mn*, ó inclinada como *op* ó *wx*, que tenga su parte superior coincidiendo con la superficie del agua comprimida por diferentes alturas de agua y sus caras opuestas como se ve en la fig. 20, estará, en una *vertical* debajo de la superficie *superior* del agua, á una distancia igual á

$$\frac{\left[\text{área de la superf } mn, \text{ ó } op, \text{ ó } wx \times \frac{\text{cuad de la prof vert } ab}{3}\right] - \left[\text{área de la superf } cn \text{ ó } eo, \text{ ó } sx \times \frac{\text{cuad de la prof vert } rb}{3}\right] - \left[\text{prof vert } ar \times \text{área de la superf } en \text{ ó } eo \text{ ó } sx \times \frac{\text{prof vert } rb}{2}\right]}{\left(\text{área de la superf } mn, \text{ ó } po, \text{ ó } wx \times \text{mitad de } ab\right) - \left(\text{área de la superf } cn, \text{ ó } eo, \text{ ó } sx \times \text{mitad de } rb\right)}.$$

8. Encontrar el centro de presión de una superficie circular, ó elíptica, comprimida por uno de los lados solamente; ya sea vertical ó inclinada, y cuya parte superior coincida con la superficie del agua ó esté debajo de ella.

Llámese *h* la altura ó dist vertical del centro de presión á la superficie del agua; *r*, el *semi*-diámetro vertical (ó inclinado, según el caso) de la superficie; *d*, la distancia *vertical* del *centro* de la superficie comprimida á la superficie del agua.

Entonces tenemos, $h = \frac{r^2}{4d} + d$. En un **círculo vertical** con su parte superior al nivel de la superficie, tenemos $h = 1\frac{1}{4}$ radio.

**Art. 10. Muros para resistir la presión de aguas tranquilas.** En relación con esta materia sería de utilidad hacer un estudio de lo que sabemos sobre los muros para el sostenimiento de tierras (pág. 647). Se supone, por supuesto, que el agua no encuentra entrada por debajo del muro y que éste no puede resbalar. Al hacer los cálculos de muros de sostenimiento, ya sea para contener tierras ó agua, es conveniente suponer que el muro no tiene sino un m de *largo* (no de altura, ni de espesor); porque entonces el número de ms cúb que contenga, será igual á los ms cuad del área de su sección transversal ó perfil; de manera que estos ms cuad multiplicados por el peso de un m cúb de mampostería darán el peso del muro. En los casos ordinarios sería bueno suponer, para mayor seguridad, que el agua llega hasta la línea de los mismos cimientos del muro.

Ahora bien, según el art. 1, la presión total de agua tranquila contra el paramento interior rectilíneo del muro, vertical ó inclinado, se halla en toneladas métricas (1,000 kg), multiplicando entre sí el área en m cuad de la parte realmente comprimida (ó en contacto con el agua) por *la mitad* de la profundidad vertical del agua en ms (que es la distancia *vertical* del centro de gravedad de su paramento interior rectilíneo á la superficie). Esta presión total es siempre *perpendicular al área de la superficie comprimida.*

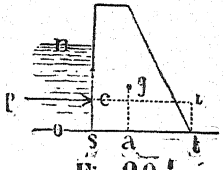

Fig 20 $\frac{t}{2}$

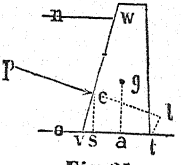

Fig 21.

Cuando el paramento interior del muro es vertical, como en la fig. 20½, esta presión, *p*, es naturalmente menor que cuando es inclinado, es también *horizontal* y tiende á volcar el muro haciéndolo girar alrededor de su arista exterior *t*. El centro de presión está en *c;* siendo $cs = {}^1/_3$ de la profundidad *vertical on*. En otras palabras, la presión total del agua, considerada como tendiendo á volcar el muro, y á éste como formado de un solo cuerpo, concentrado en el punto *c*, donde obra tendiendo á volcarle con el brazo de palanca *tl*.

La presión en kg multiplicada por este brazo de palanca en metros, da el *momento* en kilográmetros de la fuerza que tiende á volcar el muro. El muro, por otra parte, resiste en una dirección vertical *ga* con un momento igual á su peso (que se supone concentrado en su centro de gravedad *g*) multiplicado por la distancia horizontal *at*, que constituye el brazo de palanca del peso con respecto al punto *t* como punto de apoyo. Si el momento del agua es mayor que el del muro, este último será volcado; pero si es menor, resistirá. Aquí, fig. 21, el momento con que el agua tiende á volcar el muro es igual á su presión calculada *p* × su brazo de palanca *tl*, mientras que el momento de estabilidad del muro es igual á su peso × su brazo de palanca *at*. Con el auxilio de un trazado en escala podemos, basados en estos principios, saber si un muro dado podrá resistir; porque tenemos solamente que calcular la presión *p;* aplicarla entonces en *c*, perpendicular al paramento interior del muro, prolongarla hasta *l*, y medir á *tl*, por la misma escala. Luego calcúlese el peso del muro; búsquese su centro de gravedad *g;* trácese la línea *ga* vertical, y mídase el brazo de palanca *at*. Entonces tenemos los datos para calcular los dos momentos.

Si el agua en lugar de estar tranquila está expuesta á ser agitada formando olas, el muro debe hacerse de más espesor.

**Art. 11. Hallar el espesor de un muro en su base** (que esté á cubierto del *volcamiento*) bajo la presión del agua en reposo al nivel de su parte superior y ejercida contra todo el paramento interior vertical. **Advertencia**, véase art. 13.

(1) **Muro vertical**, fig. 22.

$$\text{Espesor} = \text{altura} \times \sqrt{\frac{\text{Coeficiente de seguridad*}}{3 \times \text{densidad del muro}}} = \text{Altura} \times \text{la decimal que le corresponde en la tabla que sigue.}$$

$$* \text{ Coef de seguridad} = \frac{\text{Momento de estabilidad requerida para el muro}}{\text{Momento de volcamiento del agua}}.$$

**(2) Muro triangular á ángulo recto,** fig. 23.

$$\text{Espesor en la base} = \text{Altura} \times \sqrt{\frac{\text{Coeficiente de seguridad*}}{2 \times \text{densidad del muro}}} = \text{Altura} \times \text{la decima}$$

que le corresponde en la tabla que sigue = espesor *mo* del muro vertical × 1.225.

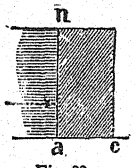

Fig. 22.

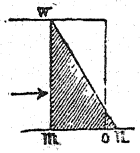

Fig. 23.

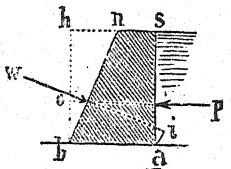

Fig. 24.

A pesar de su mayor espesor en la base, estos muros triangulares no contienen, como se ve por la figura, sino poco más de la mitad de la cantidad de mampostería requerida para muros rectangulares de igual estabilidad. Esto es debido á que su centro de gravedad está situado más adentro, aumentando de este modo el brazo de palanca, con que el peso del muro resiste al volcamiento.

**(3) Muro de paramento interior vertical y de paramento exterior inclinado,** fig. 24.

$$\text{Espesor de a base en m} = \sqrt{\frac{(\text{altura en m})\ (\text{Coef de seguridad*}) + (nh' \text{ en m} \times \text{densidad del muro})}{3 \times \text{densidad del muro}}}$$

= altura × la decimal correspondiente de la tabla siguiente.

| Fig. 22. | Densidad | Resist =1.5 presión. | Resist =2 presión. | Resist =3 presión. |
|---|---|---|---|---|

**Art. 13. Propensión de un muro ó fundación al desmoronamiento ó ruptura por compresión bajo presiones desiguales.** Los artículos 11 y 12 se aplican solamente á la *estabilidad* de un muro *rígido*, levantado sobre una base *rígida*, y por consiguiente incapaz de ceder sino al *volcamiento, considerando el cuerpo como un todo.* Ellos demuestran que la *estabilidad* es la mayor, cuando el agua ejerce su presión sobre el lado *inclinado.* Pero en la práctica, el punto donde la resultante de todas las presiones corta ó atraviesa la base, no debe estar tan cerca de la arista ó pie, que haya el riesgo del rompimiento ó *desmoronamiento* del muro ó los cimientos. Esta consideración hace á menudo preferible que la presión se ejerza contra el paramento interior *vertical*, no obstante la pérdida consiguiente de estabilidad.

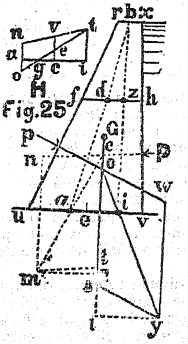
**Art. 14.** Así, la fig. 25 representa, en escala, un dique en Poona, India, proyecto del Sr. Fife, I. C. de Inglaterra. Está construído de mampostería de piedra bruta con mezcla, con peso de 2,400 kilg m cúb. Su altura vertical total es de 30.47 m; espesor *uv* en la base, de 18.50 m; en la parte superior, 4.19 m. La cara ó paramento exterior *ru* tiene una inclinación de 42 por 100 y el paramento interior *xv* de 5 por 100. Los cimientos tienen 2.13 m de profundidad; pero se supone aquí que el agua ejerce presión contra *todo* su paramento interior *xv*. Por el centro de gravedad G trácese la línea *Gs*, vertical. Desde *c*, donde la dirección de la presión P del agua corta á *Gs*, hágase la línea *cn*, por la escala, igual al número de toneladas de la presión del agua contra un m de longitud de *xv* y *ct* igual al peso de un m de longitud del muro. Complétese el paralelogramo *cnmt* de las fuerzas, cuya diagonal *cm* representa la resultante de todas las presiones ejercidas contra la base *uv* y corta la base en *a* á 6.09 m de la arista *u* hacia el interior. Hágase lo mismo con la presión *p* contra *ru* y obtendremos la resultante *oy*, que es mayor que *cm*, y corta la base (en *i*) solamente á distancia de 3.86 m de la arista *v*, 2.23 m menos de lo que dista *a* de *u*.

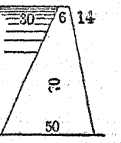
Por lo tanto, cuando el agua ejerce presión contra *xv*, el muro está menos expuesto á romperse, y en el terreno *uv* donde se apoya se distribuye más uniformemente el peso y, por consiguiente, está menos expuesto á descender desigualmente hasta producir grietas en el muro. Por esta razón *xv* se toma como paramento interior del muro, sin embargo de que entonces el momento de estabilidad es solamente 2.2 (llamando 1 el momento del agua tendente al volcamiento

del muro), mientras que si el agua comprimiese á *ru*, sería 3, 4 es decir, 36 por ciento mayor.

**Art. 15.** Los puntos *a* é *i*, fig. 25, se llaman **centros de presión** sobre la base ó **centros de resistencia** de la base. Si considerando porciones de muro (tales como *rxhf*) como si fueran muros enteros, encontramos puntos *d* y *z* semejantes á aquéllos, situados de la misma manera con respecto á *fh*. La línea ligeramente curva que los une se llama **curva de presión.** Así, *ba* es la curva de presión cuando el agua ejerce presión contra *xv*. Cada punto, como *d* en *ba*, indica en donde una junta cualquiera, como *fh*, trazada por este punto, es cortada por la resultante de todas las fuerzas que obran sobre dicha junta; *bi* es la curva de presión cuando el agua comprime á *ru*. Estas líneas no muestran las *direcciones* de las resultantes. Así es que, en *a*, esta dirección es *cm* y no *ba*. El ángulo comprendido entre la dirección de la resultante y una línea perpendicular al asiento ó junta del muro, debe ser menor que el ángulo de rozamiento de los materiales en contacto en la junta.

Si desde el extremo *m* ó *y* de la resultante de las presiones que se ejerzan sobre cualquiera junta se trazan *m*2 ó *yl*, horizontales, entonces *c*2 ú *ol* (según el caso) medirán toda la presión *vertical* que obra en esa junta y *m*2 ó *yl* medirán la presión *horizontal* que actúa contra el paramento interior del muro, que tiende á producir resbalamiento en la misma junta. Si la dirección de la resultante llega al límite mencionado en el párrafo precedente, *m*2 ó *yl* será menor que la resistencia de rozamiento que se opone al resbalamiento, la cual es = *c*2 (ú *ol*) × el coeficiente de rozamiento de las superficies que forman la junta. Por lo expuesto no hay resbalamiento. En la *mampostería* de los muros de formas ordinarias no ocurren jamás resbalamientos. La mezcla buena, bien seca, contribuye á evitarlos, pero es mejor no confiarse. Muros enteros se han deslizado sobre cimientos resbaladizos.





**Art. 16. En California se encuentra la represa,** fig. 14, de un estanque de una mina, hecha de piedra bruta sin mortero y cimentada en la roca. Altura, 21.33 m; base, 15.23 m; parte superior, 1.82 m; inclinación ó talud del lado del agua, 9.14 m; talud exterior, 4.26 m. Para evitar mermas por filtraciones, el talud interior está revestido con tablones de 76 mm, asegurados horizontalmente con pernos á unos zoquetes de 30×30 cm fijos al muro. Toda ella fué hecha á mano y con cuidado, con excepción de una parte interior como de un quinto de toda la masa que se llenó echando el material sin cuidado. El costo fué de 3,6 dólares el metro cúb más ó menos. Está en uso desde 1860.

**Observación. Si se refuerza ó rellena sólidamente un dique ó represa con tierra** que tenga su talud natural, en cantidad suficiente para evitar que el agua llegue hasta la represa, la presión contra ésta no aumentará por causa de la tierra.

**Art. 17. Encontrar el espesor de un cilindro,** que resista con seguridad la presión del agua, del vapor, etc., contra su interior. Si está remachado, véase un poco más abajo.

**Donde el espesor es menor que una treintava parte del radio,** como lo es en el mayor número de casos, se emplea la fórmula ordinaria :

$$(1) \qquad \text{Espesor en cm} = \frac{\text{presión}}{\text{resist de seguridad}} \times \text{radio} *.$$

Se considera el material como sometido solamente á un esfuerzo de tensión, directo, lo cual es bastante exacto en espesores tan delgados.

**Para espesores y presiones algo mayores,** el profesor F. Reuleaux-(Der Konstrukteur, pág. 52) da :

$$(2) \quad \frac{\text{Espesor}}{\text{en cm}} = \frac{\text{presión}}{\text{resist de seguridad}} \left(1 + \frac{\text{presión}}{2 \times \text{resist de seguridad}}\right) \times \text{radio} *.$$

**Para presiones y espesores muy grandes,** como en las prensas hidráulicas, cañones, etc., el profesor Reuleaux (Konstruckteur, pág. 53) da la fórmula de Lamé :

$$(3) \quad \frac{\text{Espesor}}{\text{en cm}} = \left(\sqrt{\frac{\text{resist de seguridad} + \text{presión}}{\text{resist de seguridad} - \text{presión}}} - 1\right) \times \text{radio} **.$$

Las tres fórmulas dan el siguiente resultado en pulgs, tomando las presiones y resistencias en lbs por pulg cuad y el radio en pulgs :

| Diám. | Radio. | Presión. | Resist de seguridad á la tensión. | Espesores en pulgs. | | |
|---|---|---|---|---|---|---|
| | | | | Fórmula (1). | Fórmula (2). | Fórmula (3). |
| 20 pulgs | 10 pulgs | 50 | 10000 | **.05** | .050125 | .05 |
| — | — | 500 | — | .50 | **.5125** | .513 |
| — | — | 5000 | — | 5.00 | 6.25 | **7.32** |

Los espesores dados por las fórmulas adaptables á las diversas presiones, se han impreso en **tipos gordos.** Se verá que en estos casos los resultados difieren muy poco, excepto en las presiones muy *grandes.*

*Observación.* **La falta de uniformidad en el enfriamiento** de las fundiciones de gran espesor las hace más débiles relativamente que las de poco espesor; de modo que, para reducir éste en casos importantes, debemos usar solamente el mejor hierro refundido tres ó cuatro veces, por cuyo medio se puede conseguir una cohesión máxima de 2109 kg por cm cuad más ó menos. Pero aun con esta precaución, **no hay regla que pueda aplicarse con seguridad** en la práctica á los cilindros de hierro fundido, cuyos espesores excedan de 8 á 10 pulgs (20 á 25 cm) próximamente.

Bajo una presión de (8,000 lbs por pulg cuad) 562.48 kg por cm cuad **se filtra el agua á través del hierro fundido de 8 á 10 pulgs (20 á 25 cm) de espesor,** y bajo una presión de sólo (250 lbs por pulg cuad) 17.58 kg por cm cuad se filtrará al través de (0.5 pulg) 12 ½ mm.

**Tabla de espesores de tubos de hierro forjado de roblonadura sencilla,** para estanques, tubos de alimentación, etc., calculados por la regla precedente, para resistir con un coeficiente 6 de seguridad, la presión de una carga de 304 m de agua en reposo ó sean 30.4 kg por cm cuad, tomando la cohesión máxima de las planchas de hierro de regular calidad en 3374 kg por cm cuad, ó sean 562 kg por cm cuad, para un coeficiente 6 de seguridad; aun reduzcámoslo á $562 \times .56 = 314.72$ kg por cm cuad por la pérdida de resistencia producida por los agujeros de los roblones; porque los cilindros de **roblonadura**

---

* En todas las tres fórmulas tómese el *radio en cm*, y la presión y la resistencia en *kg/cm cuad.*

** *N. del T.* — Tomando el radio en cm y la presión y resistencia en kg por cm cuad, obtendremos el espesor en cm. Pongamos un ejemplo para la primera fórmula : ¿Qué espesor nos dará para un radio = 25.4 cm (10 pulgs), una presión de 3.52 kg por cm cuad (50 lbs por pulg cuad) y una resistencia de 703.095 kg por cm cuad (10,000 lbs por pulg cuad) ?

(1) Espesor en cm $= \frac{3.52}{703.095} \times 25.4 = 0.127$ cm (.05 pulg). Que es igual al que da la tabla.

**sencilla** no tienen sino una resistencia de .56 más ó menos de la que tienen las planchas sólidas, y los de **roblonadura doble**, como .7.

*N. del T.* — La tabla que sigue es la **original** del autor, convertida al sistema métrico. Los diámetros y espesores están en centímetros. Hemos tomado sólo hasta el diámetro de 108 pulgs.

| Diám. | Esp. | Diám. | Esp. | Diám. | Esp. | Diám. | Esp. | Diám. | Esp. |
|---|---|---|---|---|---|---|---|---|---|
| 1.3 | .06 | 12.7 | .60 | 40 | 2.00 | 75 | 3.80 | 150 | 7.60 |
| 2.54 | .13 | 15. | .76 | 45 | 2.32 | 84 | 4.32 | 167 | 8.50 |
| 3.8 | .19 | 20. | 1.00 | 50 | 2.54 | 91 | 4.47 | 182 | 9.30 |
| 5.00 | .25 | 25. | 1.30 | 55 | 2.79 | 105 | 5.41 | 213 | 10.80 |
| 7.60 | .37 | 30. | 1.52 | 60 | 3.05 | 122 | 6.20 | 243 | 12.40 |
| 10.1 | .50 | 35. | 1.78 | 67 | 3.48 | 135 | 6.96 | 274 | 13.90 |

**Para una carga ó presión menor** ó para cualquier coeficiente de seguridad menor que 6, satisface, y es casi suficiente en la práctica, reducir los espesores de los cilindros de hierro forjado en la misma proporción en que dicha carga, presión ó coeficiente de seguridad sea menor que los de la tabla.

**Los cilindros de roblonadura doble** son, según Fairbairn, 1.25 veces más fuertes que los de roblonadura sencilla. Por tanto deben tener $^1/_5$ menos de espesor. **Las soldaduras recubiertas** son casi 1.8 veces más fuertes que las remachadas sencillamente, y por tanto no requieren sino .56 del espesor.

**En California** han estado en uso, durante muchos años, muchas millas de tubería de **roblonadura doble** con un coeficiente de seguridad de 2 á 2.6 solamente. En un caso tiene una carga de 524 m con una presión de 52.45 kg por cm cuad; diám, 292 mm; espesor, 8½ mm.

Los tubos **de hierro fundido para la distribución del agua en las poblaciones** deben tener más espesor que el dado por la fórmula (1) para que soporten el recio manejo, y el efecto de los choques producidos por el agua misma debido á la parada repentina de la corriente, véase observación, pág. 545, y para prevenirlos contra las irregularidades de la fundición, y de las burbujas de aire, ó vacíos á que están más ó menos expuestos todos los objetos fundidos.

En la tabla que sigue se ha tomado, como resistencia máxima á la tensión del hierro fundido, 1.265 kg por cm cuad. Estos espesores están calculados por la fórmula del Sr. J. T. Fanning (Hidráulica, pág. 454). Está de acuerdo con los términos medios de la práctica.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| Diámetros en milímetros. | Carga en metros. | | | | | |
|---|---|---|---|---|---|---|

| ½ | .04 | .10 | .16 | .22 | .26 | .39 |
| 1 | .08 | .18 | .28 | .40 | .52 | .67 |
| 1½ | .12 | .26 | .42 | .60 | .79 | 1.00 |
| 2 | .16 | .35 | .56 | .80 | 1.05 | 1.33 |
| 2½ | .20 | .44 | .70 | .99 | 1.32 | 1.67 |
| 3 | .25 | .52 | .84 | 1.20 | 1.58 | 2.00 |
| 3½ | .29 | .61 | .98 | 1.39 | 1.84 | 2.33 |
| 4 | .33 | .70 | 1.12 | 1.59 | 2.10 | 2.66 |
| 4½ | .37 | .79 | 1.26 | 1.79 | 2.37 | 3.00 |
| 5 | .41 | .88 | 1.40 | 1.99 | 2.63 | 3.33 |

*Nota.* **Las llaves de los tubos de agua deben cerrarse lentamente**, y la necesidad de esta precaución aumenta con el diámetro. De lo contrario la detención repentina, dada la velocidad adquirida, y conservada por el agua corriente en virtud de la inercia, causaría una gran presión contra los tubos en todos sentidos y en toda la porción de tubo situado detrás de la llave, aun cuando el tubo tenga muchos km de longitud, corriendo el peligro de romperse en cualquier punto. Por esta razón se cierran las llaves de retención por medio de tornillos que impidan cerrarlos de repente; pero en los tubos de gran diámetro, hasta los tornillos deben manejarse muy lentamente, para evitar que se revienten.

**Art. 18. Flotación en los líquidos.** Cuando se coloca un cuerpo en un líquido, sea que flote ó que se sumerja, desaloja un volumen de líquido igual al volumen de la parte sumergida del cuerpo. En ambos casos, y en cualquier profundidad y posición, el cuerpo sumergido recibe un empuje vertical de abajo hacia arriba igual al peso del líquido desalojado. De manera que si sumergimos enteramente en agua un pedazo de corcho, fig. 26, ó cualquier otro cuerpo cuyo peso específico sea menor que el del agua, el corcho tiende, por su peso, á descender á mayor profundidad; pero el empuje del agua hacia arriba siendo mayor que el peso del corcho, obligará á este último á subir con una fuerza igual á la diferencia de las dos fuerzas. En este caso el corcho recibe una presión total de arriba abajo igual al peso de la columna vertical de agua que tiene encima (indicada en el envase por líneas verticales) y una presión total de abajo hacia arriba igual al peso de la columna de agua indicada en el envase 2. *La diferencia* de estas dos columnas (véanse las figs.) es evidentemente igual al volumen del corcho mismo; por consiguiente, la diferencia de sus pesos ó presiones (ó, en otras palabras, el empuje del agua) es igual al peso ó presión del aguá que ocupa el lugar del corcho, ó, en otros términos, al peso del agua desalojada por el corcho.

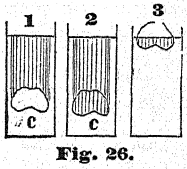

**Fig. 26.**

Esta *diferencia* ó empuje será evidentemente la misma, cualquiera que sea la profundidad á que esté sumergido. El corcho abandonado á sí mismo subirá hasta que una parte salga fuera de la superficie, como se ve en el envase 3; de modo

que la presión de la columna de arriba abajo deja de existir, y entonces el corcho está comprimido hacia abajo solamente por su propio peso. Pero como ahora permanece fijo, y sabemos que cuando dos fuerzas opuestas mantienen un cuerpo en equilibrio, estas dos fuerzas deben ser iguales, por tanto la presión del agua de abajo hacia arriba debe ser igual al peso del corcho. Pero esta presión del agua hacia arriba es producida por la columna sombreada que se muestra en el envase 3, y esta columna es igual *al volumen del agua desalojada.*

Por consiguiente, *en todos los casos* la fuerza de empuje es igual al peso del agua desalojada, y cuando el cuerpo *flota* en la superficie, el empuje ó peso del agua desalojada resulta igual al peso del cuerpo.

**Si el cuerpo sumergido, *c*, *c*, fuera de hierro** ó de cualquiera otra substancia de un peso específico mayor que el del agua, la diferencia de las presiones hacia arriba y hacia abajo sería siempre la misma : igual al peso del agua desalojada. Pero el peso del cuerpo es ahora mayor que el del agua desalojada, ó, en otras palabras, el empuje hacia abajo producido por el peso del cuerpo es mayor que el que, el agua desalojada ejerce hacia arriba, y por consiguiente el cuerpo desciende ó se sumerge con una fuerza igual á la diferencia de las dos. Por lo expuesto se ve que si el cuerpo fuera un sólido de hierro fundido de un decímetro cúb, como un decím cúb de agua dulce pesa 1 kg solamente, y el peso del hierro fundido es de 7.2 kg por litro, dicho cuerpo descenderá con una fuerza igual á 7.2 — 1=6.2 kg por cada litro de volumen que tenga. **Si el cuerpo sumergido tiene el mismo peso específico que el fluido,** no ascenderá ni descenderá, sino que permanecerá estacionario en donde se le ponga; porque entonces el peso del cuerpo y el empuje del agua son iguales.

**El aire también ejerce contra los cuerpos empujes hacia arriba iguales al peso del aire desalojado**; por consiguiente, aunque un kg de hierro y otro de plumas pesados en el aire se equilibran, sin embargo, colocados ambos en la redoma de una máquina neumática, el peso de las plumas excederá al peso del hierro, tanto más cuanto más exceda el volumen del aire desalojado por las plumas al volumen del aire desalojado por el hierro.

**Un globo sube en el aire por la misma causa que un corcho en el agua.** Su fuerza ascendente es igual á la diferencia entre su peso cuando está lleno de gas y el peso del volumen de aire que desaloja. El globo no tiende realmente á subir, sino á descender; pero siendo el aire, á volumen igual, más pesado que el globo, aquél empuja á éste hacia arriba con una fuerza mayor que con la que el peso del globo tiende á bajar. Lo mismo sucede con el humo caliente, que no tiende á subir por sí mismo, sino que es *empujado hacia arriba* por el aire frío que es más pesado. Ninguna materia tiende á subir, todas tienden á bajar hacia el centro de la tierra.

La acción de la gravedad hacia abajo puede considerarse como concentrada en el centro de gravedad G de un cuerpo flotante. La presión hacia arriba ó el empuje * del agua puede considerarse del mismo modo concentrado y obrando en el centro de gravedad W del agua desalojada †. W se llama también **centro de presión** del agua, y una línea vertical que pase por él se llama **eje de flotación.** Ordinariamente ‡ W varía de posición con cada cambio de posición del cuerpo. Así,

---

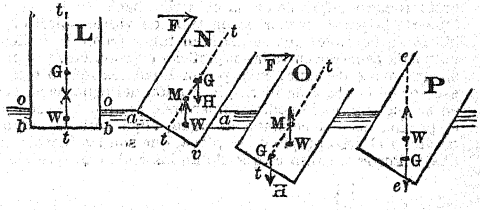
* **Este empuje se compone** de las presiones paralelas ejercidas de abajo hacia arriba por los innumerables filamentos verticales del agua desalojada, como se ve en la fig. 26, y **el eje de flotación** es la resultante de ellas, como en el caso de las fuerzas paralelas.

† **Sobre el cuerpo actúan de hecho otras fuerzas**, tales como las presiones horizontales del agua contra las partes sumergidas; pero como todas éstas están en una dirección dada, equilibradas por las de la dirección opuesta, no tienen influencia sobre las fuerzas G y W. También sufre el cuerpo la acción del aire, que lo comprime hacia abajo, con una fuerza de 1.033 kilg por cm cuad; pero ésta está equilibrada por la presión del aire que rodea la superficie del agua, la cual se transmite verticalmente hacia arriba á la parte inferior ó fondo del cuerpo sumergido.

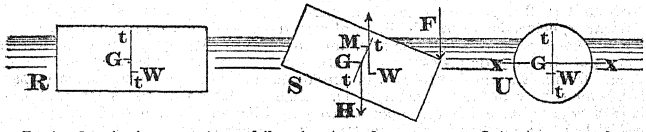
‡ La forma de un cuerpo (como la de una esfera ó un cilindro U) puede ser tal, que la posición de su centro de presión W, con relación á la de su centro de gravedad G, no cambie por la rotación del cuerpo alrededor de un eje dado (como cualquier eje de la esfera ó del eje *longitudinal* del cilindro), sino que permanezca siempre en la misma línea vertical que G, de manera que el cuerpo al rotar permanece en equilibrio. Un cuerpo así se dice que está en **equilibrio indiferente** alrededor de su eje. Pero si se hace rotar á un cilindro U en la dirección de su eje *transversal xx*, quedará comprendido en el caso de las observaciones hechas acerca de las figs. R y S, y puede hallarse (antes de rotar) en equilibrio estable ó inestable alrededor de aquel eje según el modo de distribución de su peso.

en L, está en el centro de gravedad del rectángulo *oobb;* y en N, está en el de gravedad del triángulo *aav.*

Cuando un cuerpo flotante, L, P ó R, está en reposo, sin que una tercera fuerza, F, lo perturbe, se dice que está en **equilibrio**, y G y W se hallan entonces en la misma línea vertical *tt*, figs. L y R, ó *ee*, fig. P. Esta línea se llama **eje ó vertical de equilibrio.**



Cuando una tercera fuerza, F, produce la inclinación del eje de equilibrio, como en las figs. N, O y S, entonces, se tira una línea vertical desde el centro de presión W hacia arriba, el punto M, donde dicha línea corta el eje mencionado, se llama **metacentro** del cuerpo*; G y W no continúan entonces en la misma línea vertical**, y las dos fuerzas opuestas y verticales de gravedad y de empuje, *obrando* sobre aquellos puntos respectivamente, forman un « par »; cuando se suprime la tercera fuerza F, ellas no mantienen por más tiempo el cuerpo en equilibrio, sino que le comunican un movimiento de rotación. Si las posiciones de G y W (como en las figs. O y S) son tales que el metacentro M se halle más *arriba del centro de gravedad* G, está rotación tenderá á *volver el cuerpo á su posición anterior*, y se dice que el cuerpo ha estado (antes de la aplicación de la tercera fuerza F) en **equilibrio estable** §. Pero si (como en N) M se halla *debajo* de G, la dirección de la rotación es tal que puede *volcar* el cuerpo, *alejándolo más de su posición anterior*. Se dice entonces que el cuerpo estaba en **equilibrio instable**. Véase nota ÷, pág. 546.



La tendencia ó momento en kilográmetros de un cuerpo flotante para volcarse ó para enderezarse es

= peso del cuerpo (ó su igual, es decir, la presión del agua hacia arriba) en kg × dist horizontal comprendida entre WM y GH, figs. N, O, y S, en m.

La tercera fuerza F puede ser tan grande que venza la tendencia del cuerpo á enderezarse. De esta manera, un barco puede ser volteado por un huracán á pesar de haberse cargado y lastrado bien para los vientos ordinarios. La sección horizontal de un cuerpo por la línea de flotación se llama **plano de flotación.**

**Art. 19. Un cuerpo menos denso que el agua colocado en el fondo de un envase que contenga aquel líquido, no subirá, á menos que el agua penetre por debajo de él y lo haga subir del mismo modo que el aire hace subir á un globo.** Así, si un bloque de madera liviana, perfectamente plano y liso, se coloca en el fondo de un envase igualmente plano y liso, y si se le sujeta allí hasta que se haya llenado de agua dicho envase, la presión hacia abajo le retendrá en su lugar hasta que el agua penetrando por los

---

* Este metacentro cambia de posición en la línea *tt*, según la inclinación de esta última.

§ **Una carga desigual** puede hacer las veces de una tercera fuerza y lograr que un envase en reposo se incline como en P, y sin embargo el envase inclinado de este modo puede estar en equilibrio, porque el eje *ee* de equilibrio puede ser vertical aunque no coincida con el **eje de simetría** del envase, como pasa con *tt* en L.

** Este caso puede ocurrir algunas veces en los cuerpos *flotantes* (como en las figs, R y S), aun cuando el *centro de presión* W (*no el metacentro*) se halle *debajo* del centro de gravedad G, porque cuando el cuerpo está forzado á inclinarse, W cambia de lugar en el cuerpo y esta nueva posición puede ser tal, que M venga á quedar arriba de G. W está siempre debajo de G en los cuerpos de densidad uniforme (homogéneos) que flotan en reposo, si una parte cualquiera del cuerpo está fuera del agua. Si los cuerpos están enteramente sumergidos W y G coinciden.

poros de la madera se aloje debajo de él. Pero si se alisa y se le da barniz al pedazo de madera, á fin de que el agua no penetre en sus poros, aquél permanecerá en el fondo.

**Por otra parte, se puede evitar que una pieza de metal se vaya á fondo,** sometiéndola solamente á la acción de una presión suficiente, *de abajo hacia arriba* y suprimiendo la de arriba hacia abajo. Así pues, si se alisa suficientemente la parte inferior de un tubo de vidrio abierto *t*, fig. 27, y una placa de hierro *m*, de modo que se adapten tanto (como se indica en la fig.) que el agua no pueda penetrar entre las superficies en contacto, y si en esta posición se colocan en un envase de agua, cuya profundidad sea más ó menos mayor que 8 veces el espesor de la placa de hierro, la presión del agua hacia arriba mantendrá la placa en su lugar y le impedirá sumergirse, porque está comprimida hacia arriba por la presión de una columna de agua, cuyo peso es mayor que el de la columna de aire y el peso propio de la placa, que son las fuerzas que empujan á ésta hacia abajo. Por esta causa es que flotan las embarcaciones de hierro.

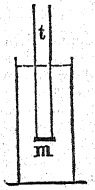


Fig 27

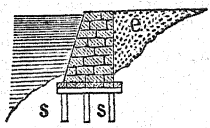

Fig 28

*Nota* 1.ª **Un muro de sostenimiento construído sobre estacas como en la fig. 28,** puede ser suficientemente fuerte para resistir el empuje de las tierras *e*, colocadas detrás de él, en el caso de que el agua no penetre por debajo, y sin embargo, puede volcarse si el agua penetra por debajo y aun si la tierra *ss*, situada alrededor de las estacas, se satura de agua y se convierte en barro ó pantano fluído. En uno ú otro caso la presión hacia arriba del agua contra la pared inferior ó base del muro, reducirá virtualmente el peso de todas las partes, *que están bajo la superficie del agua* á razón de 1000 kg por metro cúb ó casi en la mitad del peso ordinario de la mampostería de piedra bruta y mezcla.

*Nota* 2.ª Aunque las estacas situadas debajo de un muro, como en la fig. 28, sean más que suficientes para sostener el peso del muro, y éste *por sí mismo* sea igualmente fuerte para resistir la presión del relleno *e*, sin embargo, si la tierra *ss* del contorno de las estacas fuere blanda, tanto ellas como el muro pueden ser empujadas, y este último volcado por la presión del relleno *e*. Por esta razón, las alas de los puentes, *si están construídas sobre estacas* en un suelo muy blando, se abomban frecuentemente hacia afuera y se deforman. En estos casos, la estaca y la plataforma de madera que se coloca sobre ésta deben extenderse sobre todo el espacio comprendido entre los muros; ó aplicar cualquier otro preventivo.

**Art. 20. Calado de los barcos.** Como un cuerpo *flotante* desaloja un peso de líquido igual al peso del cuerpo, podemos calcular el peso de un barco y de su carga determinando el número de metros cúb de agua que desaloja. El número de m cúb multiplicado por 1,000 nos dará el peso en kilog. Suponiendo, por ejemplo, un barco plano con lados de 25 m de largo, 5 m de ancho y .15 m de calado; cuando está sin carga desalojará $125 \times .15 = 18.75$ m cúb de agua, que pesan $18.75 \times 1{,}000 = 18{,}750$ kilgs, que será también el peso del barco. Si dicho barco después de cargado cala un metro más, tendremos para peso del agua desalojada por la carga solamente $25 \times 5 \times 1{,}000 = 125{,}000$ kilgs, que es al mismo tiempo el peso de la carga. De igual modo, conociendo de antemano el peso del barco y de la carga y las dimensiones de aquél, podemos hallar el calado. Así, si el peso fuera como antes de $143{,}750 = (18{,}750 + 125{,}000)$ kilgms y las dimensiones del barco $25 \times 5$, tendremos $25 \times 5 \times 1{,}000 = 125{,}000$; y $\frac{143{,}750}{125{,}000} = 1.15$ m, cala buscada. En los barcos de formas más complejas, como los barcos de vela ordinarios, el cálculo del agua desalojada es más complicado; pero el principio es el mismo.

# HIDRÁULICA

## Movimiento del agua en las tuberías.

Muchas de las teorías hidráulicas son todavía materia de discusión. Esto, y las imperfecciones de los trabajos, hace que sea prudente usar liberales coeficientes de seguridad al emplear las fórmulas hidráulicas. Aun los tubos nuevos se oxidan y se forman escorias que disminuyen la corriente; y aquéllas se aumentan á veces considerablemente por las substancias químicas que contiene el agua. El aire en los tubos también disminuye la corriente.

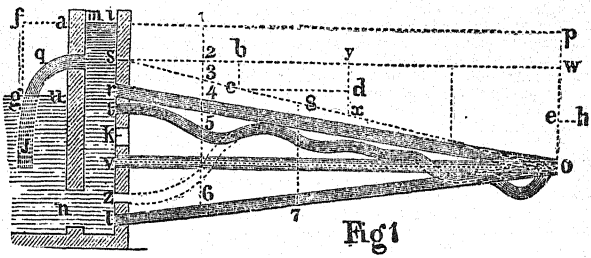

Fig 1

El término **carga ó carga total de agua** aplicado al derrame del agua por canales, tubos ú orificios en estanques, etc., quiere decir la distancia *vertical iv* ó bien *op*, fig. 1, de la superficie *m i* del agua en el estanque, ó fuente de alimentación al centro (ó más bien el centro de gravedad) *o*, del orificio (sea éste el extremo del tubo *ro*, *to*, *vo*, *zo*, *lo*), ó cualquiera otra clase de orificio por el cual tiene lugar la salida del agua libremente *al aire;* ó la distancia vertical *au*, ó *fg*, de la misma superficie *mi*, á la *superficie del nivel gu*, del agua en el estanque más bajo, cuando la salida se efectúa *por debajo del agua*. Así, en el caso de la salida del agua al aire, la distancia vertical *iv* ú *op* es la carga total para cualquiera de los tubos *ro*, *to*, *vo*, *zo* ó *lo;* siendo *ik* la carga para el orificio *k*, en la pared del estanque. Y para la salida por *debajo del agua*, *au*, ó *fg*, es la carga, tanto para el tubo *f*, como para la abertura *n*, independientemente de sus profundidades bajo la superficie del agua más baja, lo cual, según los autores más antiguos, no influye en nada en la salida del agua. Una parte del tubo puede tener una carga mayor que la carga correspondiente al tubo entero. Así, el punto 6 del tubo *ol* tiene la carga 6.1, mientras que el tubo entero no tiene sino una carga *op*.

**Tanto en la teoría como en la práctica, la velocidad y el gasto son independientes de la posición del tubo, ya esté inclinado hacia abajo, como *ro*, fig. 1, horizontal, como en *vo*, ó inclinado hacia arriba, como *lo*, con tal que la carga total del agua *op* y el largo del tubo sean los mismos.** Cuando un tubo es más largo que otro, sus paredes evidentemente producirán más rozamiento contra el agua y disminuirán de este modo la velocidad y el gasto. Los tubos inclinados *ro*, *lo*, siendo, por supuesto, un poco más largos que el horizontal *vo*, producirán por tanto, cada uno, un gasto un poco menor; pero si el tubo horizontal se prolongase un poco más allá de *o* á fin de darle la misma longitud de los otros, entonces cada uno de los tres producirá el mismo gasto.

**Art. 1 *a*. División de la carga total.** En cualquier tubo *so*, *ro*, *to*, *vo*, *zo*, ó *lo*, fig. 1, tiene la carga que realizar tres trabajos : 1.°, vencer la *resistencia* de la entrada en *s*, *r*, *t*, *v*, *z* ó *l;* 2.°, vencer la resistencia *dentro* del tubo; y 3.°, comunicar al agua que entre en el tubo, la *velocidad* con que realmente corre. Por conveniencia consideramos la carga total dividida en tres partes, correspondientes á estos tres trabajos; á saber: 1.°, la carga de *entrada;* 2.°, la carga de *resistencia* ó *rozamiento;* y 3.°, la carga *de velocidad*.

**Art. 1** *b*. **La carga de velocidad** es la altura de la cual un cuerpo tiene que caer en el vacío para adquirir la velocidad efectiva con que el agua corre dentro del tubo. Es por lo tanto $= \frac{v^2}{2g}$, en que $v$ es la velocidad en metros por segundo; y $g$ (9.81 m), la aceleración debida á la gravedad.

**Art. 1** *c*. Los experimentos hechos han demostrado que **la carga de entrada** en los orificios comúnmente usados, de arista viva, es, con una aproximación suficiente en la práctica, igual á la mitad de la carga de velocidad. Si la entrada ó boca del tubo tiene la forma de la fig. 7, casi no se necesita carga de entrada; pero en los tubos de una longitud mayor que 1,000 veces el diám, la carga de entrada es una fracción tan pequeña de la carga total, que la ventaja que ofrece aquella forma es de poca importancia; es de alguna consideración en tubos más cortos.

**Art. 1** *d*. Supongamos que, en la fig. 1, *is* represente la suma de las cargas de velocidad y de entrada para cualquiera de los tubos. Entonces lo restante *sv* ó *wo* de la carga total, es la **carga de rozamiento** ó la carga exactamente suficiente para hacer equilibrio al rozamiento y á las otras resistencias del interior del tubo, y como la carga de *entrada* equilibra la resistencia á la entrada del tubo, la carga de velocidad sólo tiene que comunicar velocidad al agua en el envase, haciéndola entrar en el tubo con la misma rapidez que corre en él, conservando así el tubo siempre lleno. Si recortando el tubo ó alisando su superficie interior, disminuímos el rozamiento total, se necesitará entonces menor carga de rozamiento; pero la velocidad aumentará al mismo tiempo y ésta necesitará una carga mayor de velocidad y de entrada, de modo que las tres unidas, juntas producen la misma carga total que antes. Como el *rozamiento* es igual á la presión ó carga que se necesite para vencerla, se representa también por *wo*.

**Art. 1** *e*. Toda la carga de rozamiento puede hallarse como en *vo*, *zo* y *lo*, fig. 1, por *encima* de la boca de entrada del tubo, y de consiguiente *por fuera* de él; ó como en un tubo colocado de *s á o*, toda ella *debajo* de la entrada, y por tanto en *el interior* del tubo, ó parte de ella por encima y parte por debajo de dicha entrada, como en *ro* y *to*, y de consiguiente parte en el exterior y parte en el interior del tubo. La velocidad y el gasto, *después de lleno el tubo*, no son afectadas por esta diferencia de la posición de la boca de entrada; pero sí lo son las presiones y las velocidades *en el tubo mientras se llena el tubo vacío* con el agua, como se explica después.

**Art. 1** *f*. **Pero es necesario que el extremo del tubo por donde entra el agua esté colocado á una distancia tal, debajo de la superficie** *mi* del agua, que deje por encima de su centro de gravedad por lo menos una carga *is* suficiente para efectuar los trabajos de la entrada y la velocidad. Si la boca de entrada de cualquiera de los tubos se eleva sobre *s*, una parte de la carga de *velocidad* estará por dentro del tubo. En otras palabras: la carga en el *interior* del tubo será más que suficiente para vencer la resistencia en dicho tubo y el sobrante obrará como carga de velocidad, comunicándole mayor velocidad al agua *dentro* del tubo. La carga *reducida*, que de este modo se deja por sobre la boca de entrada dicha, será claramente insuficiente para mantener la alimentación con esta velocidad *mayor*, y el tubo no se llenaría sino parcialmente.

En los casos ordinarios de tuberías de una longitud considerable, la suma de las cargas de entrada y de velocidad que se necesitan teóricamente, es tan sólo una pequeña fracción de la carga total, y raras veces pasa de 30 cm. En un tubo de considerable diám, la mitad superior de su sección transversal en la boca de entrada, es á menudo más que suficiente para proporcionar la carga de entrada y de velocidad con la distancia que existe entre el centro de gravedad de dicha sección transversal y el borde superior del tubo, de manera que la parte superior de la boca del tubo podría sobresalir de la superficie del agua en el estanque; pero en la práctica, la boca del tubo debe estar siempre enteramente debajo de la superficie del agua, pues de lo contrario el aire y algunas impurezas flotantes entrarían en el tubo y formarían obstrucciones. Además, la superficie del agua en los estanques siempre está expuesta á considerables cambios de altura, y el extremo ó boca de entrada del tubo debe colocarse á tal profundidad que el agua pueda entrar con suficiente velocidad cuando esté en *su nivel más bajo*. Como ya se ha dicho, esto no causará disminución ni aumento de gasto.

**Art. 1** *g*. **Hallar la carga de rozamiento requerida para una parte cualquiera de un tubo**, conociendo la carga de rozamiento de todo el tubo. Como el rozamiento en un tubo de diám uniforme (en igualdad de circunstancias)

es proporcional á su longitud, y como *wo*, fig. 1, representa la carga total de rozamiento, tenemos :

Longitud total de tubo : Longitud de la porción dada :: *wo* : Carga de rozamiento para esta porción.

O habiendo trazado *wo* por escala, *sw* horizontal, y á *so* tendremos :

Longitud total del tubo : Longitud de la porción dada :: *so* : Una dist como *sc* tomada desde *s* sobre *so*.

O :: *sw* : Una dist como *sb* tomada desde *s* sobre *sw*.

Entonces una línea vertical *bc*, tirada desde *b* ó *c*, que una á *sw* y á *so*, dará en partes de la escala la carga de rozamiento buscada.

**Art. 1** *h*. Si el tubo es recto como *ro*, *vo*, *lo*, el rozamiento en una parte cualquiera, *que empiece en el estanque*, por ejemplo, como la porción *l* 6 del tubo *lo*, puede encontrarse inmediatamente trazando la línea 6–1 verticalmente hacia arriba á partir del eje del tubo en el punto 6. La línea 2–3 dará entonces el rozamiento de *l*–6. También dará el de *r*–4 ó el de la porción de *vo* comprendida entre *v* y la línea de puntos 1–6. Debe tenerse presente que, en la fig. 1, todos los tubos se suponen de la misma long efectiva. En este caso terminarán todos en puntos distintos del punto *o*, y debe hacerse un diagrama separado para cada uno. En una porción de tubo que no principie en el estanque, como en los tubos *ro*, *vo*, *lo*, la parte comprendida entre las verticales de *c* y *x*, el rozamiento está dado, por ej., por la línea *d x*, porque es igual á *yx* — *bc*.

**Art. 1** *j*. **Si el tubo es vertical como** *vo*, fig. 1 A, sea *is* (sobre su eje *io*), como antes, la suma de las cargas de velocidad y de entrada. Desde *s*, *v* y *o* res-

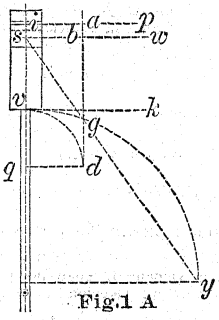

Fig. 1 A

pectivamente tírense las líneas horizontales *sw*, *vk*, *oy*, haciendo *oy*=*vo*. Tírese la oblicua *sy* para luego hallar el rozamiento en una porción cualquiera *vq* que empiece en el estanque; tírese desde *q* la línea *qd* horizontal é igual á *vq;* tírese la línea vertical *ad*, que corta á *sy* en *g*. Entonces *bg* dará el rozamiento en *vq*.

**Art. 1** *k*. **Si el tubo es curvo** y la curvatura está uniformemente distribuída en toda su longitud, ó es tan suave que puedan despreciarse las cargas de rozamiento requeridas para las diferentes partes del tubo, se pueden hallar de la misma manera que para tubos rectos, como en el art. 1 *h*. De lo contrario, deben buscarse por medio de proporciones como en el art. 1 *g*.

**Art. 1** *l*. **Durante el tiempo en que se llena de agua un tubo vacío,** el exceso de la carga total sobre la de rozamiento, etc., requerida, comunica al agua una **velocidad mayor** que la que tiene después de lleno el tubo; pero esta velocidad disminuye gradualmente, á medida que el agua que avanza va sufriendo el rozamiento de la porción creciente de tubo lleno, y llega á su mínimum cuando el agua llena todo el tubo y comienza á salir por la boca de descarga *o*. Pero si sólo queda por encima de la boca de entrada, la carga de velocidad y de entrada, como sucede en los tubos colocados en la posición *so*, es claro que no habrá tal exceso de la carga total, y en consecuencia ningún cambio de velocidad mientras se llena el tubo.

**Art. 1** *m-r**. **Relación entre el gasto, área, velocidad y presión.** En la fig. 1 B-D, el agua corre en el tubo, *b*F, á caño lleno y aquél se surte, en *b*, de un estanque ilimitado, R, y se descarga por un orificio, F; el volumen de agua que pasa por cualquier sección transversal del tubo, *b*F, es constante é igual á la que sale por F. Así, si la descarga en F es de Q litros por segundo, igual cantidad pasará por seg en cualquier sección de *b*F.

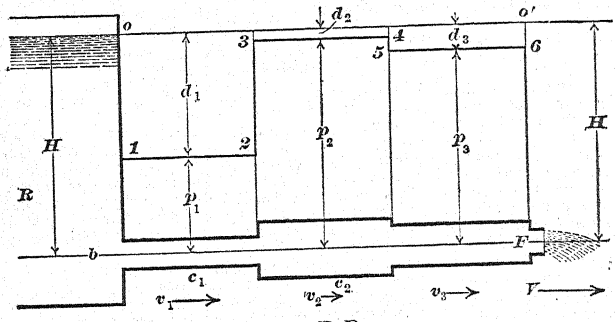

**Fig. 1 B-D.**

Sea $a$=área de la sección transversal, V=velocidad de la corriente en el tubo estrecho, después de F. V se llama la velocidad de salida. Sean $A_1$, $A_2$, etc., las diversas secciones del tubo *b*F, y $v_1$, $v_2$, etc., las respectivas velocidades del líquido en dichas secciones. Entonces $Q = aV = A_1v_1 = A_2v_2$, etc.; ó bien $V = \frac{Q}{a}$, $v_1 = \frac{Q}{A_1}$, $v_2 = \frac{Q}{A_2}$, etc. En otras palabras, la velocidad está en razón inversa del área de la sección transversal. También, $a = \frac{Q}{V}$, $A_1 = \frac{Q}{v_1}$, etc.

Las pérdidas de presión debidas á las respectivas velocidades, son $d_1 = \frac{v_1^2}{2g}$, $d_2 = \frac{v_2^2}{2g}$, etc.; como están representadas por las ordenadas entre la línea *oo'*, de la presión estática y la línea quebrada, *o* 1 2 3 4 5 6 F, de las presiones efectivas. La diferencia, debida á la velocidad, entre las presiones en dos puntos cualesquiera, como $c_1$ y $c_2$, donde las velocidades son, respectivamente, $v_1$ y $v_2$, es $p_2 - p_1 = d_1 - d_2 = \frac{v_1^2}{2g} - \frac{v_2^2}{2g} = \frac{v_1^2 - v_2^2}{2g}$ *. Lo que queda de la presión (parte de la carga) en cada punto, $p_1$, $p_2$, etc., es=á la carga total estática en el depósito — la carga de velocidad en dicho punto, $= H - d_1$, $H - d_2$, etc. La pérdida de carga en F, es (6F)=$p_3 = H - d_3$; y luego la presión baja hasta cero, es decir, á la presión atmosférica.

**Art. 1** *s*. **Piezómetros abiertos.** Si el extremo bajo de tubos verticales ó inclinados se inserta en un tubo, *b*F, fig. 1 B-D, digamos en $c_1$, ó $c_2$, etc., la superficie del líquido en estos tubos llegará á las alturas respectivas, $p_1$, $p_2$, que corresponden á las cargas (presiones) en los puntos donde se inserte el tubo. Estos tubos se llaman piezómetros abiertos. Para poder observar la altura á que llega el líquido, se hacen de cristal ó vidrio, por lo menos en la parte adonde se cree que llegará el nivel. Una obstrucción en el tubo entre $c_2$ y F, *levantará* el nivel del agua en el piezómetro en $c_2$; mientras que una obstrucción entre *b* y $c_2$ lo *bajaría*.

**Art. 1** *t*. Si imaginamos un tubo cualquiera lleno de agua provisto de cierto

* En el art. 1 *m-r*, se desprecian, para mayor sencillez, todas las resistencias, inclusives las debidas á los aumentos ó disminuciones bruscas del diámetro de los tubos.

número de piezómetros, la línea que junte los extremos superiores de las columnas de agua en los diferentes piezómetros se llama **línea de pendiente hidráulica.**

**Art. 1** *u.* En un tubo recto de diámetro uniforme en toda su extensión, como *ro*, *vo*, ó *lo*, fig. 1, lleno de agua corriente y con salida libre al aire, la línea de pendiente hidráulica es una línea recta trazada del punto de salida *o* á un punto *s* situado inmediatamente sobre la boca de entrada del tubo, y á una profundidad, bajo la superficie, igual *á la suma de las cargas de velocidad y entrada.*

**Si se reduce el orificio en** *o*, la línea de pendiente hidráulica debe tirarse de *s* á un punto *e* situado inmediatamente encima de *o*, cuya altura depende de

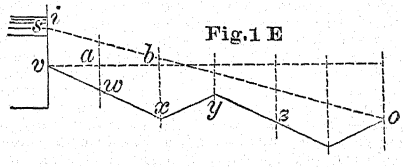

Fig.1 E

la reducción hecha en *o*. Pero en este caso el punto *s* estará también más alto que antes, porque la velocidad en el tubo está disminuída por la reducción, y la suma *is* de las cargas de velocidad y de entrada será menor.

**Si la salida ó descarga por** *o* **se efectúa debajo del agua,** el efecto que esto produce sobre la posición de la línea de pendientes, será análogo al que produce la contracción del orificio en *o*. El punto *e* estará en la superficie del agua más baja é inmediatamente encima de *o*.

**Art. 1** *v*. Si el tubo de diám uniforme (sea de salida libre ó á través de un orificio reducido en *o*, ya sea al aire libre ó bajo el agua) **está doblado ó encorvado,** la línea de pendiente hidráulica será sin embargo recta con tal que las resistencias sean iguales en cada una de las divisiones iguales en que consideremos partida la longitud horizontal del tubo, como en la fig. 1 E, en que á divisiones iguales *vw*, *wx*, etc., de la longitud total, corresponden divisiones iguales *va*, *ab*, etc., de la longitud horizontal. Pero en la fig. 1 F, la línea de pendiente hidráulica tomará la forma *sao;* porque si, de acuerdo con el art. 1 *g*, dividimos á *so* en dos partes guales *sm*, *mo* que correspondan á las partes iguales *vr*, *ro* de la longitud del tubo, obtendremos *me=ae* para la carga consumida en las resistencias de *vr*, dejando solamente *ra* para la carga de presión en *r*.

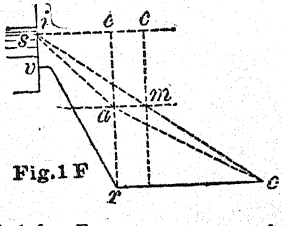

Fig.1 F

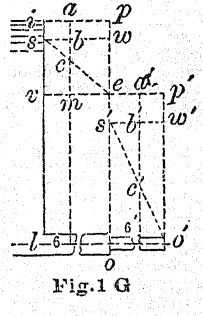

Fig.1 G

**Art. 1** *w*. En un envase muy grande, la carga total en cualquier punto al nivel de la entrada *l*, de un tubo *loo'*, fig. 1 G, está representada por *il* como ya se ha explicado; pero de esta carga total, una parte *is* obra como carga de velocidad y de entrada de la abertura *l*, quedando *sl* como carga de presión en un punto del *tubo*, situado inmediatamente á la derecha de *l*. Así, mientras que la presión en lbs por pulg cuad es en el *envase* en *l*, $p=il\times.434$; la presión en el *tubo* en *l*, es $p=sl\times.434$, ó empleando el sistema métrico tendremos, en el primer caso, $p=il$, (en m)$\times.1$, y en el segundo, $p=sl$ (en m)$\times.1$, = la presión en kg por cm cuad

Pero una parte *sv* de *sl* se emplea en *lo* en (vencer) las resistencias de esa parte del tubo; y al realizar este trabajo, disminuye gradualmente desde *sv* que es su valor (en *l*) hasta llegar á nada (en *o*), como lo indica la línea de puntos *se*. De manera que en el punto 6 una parte=*bc* se ha consumido ya en vencer las resistencias del tubo entre *l* y 6, quedando *c*6 como carga de presión en 6, de la cual *cm* se gastará aún en vencer las resistencias del tubo ancho entre 6 y *o*, quedando *m*6=*vl*=*eo* como carga de presión para un punto situado justamente al lado izquierdo de la contracción existente en *o*. La presión en *lo* ha disminuído gradualmente de *sl* que era (en *l*) á *eo* = *vl* (en *o*). Ahora se necesita que una parte *es'* de *eo* obre como carga de velocidad y de entrada en *o* en la parte más angosta *oo'* del tubo, porque necesitamos en *o* no solamente una carga de *entrada* adicional para vencer la resistencia que opone el recodo formado por el cambio de diámetro, sino también una carga de *velocidad* adicional para comunicar el aumento de velocidad que debe tener efecto cuando el agua pasa del tubo ancho *lo* al más angosto *oo'*, porque mientras que un tubo permanece *lleno* de agua corriente y la salida se conserva constante, la *velocidad* en cada parte del tubo debe estar *en razón inversa del área de la sección transversal* de aquella parte, puesto que en cada segundo pasa la misma cantidad de agua por cada uno de los puntos, y esta cantidad constante es igual al área×la velocidad. Por esto, como el área disminuye, la velocidad tiene que aumentar. Por tanto, *s'o* queda como presión sobre un punto de la porción estrecha situada justamente á la derecha de *o*, y ésta, á su vez, disminuye gradualmente hasta llegar á cero en el extremo *o'*, del tubo, como lo indica la línea de puntos *s'o'*, habiéndose gastado toda en vencer la resistencia de *oo'*. Tenemos, pues, como línea de pendiente hidráulica en la fig. 1 G, la línea quebrada *ises'o'*.

Cuando la presión disminuye de este modo con las resistencias ó por aumentos de velocidad, la disminución se llama **pérdida de carga**. Así decimos que *is* **se pierde** á la entrada *l*; *sv* como carga de rozamiento en la porción *lo*; *es'* por la contracción existente en *s* y *s'o* como carga de rozamiento del tubo *oo'*.

**Cuando el aumento de velocidad** en cualquier punto *o* **es muy grande**, entonces la carga de velocidad requerida para tal aumento (sumada con la carga de entrada) puede llegar á ser tan grande como la carga de presión total disponible en aquel punto. De consiguiente, en tal caso la presión cesa enteramente, y la línea de pendiente hidráulica desciende al nivel del eje *oo'* del tubo. Ciertamente, la carga de velocidad requerida puede *exceder* y á menudo *excede* á la carga de presión disponible, causando una presión *negativa* ó presión *hacia el interior*, es decir, una **succión** (tendencia al vacío); de manera que si, se coloca hacia abajo un piezómetro desde el tubo al interior de un envase que contenga agua, la presión del aire sobre la superficie de ésta sostendrá en el piezómetro una columna de agua que se levanta desde el envase hacia el tubo; y la línea de pendiente hidráulica, para el punto donde el piezómetro se une al tubo, se hallará *debajo del eje oo*, del tubo á una distancia vertical, igual á la altura de dicha columna. Véase medidor Venturi, págs. 570, etc.

**El sifón.** Si una rama *ab* de un tubo encorvado *abc*, fig. M, de cualquier diám, lleno de agua y tapado por ambos extremos, se coloca en un estanque con agua,

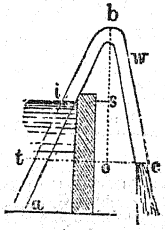

Fig. M.

como el de la fig., y si entonces se destapan ambos extremos, el agua del estanque principiará á salir en *c* y continuará saliendo hasta que su nivel llegue en *t* á la

misma altura del extremo más *alto c*, del tubo ó sifón. La salida del agua se detendrá entonces. Las partes *ab* y *bc* se llaman ramas del sifón, siendo *b* el vértice, y así se dice en lo que se refiere á dicho sifón considerado como un pedazo de tubo; pero si lo consideramos como una máquina hidráulica, la parte, *ta*, bajo el nivel del extremo más alto *c*, no tiene ninguna importancia, porque el agua en el estanque no descenderá bajo el nivel de la boca más alta, sea ésta la exterior ó la interior. Por esta razón, si el extremo de salida está más alto que la superficie del agua, por ejemplo en *w*, no habrá salida. La altura *vertical ob*, del vértice del sifón al nivel más bajo *t* (hasta donde descenderá el agua en el estanque), no debe teóricamente exceder de 10.33 m, que es la altura de una columna de agua igual á la presión atmosférica. En la práctica debe ser menor, teniendo en cuenta el rozamiento del agua corriente con el tubo y el aire que se introduce. Y aun menos todavía en los lugares situados sobre el nivel del mar, porque en estos lugares el peso reducido de la presión atmosférica no equilibrará una columna de agua de aquella altura. Para que se comprenda fácilmente, ó para que se recuerde en cualquier tiempo el principio en que se basa el sifón, imaginemos que podemos considerar teóricamente el extremo de la rama interior, como no sumergida *bajo* la superficie del agua, sino que se mantiene precisamente *en* ella, á medida que ésta va descendiendo por causa de la salida del agua en el otro extremo; pero si debemos considerar la altura *bo* como longitud de la rama exterior, el largo de la interior será una dist variable que al principio es *bs* y que finalmente llega á ser *bo* (cuando desciende el agua en el estanque). La corriente solamente continúa mientras *esta rama exterior permanezca más larga que la interior*. No hay razón en lo que dicen los libros que la rama exterior *bc debe* ser más larga que la interior *ba* para que el agua salga. El principio es simplemente el siguiente : que habiendo llenado primeramente de agua ambas ramas *bc*, *bi* (considerada primero la porción *ta* del *estanque* y no del sifón), cuando se destapan los extremos *c* y *a*, el aire ejerce la misma presión sobre éstos; pero la gran carga vertical *bo*, obrando en la rama exterior *bc*, ejerce presión contra el aire en *c* con una fuerza mayor que la que ejerce la pequeña carga *bs* en la rama interior *bi* contra el aire en *a* ó *i* *. Por consiguiente, el agua en *bc* tiende á salir más rápidamente que en *bi*, y al comenzar á salir se produciría un vacío en *b* si no fuera que la presión del aire contra el otro extremo *a* ó *i* empuja el agua de abajo arriba hacia *ib*, para ocupar el lugar del agua que sale por *c*.

De esta manera continúa la salida hasta que la superficie del agua en el estanque descienda hasta *t* al mismo nivel que *c*, y siendo entonces las presiones verticales iguales á *bo*, tanto en *bc* como en *bt*, cesa dicha salida.

El principio del sifón puede emplearse para desaguar estanques ó pozos, trasegando el agua á lugares más bajos situados á distancias considerables. En la práctica no debe *exceder* más ó menos de 8.53 m sobre el nivel á que llegará el estanque después de vaciado. En estos casos debe colocarse una **válvula** adecuada en el vértice ó vértices (si hubiere más de uno) de los codos, para dar salida al aire que inevitablemente penetra y pronto detendría el curso del agua si no se toma esta precaución. La válvula de aire no dará resultado aquí; porque tan pronto como se abre la válvula *v*, se convierte el sifón en dos tubos separados abiertos en la parte superior y el agua saldrá por ambos. Se necesita de un orificio en el escape para llenar el sifón al principio, y para evitar que el agua introducida se salga deben colocarse llaves de retención en los extremos, las que se conservarán cerradas hasta que se haya llenado el sifón completamente. Debe tenerse mucho cuidado en unir las juntas de los tubos herméticamente.

**La fuerza motriz ó carga** que produce la corriente en un sifón, es la dist vertical *so* de la superficie del estanque al extremo de salida *c*, ó, en otras palabras, la dif *so* entre las longitudes teóricas *bo* y *bs* de las dos ramas. Por consiguiente, mientras más baja esté la boca *c* respecto de *s*, más rápida será la corriente, y, por el contrario, á proporción que el nivel del estanque baje con respecto á *s*, más lenta va siendo la salida. Con esta carga, la longitud total *abc* del sifón y su diám, puede hallarse aproximadamente el gasto por cualquiera de las reglas dadas en el art. 2.º para tubos rectos. Estas reglas dan 252.16 litros por minuto en lugar de 197.64 litros que realmente salen por el sifón del coronel Crozet con una carga de 6.09 m. Véase más abajo.

---

* Se entiende que dicha presión de aire no se ejerce directamente sobre *a* ó *i* sino que se transmite á través del agua del envase hacia *a* y luego hacia *i* á través del agua del sifón.

**En un sifón real**, *agnyo*, fig. 1½, sin aire en su interior, y lleno de agua corriente, **la carga total** *op* se mide verticalmente de la superficie, *mi*, en el estanque al centro de gravedad del orificio de salida *o*, como en la fig. 1; **la línea de pendiente hidráulica** (con la restricción mencionada en el art. 1 *v*), es como antes una línea recta *sro* trazada desde el pie *s* de las cargas de entrada y de velocidad combinadas, al extremo *o*, y el gasto y la velocidad son las mismas

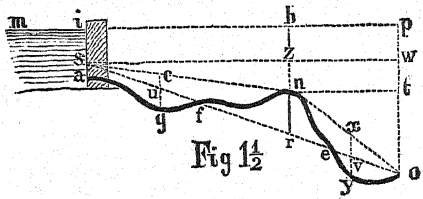

Fig 1½

que serían si todo el tubo estuviese debajo de *sro;* pero véanse las advertencias 1 y 2 que siguen.

**La presión en un punto cualquiera** *g*, *n* ó *y*, está representada por una línea vertical *gu*, *nr* ó *yv* trazada del punto en cuestión á la línea *sro;* pero para puntos como *n*, situados sobre *sro*, esta presión es *negativa* ó hacia *el interior;* mientras que en los puntos en que *sro* y el tubo están al mismo nivel, como en *f* y en *e* no hay ni presión ni vacío ó succión.

**Advertencia 1.** Pero si entra el agua á un tubo vacío por *a* estando el orificio de salida *o*, abierto, el tubo no será un sifón verdadero. En la parte *agn* correrá el agua llenando el tubo y *scn* será la línea de pendiente hidráulica de dicha parte; pero al llegar á *n* en la parte del tubo más inclinada *no*, el agua correrá con una velocidad mayor que aquella con que llegó de *an*.

Por lo tanto la vena líquida tendrá una sección transversal menor en *no* que en *an*, y no podrá llenar la parte *no* sino que correrá como en un canal abierto.

**Advertencia 2.** La tendencia al vacío en los puntos situados encima de *sro*, es causa de una acumulación de **aire** en *n* arrastrada por el agua, dentro del sifón, que penetra por las juntas no bien cerradas, etc., y esto produce un efecto que se aproxima á lo descripto en la advertencia 1.ª; porque su fuerza elástica reduce la presión negativa ó succión *nr* en *n*, disminuye la carga total *hr* de la parte *agn*, cuando al estrechar efectivamente el área transversal del sifón en *n* hace que se aplique una parte de la carga restante en *n* como carga de entrada para vencer la resistencia ocasionada por la contracción; y como carga de velocidad á dar el aumento de velocidad necesario para pasar por la sección angosta en *n*. Ahora, desde que la carga de rozamiento necesaria para la parte *agn* permanece la misma más ó menos, la carga de velocidad en el estanque está disminuída considerablemente, y el agua llega á *n* con tan poca velocidad que no puede llenar á *no*. La acumulación de aire en *n* retarda así la corriente, y perturba la distribución de las presiones de tal manera, que ya éstas no están bien representadas por las líneas verticales trazadas hacia *sro*.

**En el tunel de Blue Ridge** (Virginia), el coronel C. Crozet construyó un sifón de agua que tenía de largo 546.19 m, con tubos de hierro fundido de .076 m de diámetro interior y de 2.75 m de longitud.

El vértice estaba á 2.75 m sobre la superficie del agua que debía agotarse, y la boca de salida á 6.09 m bajo dicha superficie, teniendo así una carga de 6.09 m. En el vértice, situado á una dist de 173.73 m de la entrada, **había una válvula de aire** ordinaria, de hierro fundido, con una cámara de .91 m de altura y .38 cm de diám interior. En el mango de conexión con el sifón había una **llave de retención**, y en la parte superior un orificio de .15 cm de diám cerrado herméticamente con una tapa de tornillo. En cada extremo del sifón había una llave de retención. **Para lanzar la corriente** se cierran estas llaves terminales, y todo el sifón y recipiente de aire se llena de agua por el orificio de la parte superior del recipiente. Luego se cierra este orificio herméticamente, y se abren en seguida las llaves terminales. La llave de retención se deja abierta. Ahora principia la corriente, y aunque **teóricamente** deberá continuar sin disminución (excepto la que proviene del descenso de la carga por lo que baja el nivel de la superficie del agua en el estanque), **en la práctica** no sucede así en los sifones

muy largos, porque el aire principia á separarse del agua y sube en el sifón hasta la parte superior ó vértice donde entra al recipiente de aire, y elevándose gradualmente hasta la parte superior de la cámara, obliga al agua á salir. Si no se evita que continúe esto, el aire llenará primero toda la cámara y luego la parte superior del sifón mismo, donde obrará como un tapón deteniendo la corriente completamente. Puede saberse **el nivel á que está el agua en la cámara de aire** por el sonido producido por golpes suaves de martillo dados en el exterior de dicha válvula.

**Para evitar esta detención** se cierra la llave de retención del pie de la cámara antes que haya salido de ella toda el agua, y quitando luego la tapa de la parte superior, se llena nuevamente la cámara de agua, se coloca otra vez la tapa y se abre la llave de retención. La corriente del agua continúa mientras tanto sin interrupción, pero disminuyendo siempre gradualmente, á pesar de haber llenado de nuevo la cámara. Después de llenarla varias veces nuevamente, cesará la corriente por completo, debiendo repetirse toda la operación de llenar todo el sifón y cámara como al principio. Al principio, en el sifón del coronel Crozet, y debido á la porosidad del calafateo de las juntas que se cogían con estopa y brea solamente, el aire entraba con tanta rapidez, que desalojaba el agua de la cámara y era necesario llenarla nuevamente cada 5 ó 10 minutos; á pesar de esto el sifón se secaba á las dos horas. Entonces las juntas se calafatearon perfectamente con plomo, protegido por una capa preparada de minio y albayalde, mezclado con barniz del Japón y aceite de linaza cocido. Sin embargo, la cámara tenía que llenarse cada dos horas; y pasadas 6 horas, el sifón se secaba y había que llenarlo nuevamente. De esta manera continuaba trabajando. En opinión del autor, se ganaría mucho dándole á los tubos y al recipiente de aire una mano de barniz con alquitrán de carbón de piedra, en el interior y en el exterior.

**Art. 2. Fórmulas aproximadas de la velocidad** del agua en los tubos de hierro rectos, lisos y cilíndricos, como *ro*, *vo*, *lo*, fig. 1. Siendo conocida la carga total *op*, y el largo y diámetro del tubo.

$$\left.\begin{matrix}\textbf{Velocidad}\\ \textbf{media aprox}\\ \text{en m por segundo}\end{matrix}\right\} = \left.\begin{matrix}\text{Coeficiente } \mathbf{m},\\ \text{según la tabla}\\ \text{que sigue}\end{matrix}\right\} \times \sqrt{\frac{\text{diám en m} \times \text{carga total en m}}{\text{largo total en m} + 54\ \text{diám en m}}}$$

**Tabla de los coeficientes «m»*.**

(*N. del T.* — La fórmula y tabla del autor, las hemos transformado para usarlas en sistema métrico.)

Para cargas menores de .75 m por kilómetro, esta fórmula da resultados que prácticamente corresponden á los de la fórmula de Kutter, pág. 558, con el coeficiente *n* de asperezas=.012. Pero, pequeñas variaciones, como por ej. en la aspereza, etc., producirán considerables cambios en la velocidad, especialmente en los tubos pequeños, porque en éstos una pérdida de superficie en la sección por una

* Para diámetros intermedios, tómense coeficientes intermedios de la tabla por una simple proporción.

aspereza la disminuye en mayor proporción que cuando la sección es grande. En estas materias no se puede contar con mucha exactitud.

Como en un río la velocidad es generalmente mayor en el medio y en la superficie que en el fondo y en la orillas, asimismo la velocidad en un tubo es mayor en el centro de su sección transversal que en su circunferencia. La **velocidad media** á que se refieren nuestras reglas es una velocidad uniforme, que produciría el *mismo gasto* que la velocidad variable verdadera. Por consiguiente, tenemos :

$$\text{Gasto en m}^3 \text{ por segundo} = \text{Vel media en m por seg} \times \text{Area de la sección del tubo en m}^2.$$

En el caso de tubos largos y pequeñas cargas, la suma de las cargas de entrada y velocidad es frecuentemente tan pequeña, que puede despreciarse. Cuando esto acontece ó cuando puede saberse aproximadamente á cuánto asciende, puede usarse la **fórmula de Kutter,** también aplicable á canales abiertos. Esta fórmula es de los eminentes ingenieros suizos E. Ganguillet y W. R. **Kutter,** pero comúnmente se la cita con el nombre del último.

Es, propiamente hablando, una fórmula para hallar el coeficiente $c$ en la muy conocida fórmula :

$$\textbf{Velocidad media} = c\sqrt{\text{radio medio} \times \text{pendiente}}.$$

$$= c\sqrt{\frac{\text{diám}}{4} \times \text{pendiente}}.$$

según Kutter,

| **Para medidas inglesas.** | | **Para medidas métricas.** |
|---|---|---|
| $c = \dfrac{41.6 + \dfrac{.00281}{\text{pendiente}} + \dfrac{1.811}{n}}{1 + \dfrac{\left(41.6 + \dfrac{.00281}{\text{pendiente}}\right) n}{\sqrt{\text{radio medio en } pies}}}$ | $=$ | $\dfrac{23 + \dfrac{.00155}{\text{pendiente}} + \dfrac{1}{n}}{1 + \dfrac{\left(23 + \dfrac{.00155}{\text{pendiente}}\right) n}{\sqrt{\text{radio medio en } metros}}}$ |

Véanse también las **tablas de** $c$, en el **art. 22.**

**El radio medio** es el cociente, en metros, que se obtiene dividiendo el área de la sección transversal mojada en m cuad, por el perímetro mojado (véase abajo) en metros. En tubos llenos ó *exactamente medios llenos,* y en canales semicirculares llenos, el radio medio es igual á la cuarta parte de su diámetro interior.

**El perímetro mojado** es la suma *abco,* fig. C (pág. 561), de las porciones *ab, bc, co,* en pies ó metros hallados midiendo perpendicularmente al eje del canal la parte de sus caras laterales y del fondo, en contacto con el agua. En tubos llenos es, por su puesto, igual á su circunferencia interior.

$$\textbf{La pendiente es} = \frac{\text{Carga de } \textit{rozamiento wo}\text{, fig. 1.}}{\text{Largo del tubo medido en línea recta de extr á extr}}$$

$$= \text{seno del ángulo } \textit{wso} \text{ fig. 1.}$$

**En canales abiertos,** tenemos :

$$\textbf{pendiente} = \frac{\text{altura de la caída desde la sup del agua en una porción cualquiera de la longitud del canal}}{\text{largo de dicha porción.}}$$

$$= \text{caída desde la sup del agua, por unidad de longitud del canal.}$$

$$= \text{seno del ángulo formado por la inclinación de la sup del agua del canal y la horizontal.}$$

« **n** » es el « **coeficiente de asperezas** » del perímetro mojado, y por supuesto depende principalmente del estado de la superficie interior del tubo. Para tubos de hierro en buenas condiciones y de 2 á 120 cm de diám, puede tomarse de .010 á .012, tomando números más pequeños, cuando el tubo está en condiciones excepcionalmente buenas.

**Las curvas y codos** no afectan mucho la descarga, siempre que la carga total y la longitud de la tubería queden las mismas, y por supuesto que los vér-

tices de las curvas y codos estén bajo la línea de pendiente hidráulica y se tenga cuidado de hacer salir debidamente el aire que se acumula en la parte alta de las curvas y codos.

**Relación entre el área, la velocidad y la descarga.**

Sea $q$ = el gasto por seg,
$v$ = la velocidad media por seg,
$a$ = área de la sección transversal.

Entonces : $q = av$; $v = \frac{q}{a}$; $a = \frac{q}{v}$.

**Relación entre la descarga, el diámetro* y la pendiente.** Si suponemos la velocidad $= c\sqrt{\text{radio medio} \times \text{pendiente}}$, ó bien $v = c\sqrt{rs}$, véase pág. 558, y si el tubo es de sección circular, tenemos para el gasto (volumen de líquido por seg), Q, de un tubo de diámetro, $d$, y área, A, de la sección, corriendo lleno.

$$Q = Av = \frac{\pi d^2}{4} \cdot c\frac{d^{1/2}}{2} s^{1/2} = \frac{c\pi d^{5/2} s^{1/2}}{8};$$

donde se ve que Q es proporcional á la raíz cuad de la quinta potencia del diámetro y á la raíz cuadrada de la pendiente. Para tablas de quintas potencias y de raíces cuadradas de quintas potencias, véanse págs 69 a 71.

## Efecto de las resistencias.

**La presión** del agua que corre por un tubo, en cualquier punto de éste, entre el orificio de salida y el estanque, es :

$$= \left\{\begin{array}{c}\text{carga total}\\ \text{en}\\ \text{ese punto}\end{array}\right\} \text{menos} \left\{\begin{array}{c}\text{la carga}\\ \text{de velocidad}\\ \text{en}\\ \text{dicho punto}\end{array}\right\} + \left\{\begin{array}{c}\text{la}\\ \text{carga}\\ \text{de}\\ \text{entrada}\end{array}\right\} + \left\{\begin{array}{c}\text{la carga consumida}\\ \text{en vencer las resistencias}\\ \text{entre}\\ \text{el estanque y el punto.}\end{array}\right\}$$

Así, en el punto 6, del tubo *lo*, fig. 1, pág. 549, la presión es $h = (3\,6) = (1\,6) - [(1\,2) + (2\,3)]$; en donde $(1\,2) = is$ = suma de las cargas de velocidad y de entrada. En 4, en el tubo *ro*, $h = (3\,4) = (1\,4) - [(1\,2) + (2\,3)]$. Supongamos en la fig. 11 que la línea recta, *so*, representa la verdadera longitud del tubo, ya sea recto, con codos ó curvo, etc.; y *sv*, la suma de las resistencias (suponiéndolas uniformemente distribuídas) dentro del tubo. Entonces el ángulo, *sov*, se llama la pendiente hidráulica, y seno $sov = sv \div so$.

En el tubo vertical, *vo*, fig. 1A, la presión en $q = gd$.

### PESO DEL AGUA CONTENIDA EN UN METRO DE TUBO DE DIFERENTES DIAMETROS

(*N. del T.*—Hemos reemplazado con esta tabla la que el autor trae en medidas inglesas.)

| Diámetro en cm. | Peso agua en kg. | Diámetro en cm. | Peso agua en kg. | Diámetro en cm. | Peso agua en kg. | Diámetro en cm. | Peso agua en kg. |
|---|---|---|---|---|---|---|---|
| 1¼ | .123 | 10 | 7.854 | 30 | 70.686 | 60 | 282.744 |
| 2½ | .491 | 12½ | 12.272 | 35 | 96.212 | 65 | 331.832 |
| 3 | .707 | 15 | 17.672 | 40 | 125.664 | 70 | 384.846 |
| 4 | 1.257 | 17½ | 24.053 | 45 | 159.044 | 80 | 502.656 |
| 5 | 1.963 | 20 | 31.416 | 50 | 196.350 | 90 | 636.174 |
| 7½ | 4.418 | 25 | 49.088 | 55 | 237.584 | 100 | 785.400 |

**El peso del agua** en cualquier longitud dada (como un pie ó un metro) de un tubo cualquiera ú otro cilindro circular **es proporcional al cuadrado del diámetro interior.** De aquí que el peso del agua en un m de longitud, de cualquier cilindro de diámetro distinto á los que hemos dado en la tabla, puede hallarse

* Diámetro $= 4 \times$ radio medio, ó bien $d = 4r$, pág. 558

multiplicando el correspondiente á un tubo de un decímetro de diám por el cuadrado del diámetro interior del cilindro dado en dcm.

**Art. 3. Teoría de la corriente en tubos largos y canales.**

**Resistencia á la corriente.** Cuando un cuerpo sólido se mueve sobre otro, las más de sus partículas conservan prácticamente sus relativos puestos; pero cuando corre agua, como en un tubo ó canal, las asperezas y las irregularidades, que existen aun en las superficies más lisas, estorban la corriente, describiendo las varias partículas caminos espirales ó de otras formas no paralelos á la dirección general de la corriente. La resistencia á la corriente créese que se debe á tales estorbos antes que á la fricción propiamente dicha, como la entendemos en los sólidos. Véase pág. 425, y § 194, pág. 436.

A falta de un completo conocimiento respecto de la naturaleza de estos estorbos, estamos obligados á atenernos á los experimentos al determinar la manera y la extensión de su influencia en la corriente.

**Velocidad media. Gasto.** Figs. A, B. En un tubo ó canal, á causa del contacto con los lados y fondo, las partículas de agua se mueven en caminos tortuosos. La

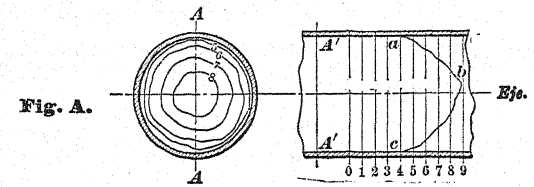

Fig. A.

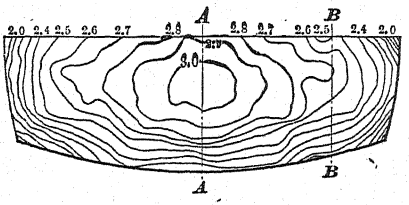
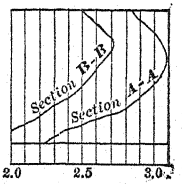
Fig. B.





**velocidad media**, al través de la sección transversal entera en cualquiey punto, es el cociente obtenido dividiendo el gasto por el área de la sección transversal. **En cualquier punto dado** en una sección transversal, la **velocidad**, tal como la registra cualquier medidor corriente, es la componente, paralela al eje del tubo, de la velocidad efectiva de lás partículas que pasan por ese punto. Tratamos, actualmente, sólo de casos de « **corriente constante** », esto es : en que la velocidad, en cada punto, permanece la misma.

**Las velocidades, medidas en puntos diferentes en la sección transversal** de un tubo ó canal, son generalmente mínimas cerca del borde de los tubos y cerca de los lados y fondos de los canales.

En la fig. A, la sección longitudinal muestra una de muchas series de medidas de velocidad por los Sres. Williams, Hubbell y Fenkell* en un tubo de hierro fundido de 16 pulgadas de diámetro. Las medidas se hicieron, por medio del tubo de Pitot, en un diámetro vertical, tal como AA de la sección transversal. Las distancias horizontales de los varios puntos en la curva, *abc*, desde la línea vertical, 0, representan, por la escala que está debajo de la figura, las velocidades en los varios puntos en el diámetro. En la sección transversal, las varias líneas curvas son líneas de igual velocidad.

La fig. B muestra los resultados de medidas de velocidades en una sección transversal, del Sudbury Conduit, Mass. †, de 9 pies (2.74 m) de ancho, y 3 pies

* Trans. Am. Soc. Civ. Engrs, vol. XLVII, lámina LV, pág, 66.
† F. P. Stearns. Trans. Am. Soc. C. E., agosto 1883, vol. VII pág. 324.

(.91 m) de hondo. En la sección longitudinal están aproximadamente indicadas las velocidades, en diferentes profundidades, de las líneas AA y BB de la sección transversal, como se hizo en la fig. A. En la sección transversal, las varias líneas curvas son líneas de igual velocidad. La interior corresponde á una velocidad de 3 pies (.91 m) por segundo; la inmediata á 2.9 pies (0.884 m.) por segundo, y así de lo demás.

**Fórmulas para el gasto** $q$, **y la velocidad media,** $v$, en una longitud dada, L, de un **tubo ó canal recto** con vena líquida de sección transversal uniforme.

Refiriéndonos á la fig. C, sean

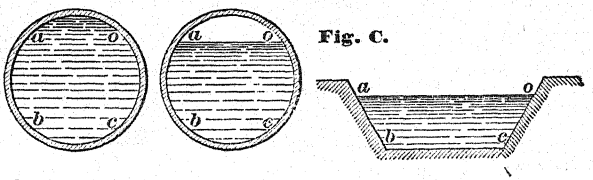


**Fig. C.**

L=longitud dada,

$p$=el perimetro mojado *abco* ;

A=L$p$ = el área de la superficie mojada;

$a$=el área de la sección transversal de la vena líquida ;

$r = \frac{a}{p}$ = el radio medio de su sección transversal;

$d$=diámetro del tubo*;

$q$=el gasto

=volumen que pasa por una sección transversal dada, $a$, en la unidad de tiempo;

$v = \frac{q}{a}$ = la velocidad media;

$h_v = \frac{v^2}{2g}$ = la carga=altura de caída;

$m$, $c$, $f$, F=factores de resistencia, como se explica abajo;

$h_f$= la resistencia (ó « fricción ») en la longitud L;

$s = \frac{h_f}{L}$ = la pendiente.

Créese generalmente que las resistencias á la corriente son directamente proporcionales á A y á alguna potencia (generalmente $v^2$)† de $v$, é inversamente proporcional á $a$.

Es decir :

**pérdida por fricción,** $h_f = m\frac{Av^2}{a} = m\frac{Lpv^2}{a} = m\frac{Lv^2}{r}$ ; y $m = h_f \frac{r}{Lv^2}$ $\frac{rs}{v^2}$

de donde

$v^2 = h_f \frac{a}{mLp} = \frac{rs}{m}$ ; y **velocidad,** $v = \sqrt{\frac{1}{m}}\,rs = \sqrt{\frac{1}{m}} \times \sqrt{r} \times \sqrt{s}$.

Sea $c = \sqrt{\frac{1}{m}}$ ; $m = \frac{1}{c^2}$. Entonces tenemos la *fórmula Chezy* : —

**velocidad,** $v = c\sqrt{rs} = c\sqrt{r} \times \sqrt{s} = cr^{0.5}s^{0.5}$.

Para la fórmula de « Kutter », que da valores de $c$, véanse arts. 2 y 20 á 23. Para tablas de $c$, por la fórmula de Kutter, véase art. 22.

**Los coeficientes de resistencia, ó fricción,** tales como $m$, $f$, F ó $c$, se

---

* En canales semicirculares llenos, y en tubos llenos ó medio llenos, $d = 4r$.

† Véanse « Fórmulas Exponenciales », art. 3 *a* que sigue.

deben elegir á nuestro juicio, ó determinarse, como por la fórmula de Kutter, arts. 2, 20, etc., según se conozca ó suponga la superficie mojada.

*N. del T.* — Reemplazando unas dos fórmulas y la tabla que da el autor en medidas inglesas, damos otra tabla, págs. 564 y 565, que suple á la del autor.

Para velocidades mayores de tres metros, que no figuran en la tabla, damos los siguientes:

| $v =$ | 4 m | 5 m | 6 m | 7 m | 8 m | 10 m |
|---|---|---|---|---|---|---|
| Coef de frotamiento = | .0191 | .0187 | .0183 | .0180 | .0177 | .0174 |

**Art. 3 a. Fórmulas « exponenciales ». El estudio** cuidadoso de los experimentos sobre tubos grandes y en canales, bajo condiciones variables, indica que la velocidad media depende, no de las raíces *cuadradas* (ó potencia ½), de *r* y de *s*, sino generalmente de potencias algo más altas; y que la inexactitud, implicada en tomar .5 como exponentes en la fórmula Chezy explica la notable variación de la *c* Chezy con *r* y con *s*, para una condición dada de la superficie interior del tubo ó del canal.

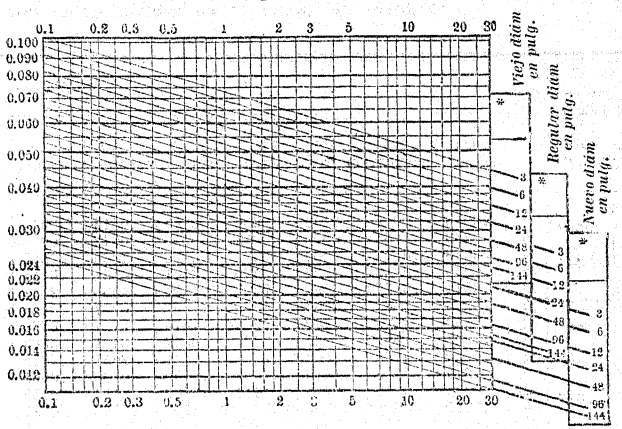
*N. del T.* — Damos á continuación algunas fórmulas para los coeficientes de frotamiento.

Según Weisbach llamándolo $\pi = .01439 + \dfrac{.0094711}{\sqrt{v}}$

— Zeuner — $= .014312 + \dfrac{.010327}{\sqrt{v}}$

Darcy cree que depende menos de la velocidad que del diámetro $= .0198 + \dfrac{.0005078}{d}$.

**Valores de la fricción, F, para tubos de hierro.** (Véase pág. 566.)



*N. del T.* — Por ser este diagrama muy práctico y de muy fácil manejo en el sistema métrico (con las pequeñas modificaciones que le hemos hecho) lo hemos dejado. En efecto: dado el diám del tubo en metros, basta multiplicarlo por 40 (suficiente exactitud en este caso) para tener su diám en pulgs, y entonces se procede así :

**Uso del diagrama.** Dado un tubo de 6 pulgadas, por ejemplo, en condición regular. En la columna, á la derecha, titulada « Regular », encuéntrese la línea, 6 pulgadas. Siguiendo á la izquierda la dirección de la línea corta inclinada, (con preferencia por medio de una regla ó una orilla derecha de papel) encontramos que ella coincide casi con una de las líneas inclinadas que cruzan el diagrama. Por medio de las intersecciones de esta línea con las otras, encontramos que, para el tubo en cuestión, una velocidad de 5 pies ó sea 1.50 m por segundo corresponde aproximadamente á F=.035; para una velocidad de .15 m ó .5 pies por segundo, F=.048, etc., etc.

| Diám en pulg..... | 3 | 6 | 12 | 24 | 48 | 96 | 144 |
|---|---|---|---|---|---|---|---|
| Diám en metros..... | .075 | .15 | .30 | .60 | 1.22 | 2.44 | 3.66 |

(*N. del T.* — Cuando se quiera entrar á la tabla con una velocidad intermedia de las marcadas con cifras, es muy fácil encontrar la línea que le corresponde por el valor de las velocidades extremas, entre las que viene quedando la velocidad dada, distribuyendo la diferencia entre aquéllas, para el número de líneas intermedias.

El factor fricción es poco sensible á las variaciones de velocidad y diámetros; de modo que este diagrama resulta suficientemente exacto para los cálculos ordinarios.)

**Valores del gasto $Q_1$ en metros cúbs; por**

Las velocidades, los coeficientes y los diám están dados en metros.

**Art. 4. Para encontrar el gasto, $q$, de una tubería de diámetro variable, fig. 1 H.**

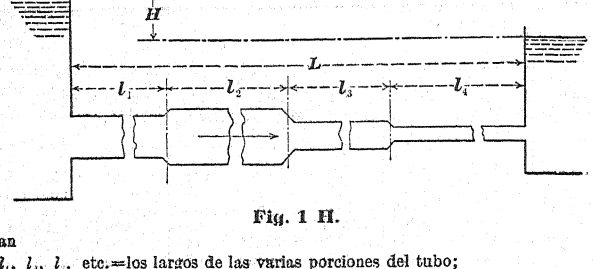

**Fig. 1 H.**

Sean

$l_1$, $l_2$, $l_3$, etc.=los largos de las varias porciones del tubo;
$d_1$, $d_2$, $d_3$, etc.=los correspondientes diámetros;
$v_1$, $v_2$, $v_3$, etc.=las correspondientes velocidades;
$F_1$, $F_2$, $F_3$, etc.=los correspondientes valores de la resistencia ó coeficiente de fricción. Véase pág. 563.
$L=l_1+l_2+l_3+$etc.=el largo total del tubo;
H=carga total (art. 1).
$q=\frac{1}{4}\pi d_1^2 v_1=\frac{1}{4}\pi d_2^2 v_2=$etc.=gasto.

En un tubo largo, las cargas de velocidad y de entrada son ordinariamente despreciables con relación á la carga de fricción. Despreciándolas, tenemos

H=carga total=carga de fricción.

En cada porción del tubo, la resistencia, y la correspondiente carga de « fricción » $hf$ *, se cree que son proporcionales directamente á la longitud $l$ y á la carga de velocidad, $\frac{v^2}{2g}$, é inversas al diámetro, $d$, ó

$$h_f = F \cdot \frac{l}{d} \cdot \frac{v^2}{2g}.$$

En consecuencia

$$H = F_1 \cdot \frac{l_1}{d_1} \cdot \frac{v_1^2}{2g} + F_2 \frac{l_2}{d_2} \cdot \frac{v_2^2}{2g} + F_3 \frac{l_3}{d_3} \cdot \frac{v_3^2}{2g} + \text{etc.};$$

y puesto que

$$v_1 = \frac{4q}{\pi d_1^2}, \; v_2 = \frac{4q}{\pi d_2^2}, \text{ etc.},$$

tenemos, también,

$$2gH = F_1 \cdot \frac{l_1}{d_1} \cdot \frac{16\,q^2}{\pi^2 d_1^4} + F_2 \frac{l_2}{d_2} \cdot \frac{16\,q^2}{\pi^2 d_2^4} + \text{etc.}$$

$$= \frac{16\,q^2}{\pi^2}\left(F_1 \cdot \frac{l_1}{d_1^5} + F_2 \frac{l_2}{d_2^5} + \text{etc.}\right)$$

de donde

$$q = \frac{\pi}{4}\sqrt{\frac{2g\,H}{F_1 \frac{l_1}{d_1^5} + F_2 \frac{l_2}{d_2^5} + \text{etc.}}}$$

**Art. 4 a †. El medidor Venturi** se destina á la medida de la corriente de líquidos en tubos de grandes dimensiones y llenos.

**El medidor** propiamente dicho, patentado por Clemens Herschel, consiste

---

* *N. del T.* — En español decimos « pérdida de carga por frotamiento ó fricción »; pero como es tan largo y hay que repetirlo tanto, abreviamos como está.

† Extracto de una descripción preparada por el autor como presidente de una Comisión del Instituto de Franklin. *Diario del Instituto de Franklin*, febrero de 1899.

esencialmente en una simple contracción del área de la sección transversal del tubo, con aberturas en sus diámetros reducidos para medir, por piezómetros ó manómetros, las presiones en esos puntos; mientras que **el registrador** patentado por los Sres. Frederick N. Connet y Wálter W. Jackson, es un complicado mecanismo, provisto de movimientos de relojería y cuadrantes.

**Teoría** *. Supongamos que las figs. 1 á 3 representen un tubo de medidor Venturi, con tres piezómetros en su lugar, esto es · n.º 1, sobre el tubo aguas arriba

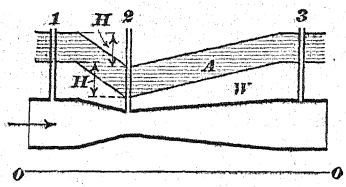

**Fig. 1.**

de la contracción; n.º 2, sobre la contracción misma; y n.º 3, sobre el tubo agua abajo de la contracción. Represente el área no sombreada W, en las figs. 1 á 3 las alturas á que llega el agua (por efecto de la presión en cada punto) respecto de cualquier plano horizontal dado O-O; y representemos por el área sombreada A la presión uniforme de la atmósfera, que, por conveniencia, podemos suponer representada en peso por una capa de algún líquido de la gravedad específica del agua, pero que se distingue del agua por su apariencia.

La distancia vertical, entre la línea superior de esta última área y cualquier punto dado en el tubo, representa la presión combinada de aire y del agua en tal punto.

Las velocidades en el tubo medidor, en cualquier instante, son inversamente proporcionales á las áreas de las secciones transversales respectivas, y, como las cargas correspondientes á las varias velocidades son proporcionales á los cuadrados de esas velocidades, las cargas ó presiones deben variar también, estando la más pequeña ó más baja carga ó presión por encima de la más estrecha sección, donde la velocidad es más grande.

El aumento de velocidad, adquirido por el fluido al pasar de la sección 1 á la sección 2, lo pierde al pasar de la sección 2 á la sección 3; y, en el caso de un

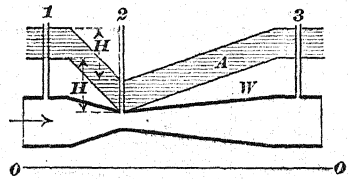

**Fig. 2.**

fluido perfecto, la presión perdida entre las secciones 1 y 2 la readquiriría exactamente al pasar de la sección 2 á la sección 3. En la práctica, hay siempre una pequeña pérdida total. Esta pérdida es mayor con grandes que con pequeñas velocidades.

Para una carga ó presión dada en el piezómetro n.º 1 y diámetro de tubo dado en la sección 1, la pérdida de carga para producir velocidad entre las secciones 1 y 2 aumenta á medida que disminuye el área del cuello ó sección y á medida que

* El medidor Venturi, aparte de sus méritos como aparato de medida, está basado en importantes principios hidráulicos. Por esto se expone aquí su teoría con bastante extensión.

la velocidad del cuello aumenta *. En la fig. 2 se muestra el caso en que toda la carga de agua que estaba sobre el cuello ó sección estrecha se ha empleado en mantener la velocidad por el cuello.

En las figs. 1 y 2, la carga, H, invertida en el aumento de velocidad entre las secciones 1 y 2, está representada por la diferencia de nivel de las dos columnas de agua 1 y 2, ó entre los límites superiores de las dos columnas de aire correspondientes. En la fig. 2, sección 2, esta diferencia es igual á la altura vertical total de la columna de agua en la sección 1.

Si ahora, fig. 3, se reduce aún más la sección del cuello (quedando como antes las demás circunstancias), la velocidad en el cuello aumentará más aún; pues la presión *total* aprovechable para aumentar la velocidad entre las secciones 1 y 2 está formada, no solamente de la presión del *agua*, *w*, sino también en la *presión atmosférica*, representada por el área sombreada A, por encima del agua W.

En la fig. 3, toda el agua ha desaparecido del piezómetro 2, y aun una porción del líquido que representa la presión del aire ha desaparecido también, dejando

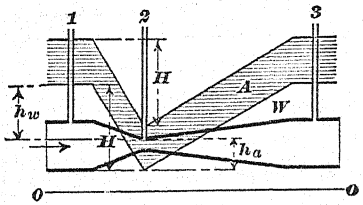

**Fig. 3.**

sólo una porción del último para representar la presión que queda en el cuello. En otras palabras, la presión dentro del cuello es ahora menor que la presión atmosférica.

En la fig. 3, la pérdida de carga, debida al aumento de velocidad entre las secciones 1 y 2, es $H=h_w+h_a$=á toda la carga de agua aprovechable, $h_w$, más una porción, $h_a$, de la presión atmosférica. La última porción, $h_a$, se llama frecuentemente « el vacío ».

Habiendo desaparecido ahora la columna de agua debajo del cuello, no se puede averiguar la pérdida de carga tomando la diferencia entre los niveles del agua en los piezómetros 1 y 2.

El grado de vacío puede encontrarse, como se indica en la fig. 4, usando, en lugar de los piezómetros, un tubo de cristal encorvado *hacia abajo*, y cuya boca

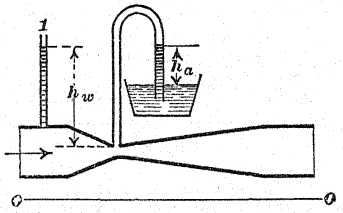

**Fig. 4.**

se introduce en una cubeta abierta que contenga agua ó mercurio. La altura á que el agua (ó el mercurio, convertido en metros de agua) sube en este tubo, da la medida del vacío, ó la porción, $h_a$, de la presión de aire que ha contribuído

* En un tubo de Venturi dado pueden también variarse la presión y la velocidad en el cuello modificando las mismas en las secciones 1 y 3; ó regulando las aberturas de las válvulas de aflujo al tubo medidor y de derrame; ó cambiando la carga total en el sistema, etc.

á producir la gran velocidad en el cuello. Añadiendo esto á $h_w$, obtenemos, como arriba, la pérdida total de carga H entre las secciones 1 y 2.

Cuando la reducción del área en el cuello ha llegado hasta el punto de que toda la presión de agua y aire disponible en la sección 1 se emplea en mantener la correspondiente velocidad en el cuello (esto es : cuando la línea superior de la superficie que representa el aire baja al nivel del borde superior del cuello), no puede conseguirse ningún otro aumento de velocidad en el cuello (con la carga total dada sobre la sección 1) estrechándolo más aún. Si el cuello se angosta más,

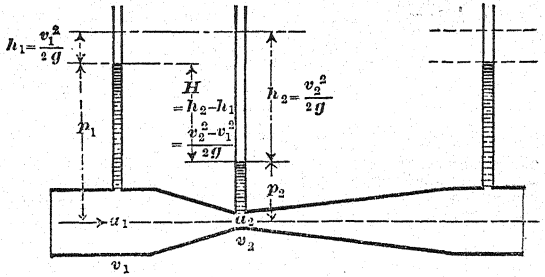

**Fig. 5.**

la velocidad en él seguirá siendo la misma, y, disminuído así el gasto, la velocidad en la sección 1 se reducirá necesariamente.

Sean $v_1$ la velocidad en la sección 1, aguas arriba del cuello, y $v_2$ la velocidad en el cuello ó sección 2.

Refiriéndonos á la fig. 5, la carga de velocidad en la sección 1, medida desde una altura ó presión supuesta representada por las líneas horizontales superiores de la figura, es :

$$h_1 = \frac{v_1^2}{2g},$$

y la de la sección 2 es

$$h_2 = \frac{v_2^2}{2g}.$$

Despreciando las resistencias á la corriente, la pérdida de carga, entre las secciones 1 y 2, es igual á la pérdida de presión, entre $a_1$, y $a_2$, ó

$$H = h_2 - h_1 = \frac{v_2^2}{2g} - \frac{v_1^2}{2g} = \frac{v_2^2 - v_1^2}{2g} = p_1 - p_2 \text{ *}.$$

En consecuencia, $$h_2 = \frac{v_2^2}{2g} = H + h_1$$

y la **velocidad en el cuello** $= v_2 = \sqrt{2g\,(H+h_1)} = \sqrt{2g\left(H + \frac{v_1^2}{2g}\right)}$.

Dicho de otro modo, la velocidad en el cuello es la correspondiente á la carga H, más la carga correspondiente á la velocidad $v_1$ en la sección 1.

Pero, puesto que las velocidades están en razón inversa de las áreas de las secciones $a_1$ y $a_2$,

$$v_1 = \frac{a_2}{a_1} v_2, \quad \text{y } v_1^2 = \frac{a_2^2}{a_1^2} v_2^2,$$

$$H = \frac{v_2^2 - v_1^2}{2g} = \frac{v_2^2 - \frac{a_2^2}{a_1^2} v_2^2}{2g} = \frac{\left(1 - \frac{a_2^2}{a_1^2}\right) v_2^2}{2g} = \frac{\frac{a_1^2 - a_2^2}{a_1^2} v_2^2}{2g}$$

* Por el teorema de Bernouilly, $p_1 + h_1 = p_2 + h_2$.

$$v_2^2 = \frac{2g\,H a_1^2}{a_1^2 - a_2^2},$$

y la velocidad en el cuello $= v_2 = \frac{a_1}{\sqrt{a_1^2 - a_2^2}}\sqrt{2gH}.$

La razón $\frac{a_2}{a_1}$,

entre el área $a_2$ de la sección transversal en el cuello, y la $a_1$, en el extremo superior del cono de aguas arriba, es llamada **razón del cuello**. Para una razón de 1 : 9 tenemos

$$\frac{a_1}{\sqrt{a_1^2 - a_2^2}} = \frac{9}{\sqrt{9^2 - 1^2}} = \frac{9}{\sqrt{80}} = \sqrt{\frac{81}{80}} = = 1.0062.$$

ó $$v_2 = 1.0062\sqrt{2gH}.$$

**El tubo de Venturi**, para tubos no mayores de 1.52 m (60 pulgs) de diámetro, se forma de varias secciones cortas de tubo de hierro fundido, que tienen la disminución requerida y están provistos de rebordes, por medio de las cuales se empatan las secciones para formar los dos conos truncados.

En los tamaños más pequeños, el cono más corto lo forma generalmente una sección y el cono más largo dos ó más secciones.

La sección del cuello se hace generalmente en una pieza separada, y ó se hace de bronce ó se forra con ese metal.

Los extremos del tubo Venturi están provistos de campana, de espita ó con extremos guarnecidos de rebordes, según el sistema de la tubería en que el tubo vaya á usarse.

**Para corrientes aún más grandes**, tales como las de conductos de mampostería ó de canales remachados, el tubo de Venturi puede hacerse de duelas de madera, láminas de acero, hormigón de cemento, ladrillos ú otro material conveniente, usándose metal para la pieza del cuello y donde lo exige la presión.

**La pieza del cuello** está rodeada por una cámara anular llamada la **cámara de presión**, que se comunica con el interior del cuello por medio de varios agujeros taladrados radialmente al través de las paredes del último á distancias iguales ó casi iguales en torno á la circunferencia.

Hay una cámara de presión semejante en el extremo más grande del cono corto para observar la presión en la sección normal aguas arriba del cuello; y, si se desea conocer la pérdida final de carga debida al paso del agua por el Venturi, debe proveerse una cámara semejante en el extremo más grande del cono más largo ó de aguas abajo.

**Al designar el tamaño** del medidor, úsase el diámetro del tubo de que él orma parte, y no el diámetro del cuello. Así, un medidor para usarlo en un tubo de 15 cm, se llama un medidor de 15 cm.

**El registro** da indicaciones periódicas, ordinariamente cada diez minutos, en las cuales la pérdida de carga $H = h_2 - h_1$, existente en el instante del registro, es anotada en pies cúbicos, litros, etc., de la descarga total desde el último registro y como un aumento en los volúmenes registrados. En otros términos, el registro supone que la velocidad media entre dos indicaciones, es igual á la velocidad en el instante de la indicación subsiguiente.

El registro puede colocarse á considerable distancia (que no exceda, digamos, de 150 m) del tubo de Venturi. Debe colocarse á tal profundidad por debajo de la línea de presión, que las presiones existentes en el tubo Venturi sean transmitidas al registro.

Las tuberías que unen el tubo de Venturi con el registro, deben estar cubiertas y el registro debe estar abrigado contra la intemperie y la helada.

El tamaño y costo del registro son independientes del tamaño del Venturi.

**Resultados.** De los experimentos hechos por el Sr. Herschel * †§, por la Oficina del Agua, Filadelfia †, y por otros †, resulta que puede contarse ordinariamente

---

* Trans. Am. Soc. Civil Engrs, nov. 1887, vol. XVII, pág. 228.

† Diario del Instituto de Franklin, feb. 1899.

§ Diario de la Asociación de las Obras Hidráulicas de Nueva Inglaterra, vol. VIII, nº 11, sept 1893.

con que el medidor Venturi da resultados dentro del 3 por cierto del verdadero gasto.

Con un Venturi de 1.22 m (48 pulgs), encontró el Sr. Herschel una **pérdida total** de carga, debida al paso del agua por el tubo Venturi, de cerca de 10.6 por ciento de la carga H en el Venturi. Con dos Venturis de 1.37 m (54 pulgs), encontraron los profesores Marx Wing y Hoskins* una pérdida de 14.9 por ciento; parte de la cual se debía, sin duda, á la presencia de una llave de válvula de 1.07 m (42 pulgs) en el cono, aguas abajo. Este último resultado añadiría cosa de .34 m á la carga necesaria para bombear diariamente 75,600 m cúb por un conducto de 1.22 m y un Venturi que tuviese una estrechez de cuello de 1 : 9.

Hase encontrado que el medidor Venturi da resultados perfectamente satisfactorios midiendo una corriente de salmuera y agua muy caliente.

Los tubos de Venturi se hacen con cuellos (sección estrecha) que varían de 1 : 4½ (6.2 : 9) á 1 : 16. Los primeros se adaptan á grandes velocidades y los últimos á pequeñas; porque, cuando la velocidad en el tubo es pequeña, es necesario aceleraría considerablemente en el cuello, á fin de obtener suficiente pérdida de presión para conseguir indicaciones precisas en el registro. Éstas no pueden obtenerse cuando la velocidad en el cuello es menor m. ó m. de 1 metro por segundo. Con una estrechez del cuello de 1 : 16, daría en dicho caso una velocidad en el tubo de 57 mm (3/16 de pie) por segundo. Por otra parte, un medidor con una fuerte estrechez de cuello, adaptada á pequeñas velocidades, excedería, con las grandes, el límite superior del registro.

Debido á su conducto sin obstrucción ni partes movibles, con el medidor Venturi hay muchas menos probabilidades de estorbar el movimiento del líquido que con las formas de medidor en uso común.

Los **precios** de los tamaños principales del medidor Venturi son como siguepuestos en los carros en Providencia, R. I.:

| | | |
|---|---|---|
| .15 m, $600.00 | .60 m, $1,130.00 | 1.22 m, $3,060.00 |
| .30 m, $770.00 | .91 m, $1,680.00 | 1.52 m, $4.890 00 |

Estos precios incluyen el registro que, en los tamaños más pequeños, constituye a parte principal del costo. Descuento, 1901, 10 por ciento.

**Art. 4 b. El medidor Ferris-Pitot**, inventado y patentado por el Sr. Wálter Ferris, de Filadelfia, sirve para medir la corriente de líquidos en tubos á caño lleno. Consiste en la invención de un aparato registrador de los resultados obtenidos por el tubo Pitot, descrito más adelante, art. 19, y de otros inventos especiales para impedir la perturbación del movimiento en los tubos y permitir su examen estando en uso.

En la fig. 6, sea P el nivel del agua en el tubo recto *s* de Pitot. Entonces $h = kv^2$, ó la diferencia de nivel entre las columnas en los dos tubos, es la carga (teóricamente $= \frac{v^2}{2g}$) debida á la velocidad del agua en el tubo á medida que ella choca

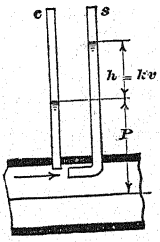

**Fig. 6.**

contra el extremo abierto aguas arriba del tubo encorvado, *s*. Para una velocidad dada, *v*, esta diferencia, *h*, es constante é independiente de la presión representada por P.

El registro Ferris, como el medidor Venturi, indica la velocidad (en el momento

* Trans. Am. Soc. Civil Engrs, vol. XL, dic. 1888, págs. 471, etc.

en que se registra) en partes del gasto total desde el último registro y como un aumento en los volúmenes registrados. El registro supone así que la velocidad media entre los valores registrados es igual á la velocidad al fin de ese período. En el medidor Ferris el registro se hace cada dos minutos.

Evidentemente el instrumento mide la velocidad en sólo un punto de la sección transversal del tubo, y así puede usarse para determinar sucesivamente las velocidades en cualquier número de puntos de dicha sección; pero la velocidad en tal punto puede ó no ser igual á la velocidad media de toda la sección transversal. El instrumento es por tanto calibrado de ordinario con referencia á alguna medida ó medidas aceptadas, y el coeficiente ó coeficientes obtenidos se usan en las observaciones subsiguientes.

El mecanismo del registro se mueve con un pequeño motor hidráulico, movido á su vez por el agua del tubo mismo. Para esto, un segundo par de tubos de Pitot se insertan en el tubo; y la corriente, fluyendo por estos tubos, pone en acción al motor sin pérdida de agua, pues ésta vuelve al tubo. Si la velocidad en el tubo es menor de 1 m por segundo, debe aumentarse por medio de un « reductor ».

Los experimentos hechos por el Sr. Ferris y por la Oficina del Agua, Filadelfia, indican que el medidor Ferris-Pitot es exacto hasta dentro de un 3 por ciento.

En general, el tamaño y costo del aparato registrador son independientes del tamaño del tubo.

**Art. 5. Resistencia de las curvas y codos en las tuberías de agua.** Mucha incertidumbre existe respecto de estos asuntos. La **fórmula * de Weisbach** para la resistencia debida á una curva circular, figs, 2 y 3, es de

$$h = C\,\frac{A}{180}\cdot\frac{v^2}{2g} = \left[.131 + 1.847\left(\frac{r}{R}\right)^7\right]\frac{A}{180}\cdot\frac{v^2}{2g}$$

$h$ = pérdida de carga para vencer la resistencia debida á la curva ó codo.
C = coeficiente experimental;
A = ángulo de flexión, en grados;
$v$ = velocidad media de la corriente en el tubo;
$g$ = aceleración de la gravedad = 9.81 m;
$\frac{v^2}{2g}$ = carga teórica para la velocidad $v$;
D = diámetro interior del tubo;
$r$ = radio interior del tubo;
R = radio del eje de la curva.

| Si $r \div R =$ | .1 | .2 | .3 | .4 | .5 | .6 | .7 | .8 | .9 | 1.0 |
|---|---|---|---|---|---|---|---|---|---|---|
| entonces C = | .131 | .138 | .158 | .206 | .294 | .440 | .661 | .977 | 1.408 | 1.978 |

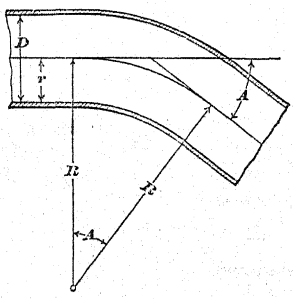

Fig. 2.

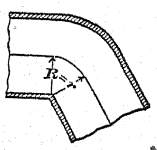

Fig. 3.

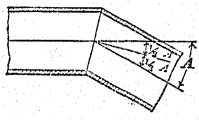

Fig. 4.

Conforme á esta fórmula, la resistencia debida á la curvatura disminuye tan rápidamente como R aumenta desde ½ D á 2 D; y sólo hay otra pequeña disminución más allá de R=5 D; pero, de experimentos muy cuidadosos en canales,

* El Ingeniero, págs. 444, 445.

desde .30 m á .75 m de diámetro, en Detroit, Mich. *, deducen los investigadores que una línea de tubos con una curva de *corto* radio R (hasta un límite de R = 2½ D) produce *menos* resistencia que una línea de igual largo é igual ángulo total A, con una curva de radio mayor que R. Sus resultados fueron aproximadamente los siguientes; donde

H = resistencia debida á una sección de 80 diámetros de largo, con una curva de A = 90° en el medio;

$h$ = resistencia en una tangente de largo = 80 diámetros.

| Si R ÷ D = | 1 | 2 | 2.5 | 3 | 4 | 5 | 10 | 15 | 20 | 25 |
|---|---|---|---|---|---|---|---|---|---|---|
| entonces H ÷ $h$ = | 1.35 | 1.14 | 1.13 | 1.14 | 1.18 | 1.24 | 1.50 | 1.66 | 1.80 | 1.93 |

Ellos encontraron también que **la pérdida de carga**, debida á una curva, ocurre **no sólo en la curva misma**, sino que se sigue perdiendo carga en la tangente que sigue por alguna distancia **aguas abajo** de la curva.

De sus experiencias se deduce que, aun muy **pequeñas flexiones**, A, en la línea, producen **importantes pérdidas de carga**, y que, por tanto, es muy recomendable tratar de colocar las tuberías rectas. Para **codos**, véase lo que sigue.

**Para ángulos**, fig. 4, da Weisbach : Pérdida de carga por resistencia =

$$h = c\frac{v^2}{2g} = (.95\ \text{sen}^2\ ½\ A + 2.05\ \text{sen}^4\ ½\ A)\frac{v^2}{2g}.$$

| Si ½ A = | 10° | 20° | 30° | 40° | 45° | 50° | 55° | 60° | 65° | 70° |
|---|---|---|---|---|---|---|---|---|---|---|
| entonces $c$ = | .03 | .14 | .36 | .74 | .98 | 1.26 | 1.56 | 1.86 | 2.16 | 2.43 |

**Además de la resistencia** opuesta á la corriente, las curvas y codos envuelven trabajos y gasto adicionales en la manufactura y en la colocación; y los codos y curvas verticales conducen á la formación de depósitos de sedimento á los pies de los declives y de cámaras de aire en sus cimas.

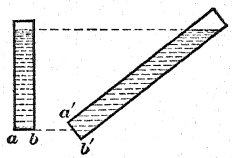

**Fig. 5.**

**Art. 6.** Aunque, en la fig. 5, las presiones estáticas sobre las bases iguales, *ab* y *a'b'*, de los dos tubos son iguales (véase Hidrostática, art. 1); con todo, para extraer agua por uno ú otro tubo, con una velocidad dada, necesítase una *fuerza adicional*, para vencer las resistencias de la corriente; y estas resistencias y la fuerza adicional requerida para vencerlas serán más grandes en el tubo más largo que en el más corto.

**Art. 7. Salida del agua por orificios.** *Teóricamente*, la velocidad con que el agua debe salir por tales aberturas es igual á la que adquiriría un cuerpo pesado que cayese libremente de una altura igual á la *carga h* ó profundidad del agua, medida *verticalmente* desde el nivel del líquido en el estanque al *centro de gravedad* de la abertura. Esta velocidad teórica se encuentra así :

$$v = \sqrt{2gh} = \sqrt{2 \times 9.81\ h}\ ;\quad h = \frac{v^2}{2 \times 9.81}\ ;$$

$g$ = á la intensidad de la pesantez = 9.81 m.

**Estas leyes se aplican igualmente á todos los fluidos.** Así, teóricamente, el mercurio, el agua, el aire, etc., todos salen con igual velocidad por un orificio dado, con una carga dada. **Para las diferencias** entre la experiencia y la teoría, véase art. 9, etc.

---

* Gardner S. Williams, Clarence W. Husbell y George H. Fenkell, Transacciones Sociedad Americana de Ingenieros Civiles, vol. XLVII, abril de 1902.

**Art. 8. Salida del agua por aberturas verticales provistas de tubos cortos.** Cuando el agua sale de un estanque, fig. 6, á través de una pared vertical *mmaa*, cuyo espesor *am* es más ó menos de 2½ á 3 veces la menor dimensión transversal de la abertura (sea esta dimensión el alto ó el ancho de la abertura), ó si la pared *nn*, es muy delgada y el agua sale por un tubo *t*, cuya longitud es 2 ó 3 veces la menor dimensión de la abertura, entonces, el agua que afluye llenará toda la abertura, ó el tubo, como se indica en la fig. 6; es decir, *correrá á caño*

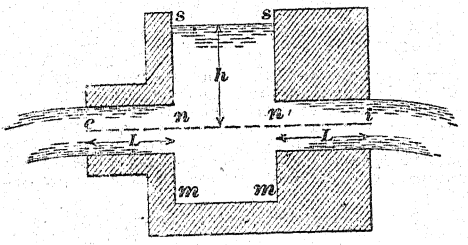

**Fig. 6.**

*lleno* y suministrará un gasto mayor; por tanto, saldrá más agua en un tiempo dado, que si fuera el tubo más largo ó más corto. Porque siendo su longitud más de tres veces la menor dimensión de la abertura, la corriente sufrirá mayor rozamiento contra las paredes del tubo; y si fuere menor que el doble de la menor dimensión transversal, más ó menos, el agua no saldrá á caño lleno, sino como vena contracta, como se ve en la fig. 11. Así sucederá ya sea la sección del tubo circular ó poligonal.

**Hallar aproximadamente la velocidad y el gasto real del agua que sale al aire libre por un tubo ó abertura, de sección circular ó poligonal, cuya longitud *n' i* ó *n e* en la dirección de la corriente sea más ó menos 2½ á 3 veces su menor dimensión transversal, cuando el nivel de la superficie *s*, fig. 6, es constante y de una altura mayor ó igual á la del borde superior del tubo ó abertura.**

*Regla* 1. Tómese la velocidad teórica por la fórmula del art. 7 correspondiente á la carga medida *verticalmente* desde el centro *e* (ó más exactamente desde el centro de gravedad) del orificio hasta el nivel de la superficie *s*. Multiplíquese por el coeficiente del gasto .81. El producto será la velocidad buscada por segundo. Multiplíquese esta velocidad real por la sección transversal del orificio. Si el orificio es circular y se conoce su diámetro $=d$, el área será $\frac{1}{4}\pi d^2 = .7854\ d^2$. El producto será el gasto ó cantidad de agua que sale por segundo con una aproximación de 3 á 4 por ciento.

*Regla* 2. Búsquese la raíz cuadrada de la carga (Tablas págs. 57 á 64) en metros y multiplíquese por 3.586. El producto es la velocidad real por segundo.

Ej.: Sea una abertura *n e* ó tubo en forma de cajón *ct*, fig. 6, de 1 metro de ancho por .25 m de alto y su longitud en la dirección de *n' i* ó *n e* de la corriente del agua de .62 m ó más ó menos 2½ veces su menor dimensión transversal ó su altura. La carga, desde el centro de gravedad *e* de la abertura al nivel constante *s*, de 2 metros. ¿Cuál será la velocidad del agua y cuál su gasto?

*Por la Regla* 1. La velocidad teórica que corresponde á una carga de 2 metros es de $\sqrt{2\times 9.81\times 2} = 6.26$ m por segundo, y $6.26\times .81 = 5.070$ m por segundo será la velocidad real buscada. El área transversal de la abertura ó del tubo, es $1\times .25 = .25$ m cuad y $.25\times 5.07 = 1.268$ metros cúbicos, el gasto ó cantidad que sale por segundo.

*Por la Regla* 2. La raíz cuadrada de 2 es 1.4142 y $1.4142\times 3.586 = 5.071$ por segundo, velocidad buscada como antes.

*Nota* 1. **Si el tubo corto, *n e*, sobresale en parte hacia el interior de la pared vertical, *s m*,** el gasto disminuirá más ó menos en $\frac{1}{8}$ parte. En este caso, úsese .71 ó .7 en lugar de .81 (*Regla* 1), y el coeficiente 3.15 en lugar de 3.586 de la *Regla* 2.

*Nota* 2. Cuando el espesor L de la pared vertical, ó el largo *n e* del tubo, fig. 6, llega á ser 4 veces más ó menos la menor dimensión transversal de la abertura, ó del diámetro, si fuere circular, entonces el rozamiento adicional contra sus paredes principia á disminuir apreciablemente la velocidad y el gasto. En este caso, y para longitudes mayores todavía, hasta 100 diámetros, puede encontrarse aproximadamente usando en lugar del coeficiente .81 de la *Regla* 1, los coeficientes que siguen, por los cuales deben multiplicarse las velocidades teóricas.

**TABLA 11.**

| Longitud del tubo en diám. | Coeficientes. | Longitud del tubo en diám. | Coeficientes. |
|---|---|---|---|
| 4 | .80 | 40 | .62 |
| 6 | .76 | 50 | .60 |
| 10 | .74 | 60 | .57 |
| 15 | .71 | 70 | .55 |
| 20 | .69 | 80 | .52 |
| 25 | .67 | 90 | .50 |
| 30 | .65 | 100 | .48 |

(*Obs. del T.* — Esta tabla se aplica cualquiera que sea la unidad que se use : el pie, el metro, etc.)

*Nota* 3. — Cuando el largo de la abertura ó del tubo, en la dirección de la corriente del agua, se hace, más ó menos, *menor* de dos veces su menor dimensión transversal, el gasto disminuye; de manera que para longitudes desde 1½ veces ó menores hasta aberturas en paredes muy delgadas, podemos usar .61 en lugar de .81 de la *Regla* 1. Para estas aberturas véanse los arts. 9 y 10.

*Nota* 4. Pero, por otra parte, el gasto de los tubos y aberturas tan cortas como la de la fig. 6, puede aumentarse hasta llegar casi á las teóricas $(\sqrt{2gh})$ con sólo redondear bien los bordes del orificio de entrada ó boca, como en la fig. 7, que es de la misma forma y tiene la mitad del tamaño real de una con que Weisbach obtuvo .975 de la velocidad y gasto teóricos, con una carga de 3.05 m, y .958 con una carga de .305 m; de modo que en casos semejantes puede usarse .975 y .958 en lugar del coeficiente .81.

Puede obtenerse de .92 á .94 ensanchado la abertura *nm* hacia la boca exterior *os*, fig. 8, dando al ángulo *a* más ó menos 5° ó haciendo el ensanche hacia su boca interior, como en *tc*, fig. 9, pero aumentando el ángulo de divergencia del *b* de 11° á 16°. En todos los casos consideramos el extremo pequeño como la abertura, cuya área debe multiplicarse por la velocidad para hallar el gasto.

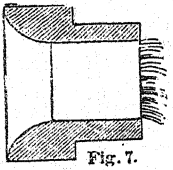

Fig. 7.

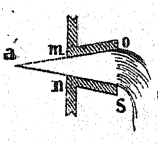

Fig. 8.

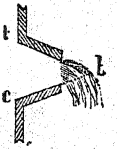

Fig. 9.

**En algunos experimentos hechos con canales piramidales de madera** de 2.90 m de largo con una boca interior de .97 m×.73 m., y una de salida de .19 m×.13 m con una carga de 2.90 m, se encontró un gasto de .98 m del gasto teórico, debido á que era más pequeña la boca; por lo tanto puede usarse .98 en semejantes casos en lugar de .81 de la *Regla* 1.

*Nota* 5. Usando un regulador de salida de la forma de la fig. 10, el gasto puede aumentarse y llegar á ser mayor que el correspondiente á la carga sobre el *centro de gravedad s* del orificio *mn*, porque en estos casos, como se dijo en el art. 1 *w* de Hidráulica, la carga *verdadera* en *s*, ó sea la carga que causa la salida rápide por la parte más angosta *mn*, puede ser mucho mayor que la carga sobre *s*. Véasa el medidor Venturi, art. 4 *a*.

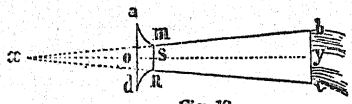

Fig. 10.

**Art. 9. Gasto por aberturas practicadas en paredes verticales delgadas de caras planas** *ee* ó *nn*, fig. 11 *. Si la cara *ee* ó *nn*, en lugar de ser plana y vertical, fuere curva ó inclinada en diferentes direcciones, hacia la abertura, el gasto se alterará. Cuando el agua sale de un estanque, fig. 11, por una pared vertical plana *nn*, cuyo espesor no sea mayor que la menor dimensión transversal de su abertura, más ó menos, ya sea esta dimensión el ancho de ella ó su altura *oo* †, ó cuando siendo la pared *ee* mucho más gruesa, damos á la abertura la forma que se ve en *b* (lo que viene á ser lo mismo); entonces la vena líquida afluente no saldrá cilíndrica ó á *caño lleno* como en la fig. 6, sino que tomará la forma de la fig. 11, formando muy cerca de la parte exterior de la abertura lo que se llama la *sección contracta*. Para que esta contracción sea *completa* ó llegue á su máximum, el borde interior del orificio no debe hallarse de la superficie del agua, del fondo ni de las paredes del estanque, á menos de 1½ veces la más pequeña dimensión transversal de la abertura. La vena se contrae á una dist del orificio igual á la mitad, más ó menos, de su menor dimensión. En un orificio circular, dicha contracción tiene efecto á una dist de medio diám más ó menos, y de ordinario, el área de la sección contracta es de .62 ó cerca de $^{2}/_{3}$ de la del orificio. En este punto la velocidad media *verdadera* de la vena líquida es muy aproximadamente .97 de la velocidad teórica dada por la fórmula $\sqrt{2gh}$. *El gasto* efectivo no es sino .62 ó casi $^{2}/_{3}$ del gasto teórico.

*Caso* 1. **Hallar el gasto efectivo cuando el agua sale al aire ‡ libre, por una abertura de sección circular ó poligonal § practicada en una pared delgada vertical, cuando la contracción es completa y cuando el nivel de la superficie *s* se conserva constantemente á la misma altura entrándole agua al estanque en igual cantidad á la que sale.**

*Regla* 1. Cuando la carga medida verticalmente desde el centro *c* (ó más bien desde el centro de gravedad) de la abertura, al nivel de la superficie *s*, no es menor de .30 m ni mayor de 3 m; y cuando la menor dimensión transversal de la abertura no es menor de .025 m, multiplíquese la velocidad teórica $\sqrt{2gh}$ por el coeficiente de gasto .62. El producto será la velocidad media verdadera del agua

* Creemos que estas Reglas son bastante aproximadas en casi todos los casos prácticos, para paredes delgadas, si la abertura está en el *fondo* del estanque, ó en una cara *inclinada* en lugar de una *vertical*.

† Cuando el lado del estanque, ó la arista del tablón, etc., por donde fluye el agua no tiene mayor espesor que ésta, se dice que el agua sale por *pared delgada*.

‡ Si la salida tiene lugar por *debajo del agua* como en la fig. 12, *permaneciendo constantes ambas superficies*, entonces la carga que debe usarse es la diferencia *vertical*

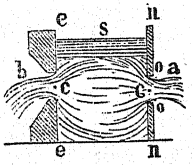

Fig. 11.

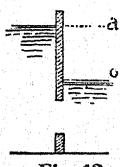

Fig. 12.

*ao* de los dos niveles. Después de hacer el cálculo con esta carga, debemos, según Weisbach, deducir 1/75; porque él dice que el gasto es menor en esta cantidad cuando la salida se efectúa por debajo del agua (á caño ahogado) que cuando tiene efecto al aire libre. Sin embargo, otros experimentadores afirman que el gasto es exactamente igual en ambos casos.

§ Si la forma del orificio es ovalada, triangular ó irregular, la carga debe medirse verticalmente sobre su centro de gravedad.

en la abertura. Multiplíquese esta velocidad por el área de la abertura, y el producto será el gasto por segundo aproximadamente.

Cuando la carga es mayor de 3 m, úsese .60 en lugar de .62.

*Regla* 2. Búsquese la raíz cuadrada de la carga en metros y multiplíquese por 2.75; el producto será la velocidad verdadera en metros por segundo, la cual multiplicada por el área como antes, dará el gasto.

(*Obs. del T.* — Comparados los resultados con estos diversos coeficientes, pueden resultar diferencias por razón de las decimales que se aprecien, pero serán insignificantes.)

Ej.: ¿Cuál será el gasto por una abertura con contracción completa, cuyas dimensiones sean .15 m verticalmente y 1.22 m horizontalmente, y la carga vertical sobre el centro de gravedad de la abertura de 1.83 m?

*Por la Regla* 1. Empleando el metro, tenemos:

$$\text{Velocidad verdadera} = .62\sqrt{2gh} = .62\sqrt{2\times 9.81\times 1.83} = .62\times 4.43\times 1.35 = 3.71 \text{ m.}$$

El área de la abertura es

$$= .15\times 1.22 = .183, \text{ y } 3.71\times .183 = .679 \text{ m}^3, \text{ ó sean 679 litros por segundo.}$$

*Por la Regla* 2. La raíz cuad de 1.83 es=1.35 y $1.35\times 2.75 = 3.71$ m velocidad verdadera como antes, la cual multiplicada por el área dará el gasto. Ambos muy aproximados aun cuando el orificio llegue hasta la superficie del agua que sale.

*Nota* 1. **El coeficiente .62 es el término medio** de los resultados de muchos experimentadores antiguos. En 1874, el general T. G. Ellis, de Massachusetts, dirigió una serie de experimentos (Trans. Am. Soc. C. E., Feb. 1876) en grande escala, cuyos resultados generales, con menos de 1% de diferencia, se dan en la tabla siguiente. Véase también la *Nota* 3. Los orificios de arista viva se hicieron en plancha de hierro de 6 á 12 milímetros de espesor.

| Orificios. | Cargas sobre el centro. | Coeficientes. |
|---|---|---|
| .609 × .609 m | .609 m á 1.067 m | de .60 á .61 |
| .609 × .305 » | .549 » 3.444 » | » .60 » .61 |
| .609 × .152 » | .427 » 5.182 » | » .61 » .60 |
| .609 m de diámetro. | .549 » 2.926 » | » .59 » .61 |

*Nota* 2. Se requiere **un cuidado extremo** para obtener resultados exactos; pero para muchas aplicaciones de ingeniería es de poca importancia un error de 5 á 10%.

Raras veces habrá necesidad de una exactitud mayor que la que se obtenga por las reglas precedentes; pero cuando esto ocurra, servirá de auxiliar la **tabla siguiente, deducida de los experimentos de Lesbros y Poncelet**, en orificios de 8 pulgadas (203 mm) de ancho, de diferentes alturas y con cargas diferentes. Usese el coeficiente de la tabla que venga al caso en lugar del .62 de la *Regla* 1. En algunos casos de esta tabla la arista superior del orificio dista menos de 1½ veces su menor dimensión transversal, del nivel de la superficie del estanque.

**TABLA 12. Coeficientes para aberturas rectangulares practicadas en paredes delgadas verticales con contracción completa.**

El ancho en todas las aberturas es=8 pulgs=.203 m.

| Carga sobre el centro de gravedad de la abertura en metros. | Carga sobre el centro de gravedad de la abertura en pies. | Altura de la abertura. | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | Metros .203 Pulg. 8 | Metros .152 Pulg. 6 | Metros .102 Pulg. 4 | Metros .076 Pulg. 3 | Metros .051 Pulg. 2 | Metros .025 Pulg. 1 | Metros .010 Pulg. .4 |

| 3.048 | 10 | .60 | .60 | .60 | .60 | .60 | .61 | .61 |

*Nota* 3. **Experimentos hechos cuidadosamente con aberturas de 1.30 m de ancho y 0.46 m de altura**, bajo cargas de 1.83 á 4.57 m muestran que el coeficiente .62 da resultados exactos con $^1/_{30}$ de aproximación para aberturas también del mismo tamaño, bajo grandes cargas; aunque el espesor de la pared varíe en sus diferentes lados de .30 m á .51 m. Debe tenerse, sin embargo, en cuenta que en esta materia sólo puede llegarse á resultados *muy aproximados*.

*Nota* 4. Algunos escritores aseguran que **cuando el agua sale por dos ó más aberturas** *contiguas* al mismo tiempo y del mismo estanque, sale en proporción menos agua por ellas que cuando el agua sale por una sola abertura de las existentes. Sin embargo, otros experimentos demuestran que esto no es así, y es muy probable que la diferencia, si existe, sea de poca importancia.

*Caso* 2. **Salida del agua á través de paredes verticales, delgadas, con contracción completa, cuando el nivel de la superficie, *m*, fig. 13, desciende á medida que el agua sale al aire.** En este caso, si el estanque es prismático, es decir, si sus secciones horizontales son iguales en toda su altura, y si no entra agua al estanque para reponer la que sale, entonces, para hallar el tiempo en que se vacía, se observará la siguiente

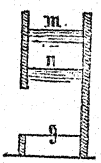

Fig. 13.

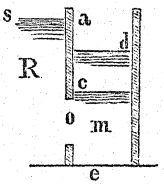

Fig. 14.

*Regla.*—Como el tiempo que se requiere para que este estanque se vacíe es doble del que se necesita para que salga igual cantidad de agua, bajo una carga constante (como en el caso 1), calcúlese el gasto por segundo, por la *Regla* 1, art. 9, divídase el número de metros cúbicos contenidos en el estanque desde el nivel *g*

de la parte inferior de la abertura hacia arriba, fig. 13, por este gasto; y el cociente dará el número de segundos en que saldría del estanque hasta la profundidad $g$, un volumen igual de agua al calculado en el caso 1, *con una carga constante;* y *el doble* de este número de segundos será el tiempo que se necesita para vaciar dicho estanque en el caso 2, con una *carga variable.*

*Nota.* Si fuere necesario buscar el tiempo durante el cual dicho estanque prismático se vacía *parcialmente*, como por ejemplo de $m$ á $n$, fig. 13, entonces calcúlese primeramente por la regla anterior, el número de segundos necesario para vaciarlo en el caso en que sólo estuviese lleno hasta $n$, y en seguida calcúlese como si lo estuviera hasta $m$. La diferencia entre los dos números de segundos es evidentemente el tiempo que se requiere para vaciarlo de $m$ á $n$. Si la abertura no produce una contracción completa, véase el art. 11, etc.

**Si el agua se vacía en un estanque más bajo, cuyo nivel sea constante,** procédase de la misma manera; sólo que se tomará como carga la diferencia de nivel de las dos superficies, y después (según Weisbach) se aumentará el tiempo en $^1/_{27}$.

**Art. 10. Salida del agua de un estanque, B, fig. 14, de nivel constante, $s$, á un estanque prismático, $m$, por una abertura, $o$, practicada en pared delgada, con contracción completa y situada enteramente debajo del agua.** (Medidas en m.)

**Número de segundos requeridos** para verter una cantidad = *cda* permaneciendo el nivel $c$ constante.

$$= \frac{\text{área horizontal del envase } m \times \sqrt{\text{altura } ac}}{\text{área de la abertura } o \times .62 \times 4.43.}$$

**Número de segundos requeridos para** elevar el nivel del envase $m$ de $c$ á $a$.

$$= \frac{\text{área horizontal del envase } m \times 2 \times \sqrt{\text{altura } ac}}{\text{área de la abertura } o \times .62 \times 4.43.}$$

**Número de segundos requeridos para** elevar el nivel del envase $m$ de $c$ á cualquier otro nivel $d$.

$$= \frac{\text{área horizontal del envase } m \times 2 \times (\sqrt{ac} - \sqrt{ad})}{\text{área de la abertura } o \times .62 \times 4.43.}$$

*Nota* 1. **Si se busca el tiempo necesario para llenar el envase $m$ desde su fondo $e$ hasta** $d$, podemos obtenerlo muy aproximadamente calculando, por la primera regla del art. 9, el tiempo gastado de $e$ hasta el centro del orificio $o$, como si la salida del agua en esta porción tuviera lugar al aire libre, y luego desde el centro del orificio hasta $d$, por la regla que acabamos de dar. Este caso es análogo al de llenar una esclusa desde la parte superior del canal en el que se considera constante el nivel del agua.

*Nota* 2. **Si la parte inferior de la abertura $o$ coincidiese con el fondo del estanque,** entonces el coeficiente se hará mayor que .62. Véase art. 11, que trata de coeficientes para contracciones imperfectas.

*Nota* 3. **Si la abertura en lugar de ser de contracción completa,** tiene una de las formas de las figuras 6 á 9, entonces el art. 8 indicará cuál coeficiente debe usarse en lugar de .62.

*Caso* 3. **Salida del agua de un receptáculo prismático, W, fig. 15, á otro X, de cualquier tamaño, cuando el agua asciende en X, al**

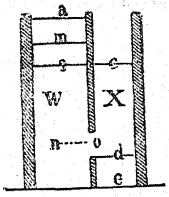

Fig. 15.

**bajar en W, efectuándose la salida por una abertura $o$ practicada en una pared plana, delgada y vertical y con contracción completa.**

*Hallar el tiempo durante el cual el agua, pasando de* W *á* X *por la abertura o desciende la distancia* a s, *hasta situarse al mismo nivel* s c, *en ambos estanques.* El agua requerida para llenar el envase X de *e á d* (siendo *d* el fondo de la abertura *o*) efectúa su salida al aire libre, y el tiempo que se requiere para ello debe calcularse aparte del que se necesita para llenar la porción del envase de *d* hacia arriba; pues en esta parte la salida se efectúa por debajo del agua.

*Regla.* Estudiemos primeramente de *e á d*: Búsquese el área horizontal de cada uno de los envases ó estanques en m cuad; multiplíquese el área horizontal de X por la altura vertical *d e* en m para obtener el número de m cúb contenidos en aquella porción; divídase este número de m cúb por el área ó sección horizontal de W. El cociente será la dist *am* en m que debe descender el agua en W para llenar á X hasta el punto *d*.

**Número de segundos que se requieren** para descender de *a á m* y por tanto para ascender de *e á d*.

$$= \frac{\text{Doble del área horizontal del envase W} \times \left(\sqrt{\text{carga } an} - \sqrt{\text{carga } mn}\right)}{\text{Area de la abertura} \times .62 \times \sqrt{2g}}$$

**Número de segundos que se requieren** para descender de *m á s* y para ascender de *d á c*. (Muy aproximadamente.)

$$= \frac{\text{Area horizontal del envase X} \times \text{doble del área horizontal del envase W} \times \sqrt{\text{carga } mn}}{\text{Area de la abertura } o \times \left(\begin{matrix}\text{área horizontal} \\ \text{de W}\end{matrix} + \begin{matrix}\text{área horizontal} \\ \text{de X}\end{matrix}\right) \times .62 \times \sqrt{2g}}$$

(*Obs. del T.* — Estas fórmulas se usan indiferentemente en pies ó en metros. Cuando se usan en pies, $g = 32.2$; y cuando se usan metros, $g = 9.81$.)

Ej.: Supongamos el área de W = 100 pies cuad = 9.29 m cuad; la de X = 60 pies cuad = 5.574 m cuad; *an* = 20 pies = 6.096 m; *mn* 16 pies = 4.88 m; y el área de la abertura, *o* = 3 pies cuad = .279 m cuad. ¿En cuánto tiempo descenderá el agua de *a á s* y ascenderá de *e á c*? Por cuanto el método para hallar el tiempo que se gasta en llenarse de *e á d* con el agua que cae de *a á m* no requiere más explicación, nos limitaremos al tiempo *adicional* que se necesita para llenar dicho envase de *d á c* con el agua que cae de *m á s*. Para lo cual tenemos: raíz cuad de la carga *mn* = 4 pies; y la suma de las dos áreas = 100 + 60 = 160. Además, con *g*, en pies, $\sqrt{2g} = 8.03$; y con *g*, en metros, $\sqrt{2g} = 4.43$. Usando la fórmula, nos da: $\frac{60 \times 200 \times 4}{3(100 + 60) \times .62 \times 8.03} = \frac{48000}{2389.73} = 20.1$ seg, tiempo adicional requerido, muy aproximadamente.

Aplicando el mismo ejemplo en sistema métrico, tenemos:

$$\sqrt{mn} = \sqrt{4.88} = 2.2091 \text{ m};$$

suma de las dos áreas = 9.29 + 5.574 = 14.864. Luego obtendremos

$$\frac{5.574 \times 2 \times 9.29 \times 2.2091}{.279 \times 14.864 \times .62 \times 4.43} = 20.09 \text{ segundos.}$$

Como antes, con una pequeña dif debida á las decimales que no se han apreciado.

*Advertencia* 1. **Cuando la abertura *d*, fig. 16, llega hasta el fondo del estanque,** podemos considerar toda el agua que pasa de R á T como efectuando su salida dentro del agua. Por lo tanto, al usar la carga *am*, calculamos desde luego el tiempo necesario para que el agua de los dos estanques llegue al

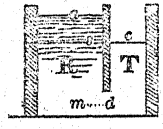

Fig. 16

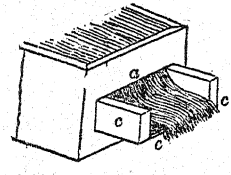

Fig. 17.

mismo nivel *sc* por el procedimiento seguido en el ejemplo precedente. Pero en este caso debe tenerse presente que la abertura *d* ya no dará contracción *completa*

puesto que está suprimida la contracción á lo largo de su borde inferior. El gasto aumentará algo y, de consiguiente, debe emplearse un coeficiente mayor de .62. El método para hallar éste se da en el siguiente caso 4. En el art. 8 se da el coeficiente en el caso de que la abertura tenga una de las formas de las figs. 6 á 9.

**Art. 11**, *Caso* 4. **Salida del agua por aberturas hechas en paredes delgadas, planas y verticales, pero con contracción incompleta.** La abertura puede ser tal, que la contracción tenga lugar en una porción de su perímetro ó en la parte superior de la abertura *a*, fig. 17, donde, por ejemplo, está suprimida en el fondo y las dos caras de dicha abertura *a*, por la adición de piezas *cortas* en el fondo y costados *c*, *c*, *c* del orificio. En estos casos el gasto será mayor que en los de contracción completa, pero menor que en los que el agua sale á caño lleno, puesto que la abertura se asemeja ahora en parte á los tubos *cortos* del art. 8; y el coeficiente subirá de .62 ó del que *generalmente* corresponda á las aberturas de contracción completa, acercándose á .8 ó al que corresponde á caño lleno, según sea la extensión del perímetro en que se ha suprimido la contracción; ó aun á .9 ó .98 usando las aberturas que se indican en las figs. 7, 8, 9.

**Hallar aproximadamente un coeficiente nuevo de gasto; y el gasto mismo en casos de contracción incompleta.**

*Regla.* Primero : búsquese por las reglas anteriores cuál sería el gasto en el caso particular que se considera, suponiendo que la contracción fuese completa. Entonces divídase la parte del perímetro de la abertura en que está suprimida la contracción por el perímetro total. Multipliquese el cociente por la decimal .152 si la abertura es rectangular, ó por .128 si es circular. Al producto agréguese la unidad. Llámese la suma *g*. Entonces dígase : la unidad : *g* :: el coeficiente para la contracción completa en los casos ordinarios (generalmente .62) : al coeficiente nuevo que se busca. Finalmente, repítase el cálculo primitivo, sustituyendo solamente este coeficiente nueve en lugar de .62.

Según esta regla, tenemos los coeficientes de gasto siguientes para aberturas rectangulares, con una aproximación de 3 ó 4 por ciento, cuando la contracción no está suprimida en más de $^{7}/_{8}$ del perímetro. El gasto teórico multiplicado por el coeficiente correspondiente, dará el gasto real. Cuando la contracción aumenta, el coeficiente se hace extremadamente irregular, y probablemente es indeterminable.

| | | | | |
|---|---|---|---|---|
| *Para contracciones completas (generalmente)* | | | | .62 |
| *Cuando la contracción está suprimida en un* | | | $^{1}/_{4}$ *del perímetro* | .64 |
| — | — | — | $^{1}/_{2}$ — | .67 |
| — | — | — | $^{3}/_{4}$ — | .69 |
| — | — | — | *enteramente alrededor de la abertura* | .80 |

Los coeficientes intermedios pueden calcularse con suficiente exactitud por una simple proporción.

*Nota* 1. **Cuando, en lugar de un vertedero corto como el de la fig. 17, la abertura está provista de un canal horizontal de un largo indefinido,** adherido de un modo semejante y abierto en su parte superior, no habrá prácticamente disminución sensible del gasto, comparado con el que suministra la abertura sencilla *a*, fig. 11, con tal que la carga medida por sobre el centro de gravedad de la abertura sea por lo menos de 2 á 2½ veces la altura de la abertura misma. Por lo tanto, en tales circunstancias debe calcularse el gasto por la regla del art. 9. Pero con cargas menores el gasto disminuye considerablemente; de tal manera que cuando la carga sobre el centro es sólo de la altura de la abertura, el gasto no será sino $^{1}/_{2}$ del calculado. Con carga más pequeñas aún, la salida se hace menor, mucho más rápidamente. Para este caso no se ha establecido todavía ninguna regla.

*Nota* 2. **Si en lugar de ser horizontal el canal, es inclinado como de 1 en 10,** el gasto *aumentará* muy poco (como 3 ó 4 por ciento) sobre el calculado por las reglas del art. 9, para una abertura ordinaria. Estos resultados se han obtenido por experimentos en muy pequeña escala y deben considerarse como meras aproximaciones.

**Art. 12. En casos semejantes al de la fig. 18, en el cual se supone suprimida la contracción en el fondo y en los lados verticales de la abertura** *o*, por su coincidencia con el fondo y los lados del depósito, pero en que el frente del depósito en lugar de ser vertical está inclinado como en *f*, y cuando el agua después de haber pasado la abertura fluye por sobre un canal *g*, ligeramente inclinado hacia abajo, entonces el gasto puede hallarse aproximadamente por la *Regla* 1, caso 1, art. 9, sustituyendo solamente .8 en lugar de .62

cuando *f* tenga una inclinación hacia atrás de 45° ó de 1 en 1; se tomará el coeficiente .74 si *f* está inclinado hacia atrás 63°, ó, lo que es lo mismo, para *uno* de base y *dos* de altura. En estos casos de frentes inclinados, la altura de la abertura debe medirse *verticalmente ó, más bien, en ángulo recto al piso del depósito*, y no en la línea inclinada del frente.

*Nota.* **Cuando el frente *f* del estanque es vertical, y se aplica una prolongación ó canal *g* inclinada**, con su cara superior al nivel del fondo de la abertura, el gasto no disminuye en cosa apreciable, comparado con el que se obtiene libremente al aire, con tal que la carga sobre el centro de gravedad de la abertura no sea menor

| | | | |
|---|---|---|---|
| de 46 á 60 cm | para una abertura de | 10 á 23 cm de altura; |
| de 30 á 40 | — | — | 10 cm de altura; |
| de 23 | — | — | 5 ó menos de altura. |

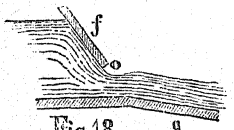

Fig 18

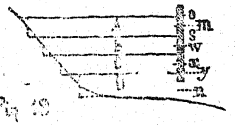

Fig 19

**Art. 13. Hallar aproximadamente el tiempo necesario para vaciar un pozo ó cualquier otro estanque como el de la fig. 19, cuya forma no sea prismática, por una abertura *n* practicada cerca del fondo.**

*Regla.* Fijemos primeramente la forma y dimensiones exactas del estanque. Si es grande y de forma irregular, debe medirse con cuidado, sondearse y hacerse un plano de él y secciones transversales exactas. Luego considérese dividido todo el volumen de agua en capas horizontales delgadas A, B, C, D, situando la parte superior de la capa más baja D, por lo menos algunos cm sobre la parte superior de la abertura *n*. No es necesario que estas capas sean del mismo espesor; sin embargo, mientras más delgadas sean, más exacto será el resultado.

El espesor de la capa más baja D, depende de la altura de la abertura; las de arriba próximas á ésta, no deben tener más de 30 cm de espesor hasta una altura de 1.80 m ó 2.40 m; entonces se puede aumentar convenientemente y con suficiente exactitud hasta 60 cm más ó menos durante otro espacio de 1.80 m ó 2.40 m; y así sucesivamente, dándoles á las capas más espesor á proporción que se aproximan más á la superficie del agua. Con la ayuda de los planos calcúlese el volumen de cada capa. Ahora bien: como las capas son delgadas, podemos, sin error sensible, suponer que todas ellas son prismáticas, como lo indican en las figuras las líneas de puntos; y podemos también suponer que la carga, bajo la cual cada una de las capas (con excepción de la última ó más baja) fluye por *n*, es igual á la altura vertical medida desde el centro de la abertura hasta el centro de la capa de agua. De este modo *mn* será la carga de A; *wn*, la de B; *xn*, la de C. Entonces, respecto de la capa A, por la *Regla* 1. art. 9 (tomando solamente á *mn* como carga en lugar de *on*), y en lugar del coeficiente .62 de aquella regla (que solamente puede usarse si *n* es de contracción completa), tómese .64 ó cualquier otro coeficiente que pueda aplicarse según el final del art. 11, y calcúlese el gasto por segundo. Divídase el volumen de la capa A por este gasto, y el cociente dará el número de segundos que se necesita para vaciar á A. Tomando la carga *wn*, procédase exactamente lo mismo con la capa B; y tomando la carga *xn*, hágase lo mismo con C. Finalmente, para la capa más baja D, búsquese por la *Regla* 1, del art. 9 (con la misma precaución que antes respecto al coeficiente adecuado), en cuánto tiempo se vaciaría bajo una carga *constante* igual á *yn* medida desde su *superficie* al centro de la abertura. El *doble* de este tiempo será el que se necesita para vaciarse en el caso presente, bajo su carga *variable*. Por último, súmense todos estos tiempos: y la suma total será el tiempo que se necesita para vaciar el estanque ó pozo con suficiente aproximación en la práctica.

**Art. 14.** (*a*) **Salida del agua por vertederos.** El vertedero proporciona un medio muy conveniente para el aforo de pequeños arroyos, como cuando se quiere calcular la cantidad de agua que se suministra á las ruedas hidráulicas, etc.

(*b*) Un dique de aforo ó vertedero está siempre dispuesto de manera que su cara interior *ab*, ó sea la situada aguas arriba, fig. 20, sea vertical, y tan próximamente como se pueda en ángulo recto á la dirección de la corriente. Las

caras *ah*, *ah*, figs. 21 y 22, son verticales, y el borde ó arista *aa*, horizontal. (Véase más adelante « Ranuras ó Muescas triangulares », art. 15, pág. 598.)

(*c*) **Contracciones en los extremos del vertedero.** Cuando el vertedero *aa* ocupa transversalmente todo el canal de entrada, como en la fig. 21, de manera que sus caras extremas *ah*, *ah*, coincidan con los costados *ss* del canal ó formen parte de él, la contracción, art. 9, tiene efecto solamente en la parte *superior* é *inferior* de la lámina de agua que pasa por el vertedero, como en *mc* y en *a*, fig. 20, y está del todo « suprimida » en los *extremos*, de manera que la salida del agua se hace como lo indica la fig. 21 *a*.

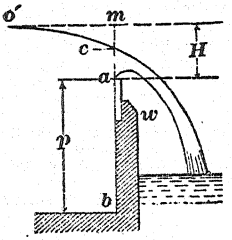

Fig. 20.

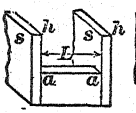

Fig. 21.

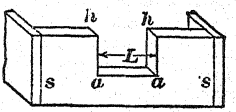

Fig. 22

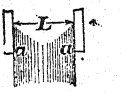

Fig. 21 *a*.

Fig. 22 *a*.

Esta clase de vertederos se llaman **vertederos sin contracciones extremas.** Pero como cuando en las figs. 22 y 22 *a*, las caras extremas *ah*, *ah* se hallan distantes de los costados *ss* del canal ó del estanque, también hay contracciones en los *extremos*, como se ve en *a* y *a*, así como sobre la arista. Tales contracciones disminuyen el gasto. Esta especie de vertederos se llaman **vertederos con contracciones extremas.** En igualdad de circunstancias, la magnitud de la contracción y su efecto sobre el gasto aumenta con la carga H.

Cuando el largo *aa* ó L del vertedero es mayor de 10 veces la carga H, el efecto de las contracciones en las extremidades, sobre el gasto, es casi imperceptible; pero á medida que el largo disminuye en relación á la carga, el efecto de la contracción aumenta rápidamente. Francis (art. 14 *m*) halló que cuando L era solamente $=4\times H$, el gasto se reducía un 6 por ciento, por la contracción completa de las extremidades. En vista de la incertidumbre de los efectos producidos por la contracción de las extremidades, es mejor evitarlas y usar vertederos como los de la fig. 21, donde la contracción está suprimida; pero si se admite la contracción en las extremidades, debe hacerse *completa* *, porque los coeficientes dados no sirven para **contracciones incompletas**, es decir, con contracciones sólo parcialmente suprimidas.

(*d*) **En un vertedero sin contracción en las extremidades**, debe tenerse cuidado de que *el aire tenga acceso libre* al espacio (*w*, fig. 20 ó 22 *b*) por

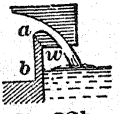

Fig.22b

detrás de la caída formada por la lámina de agua, de lo contrario se formaría allí un vacío parcial y la lámina de agua sería atraída hacia el vertedero, modificándose el gasto notablemente. Al mismo tiempo debe evitarse que la lámina de agua se *esparza lateralmente* cuando abandona el borde del vertedero. Ambos objetos pueden lograrse prolongándose un poco la *parte superior solamente* de los dos costados del canal aguas abajo, más allá del borde ó arista y de la parte

* La contracción se dice que es « completa » cuando es prácticamente tan grande como puede hacerse por un aumento cualquiera ulterior de la dist *as*, figs. 22 y 22 *a*, y se cree que éste se obtiene cuando se hace *as* igual á la carga H.

superior de la caída formada por la lámina de agua, como en la fig. 22 *b*. Francis encontró que estas prolongaciones, limitando lateralmente la lámina de agua, disminuían el gasto en .4 por ciento.

(*e*) Ordinariamente el **copete** del vertedero es en « pared delgada » (véase nota †, pág. 576), de modo que la lámina de agua que pasa por sobre el vertedero, lo toca solamente en la propia arista ó ángulo *a*, fig. 20. Un ángulo ó borde *redondeado* aumenta el gasto, del mismo modo que los bordes redondeados de un orificio (art. 8), y un copete ó borde suficientemente ancho para desviar la caída de la lámina de agua, disminuye el gasto (véanse los coeficientes para este caso en la tabla 15, pág. 592); pero ambas formas producen mucha incertidumbre y deben por lo tanto evitarse.

(*f*) **La longitud L del copete ó cresta**, figs. 21 y 22 *a*, debe ser por lo menos el triple de la carga H, con el fin de reducir los efectos del rozamiento de los costados *ss* y el de la contracción de las extremidades cuando ésta existe. **La altura** *p*, fig. 20, de la cara interior vertical *ab* en contacto con el agua, no debe ser menor del doble de la carga H; porque con el fin de reducir la velocidad al acercarse el agua á la compuerta del vertedero, ó sea la velocidad de acceso (véase art. 14 *u*), la sección transversal **del canal** que conduce al vertedero debe ser grande en proporción con la de la corriente *ac*. La sección transversal del canal de entrada ó acceso debe ser lo más *regular* posible.

(*g*) El vertedero debe ser de construcción fuerte, porque las **vibraciones** pueden modificar seriamente el gasto.

(*h*) *Teóricamente*, **la carga** es la dist vertical H', fig. 24, de la cresta *a*, á un punto *o' en donde el agua se encuentra perfectamente tranquila*, y por consiguiente la superficie es *horizontal*. Pero de hecho la carga se mide generalmente desde la cresta *a* á un punto *o*, á algunos metros detrás del vertedero, donde el agua está sólo *relativamente* en equilibrio, siendo perceptible la velocidad de acceso. (Véase art. 14 *u*.) La diferencia entre la carga H realmente medida y la carga H' en el agua *tranquila* es muy pequeña generalmente. En la figura está muy exagerada. **La medida correcta de la carga** es una operación delicada, aumentando ó disminuyendo el gasto más ó menos 1½ por ciento por un aumento ó disminución de 1 por ciento de la carga. Las agitaciones del agua y otras perturbaciones de la superficie, y la atracción capilar son las causas principales de error.

(*i*) Para evitar esta última dificultad se emplea la **sonda aforadora de gancho**, para medir, en casos importantes, la altura de la superficie del agua. Se compone ésta de una larga regla graduada, provista en su parte inferior de un gancho ó punta vuelto hacia arriba, el cual se desliza verticalmente (por medio de tornillos) en un soporte fijo provisto de un nonio que indica en la escala la altura del gancho ó punta. Se baja primeramente la regla corredera hasta que la punta se halle bien debajo de la superficie, y luego se levanta gradualmente por medio del tornillo hasta que la punta ó gancho llegue justamente á la superficie, lo que se conoce por la aparición de un « botoncito » en la superficie del agua inmediatamente sobre el gancho. Bajo circunstancias favorables, con un buen aforador de gancho se pueden hacer lecturas con aproximaciones hasta de 6 á 15 centésimos de milímetro.

(*j*) Para evitar inexactitudes, debidas á las **perturbaciones de la superficie** producidas por las corrientes, el viento, etc., se toma el nivel algunas veces (con la sonda aforadora de gancho ó de cualquiera otro modo) en un departamento lateral que comunique con el canal principal del acceso. La superficie del agua en el departamento conserva el mismo nivel que el del canal mismo, pero está relativamente libre de perturbaciones. También puede servir al efecto un balde ó tobo comunicado con el canal por medio de un tubo. Ambos deben estar, por supuesto, á cubierto del viento. **Advertencia.** Fteley y Stearns hallaron que, cuando el tobo ó departamento estaban comunicados con el agua *cerca del fondo y próximamente detrás del vertedero*, la carga así obtenida era generalmente algo mayor que la hallada por medidas hechas cerca de la superficie y á 1.80 m detrás del vertedero. Pero Francis encontró esta diferencia apenas perceptible.

(*k*) Debe tenerse mucho cuidado en **arreglar la sonda aforadora de gancho con respecto á la altura de la cresta ó copete**, porque un error en esto afecta todas las operaciones subsiguientes. El gancho se ajusta generalmente á la altura de la superficie cuando esta última llega exactamente al nivel de dicho borde ó cresta; pero este método se hace inexacto por la atracción capilar de aquélla. Más exacto es tener, además del aforador de gancho, un punzón fuerte, *fijo*, con la punta hacia arriba, cuyo nivel con relación al de la cresta pueda deter-

minarse por medio de un nivel de ingeniero colocando la regla graduada sobre dicho borde ó arista.

Entonces se deja descender la superficie del agua lentamente hasta que aparezca un *botoncito ó menisco* en la punta del gancho fijo. Luego se mantiene el agua á este nivel y, de acuerdo con esto, se ajusta el aforador de gancho. O, si el aforador es fuerte, puede colocarse desde luego la regla graduada sobre su extremidad sin tener que recurrir al gancho fijo. Lo mejor es arreglar el aforador de manera que el *cero* corresponda al nivel de la cresta del vertedero, que servirá entonces de origen ó punto de partida de la graduación, pues la lectura del aforador con respecto á la superficie del agua dará entonces desde luego la carga H sin tener que restar la altura de la cresta del vertedero.

**(1) Fórmulas del gasto de los vertederos.**

Sean

$\mathbf{Q}$ = gasto real del vertedero por segundo*;
$\mathbf{Q'}$ = gasto teórico del vertedero por segundo;
$\mathbf{H} = \mathbf{H'}$ + = dist vertical ó carga *am*, fig. 24 (art. 14 *u*), medida desde la arista *a* á la superficie horizontal *o'* del agua *tranquila*, aguas arriba del vertedero *:
$\mathbf{L}$ = largo *aa* del vertedero *, figs. 21 á 22 *a*;
$g$ = intensidad de la gravedad = 32.2 pies = 9.81 metros * por segundo.

$$\left.\begin{aligned} c &= \text{coeficiente de gasto} = \frac{\text{gasto real}}{\text{gasto teórico}} = \frac{Q}{Q'}; \\ m &= \frac{2}{3}c; \\ x &= \frac{2}{3}c\sqrt{2g} = m\sqrt{2g} \end{aligned}\right\} \div$$

Luego, para **el gasto teórico**, tenemos:

$$\mathbf{Q'} = \frac{2}{3}\,\mathrm{LH}\sqrt{2g}\,\mathrm{H},\ \S\ldots\ldots\ (1)$$

y para el **gasto real**

$$\left.\begin{aligned} \mathbf{Q} &= \mathbf{cQ'} \\ &= \frac{2}{3}\,\mathbf{cLH}\sqrt{2g\mathrm{H}} \ldots\ldots\ (2) \\ &= \mathbf{mLH}\sqrt{2g\mathrm{H}} \ldots\ldots\ (3) \\ &= \mathbf{xLH}\sqrt{\mathrm{H}} = \mathbf{xL}\sqrt{\mathrm{H}^3} = \mathbf{xLH}^{\frac{3}{2}} \ldots\ (4) \end{aligned}\right\} \text{Véanse notas al pie } *\dagger\ddagger.$$

**Para el valor del coeficiente** ($c$, $m$, ó $x$ ‡) hemos recurrido á experimentos, midiendo el gasto real y comparándolo con el gasto teórico como se indica en los artículos siguientes.

---

* Estas fórmulas se aplican igualmente á cualquier sistema de medidas: inglés, métrico, etc.; sólo se requiere que la carga, el largo y la intensidad de la gravedad ($g$) se expresen en la *misma* unidad: todos en pies, todos en metros, etc., y el gasto en el cubo de esta unidad. En medida métrica $g$ es = 9.81 *m* por segundo.

† *Por ahora* suponemos que la carga se mide en el agua *tranquila*, de modo que H = H'; cuando no sea este el caso, véase « Velocidad de acceso », art. 44 (*u*) más adelante.

‡ Se notará que las fórmulas (2), (3) y (4) con sus correspondientes coeficientes, $c$, $m$ y $x$, son realmente idénticas, diferenciándose solamente en la forma. La última es la más conveniente en la práctica, pero todas ellas se usan en hidráulica.

§ Cuando el agua sale bajo una carga H, por un orificio *horizontal* practicado en el *fondo* de un envase, la velocidad teórica (art. 7) es = $\sqrt{2g\mathrm{H}}$; y ésta también se puede considerar como exacta para orificios *verticales* practicados en las *paredes* de los envases, con tal que la carga H sobre el centro de gravedad del orificio sea á lo menos dos ó tres veces la dimensión vertical del orificio; porque en ambos casos las velocidades teóricas en los diferentes puntos del orificio pueden considerarse *iguales*. Pero cuando un orificio vertical está más cerca de la superficie, ó *llega* hasta ella como en un vertedero, entonces debemos tomar en consideración las diferencias de velocidades de la salida del agua en los puntos de profundidades diferentes.

Teóricamente las moléculas atraviesan el plano oblicuo *ao'*, fig. 23, en líneas horizontales, con velocidades (= $\sqrt{2gh}$ = 4.43 $\sqrt{h}$) (hablando en metros) proporcionales á las raíces cuads de sus respectivas y diferentes profundidades verticales $h$ (que no se indi-

*(m)* **James B. Francis*** experimentó en « las esclusas bajas » en Mass, 1852, con vertederos de 3.05 m de largo, 1.52 m y .61 m de alto, bajo cargas de .18 m á .48 m. Para aplicar sus resultados, deben existir las condiciones siguientes : la carga H, fig. 20, debe estar comprendida entre .15 m y .61 m. La altura *p* de la cara vertical interior del vertedero sobre el fondo *b* del canal, fig. 20, debe ser por lo menos el doble de la carga H. El copete *a* debe ser de « pared delgada » (nota †, pág. 576) y su longitud L, figs. 21 á 22 *a*, debe ser por lo menos el triple de la carga H. Las extremidades *ah*, *ah*, deben ser verticales, y cuando haya contracción de extremidades, que sean de « pared delgada ».

Cuando hay contracción de extremidades, Francis rebaja primeramente de la longitud L del vertedero *una décima † parte de la carga* H, por *cada extremidad* donde haya contracción. Así : si *n* es=al número de contracciones de las extremidades (dos en la fig. 22),

$$Q = x\left(L - n\frac{H}{10}\right)H\sqrt{H} = x\left(L - n\frac{H}{10}\right)H^{\frac{3}{2}} \div \ldots. \quad (5)$$

$$\text{En la fig. 22, } Q = x\left(L - \frac{H}{5}\right)H\sqrt{H} \div = x\left(L - \frac{H}{5}\right)H^{\frac{3}{2}}$$

Pero entre los límites especificados arriba, la fórmula es muy aproximada *sin* correción por las contracciones de las extremidades, con tal que el largo L del vertedero sea por lo menos 10 veces la carga H; y con un 6 por ciento de aproximación cuando L=4 H. Cuando no existe contracción en las extremidades, tal corrección no es necesaria, y la fórmula permanece igual á $Q = xLH\sqrt{H} \div = xLH^{\frac{3}{2}}$.

---

can en la figura) bajo la superficie tranquila del agua en *o'*. Por lo tanto, si imaginamos trazadas desde *am* líneas horizontales *aa'*, *dd'*, *vv'*, *cc'*, etc., etc., que representen dichas velocidades en cualquiera escala, entonces los extremos exteriores *a'*, *d'*, *v'*, *c'*, etc., de estas líneas, formarán con *am* y *aa'* un segmento parabólico *amc'a'* cuya área será = 2/3 del área del rectángulo *an* (véase parábola, pág. 203)=2/3 *am* × *aa'*=2/3 H $\sqrt{2gH}$; y esta área multiplicada por el espesor de la lámina de agua que fluye por el largo L del vertedero dará el gasto teórico por segundo. O

$$Q' = L \times \text{área } amc'a' = L \times 3/2\ H\sqrt{2gH}.$$

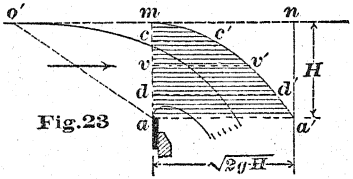

Fig.23

Por lo tanto, el área *amc'a'* en metros cuads. representará el gasto teórico en metros cúbs por segundo, suministrado por un metro de longitud del vertedero bajo la carga H. La *velocidad media* teórica en la sección *ao'* es

$$V = vv' = \frac{\text{gasto teórico } Q'}{\text{área } am} = 2/3\ LH\sqrt{2gH} \div LH = 2/3\sqrt{2gH},$$

ó dos tercios de la velocidad horizontal teórica *aa'* de las moléculas que pasan inmediatamente por sobre el vertedero. Como en el caso de los orificios (art. 9), la velocidad real *en la sección mas pequeña* de la lámina de agua después de haber pasado el vertedero (que corresponde á la « sección contracta » de la vena) es probablemente casi igual á esta velocidad teórica.

* « Lowell Hydraulic Experiments ». Van Nostrand, Nueva York, 1883

† En los experimentos de Fteley y Stearns, este número no permanecía constante en .10, sino que variaba entre .061 y .124, aumentando generalmente á medida que disminuía la carga.

---

÷ Suponemos aquí que la carga se mide hasta la superficie del agua *tranquila*, de manera que H y H' (véase art. 14 *h*, pág. 584), son iguales. Véase « Velocidad de acceso », art. 14 *(n)*.

**Francis da x=1.838** empleando unidades métricas; ó

$$\textbf{Gasto} = 1.838 \times \left( \text{largo} - \frac{\text{número de contracciones de las extremidades}}{10} \times \text{carga H} \right) \times H^{3/2}, *$$

El término medio de 88 experiencias dió $x = 1.8394$. El mayor valor obtenido fué $^1/_{105}$ mayor; y el menor, resultó $^1/_{112}$ más pequeño. Usando, $x = 1.838$, tendremos para **c y m**, los valores siguientes : $c = .622$; $m = .415$.

La altura de la superficie se midió (1.83 m) detrás del vertedero, por medio de dos sondas aforadoras de gancho, situada una de cada lado del canal, y se tomó el término medio de sus lecturas para calcular el coeficiente $x$.

**Tabla 13 **. Gasto en pies cúbicos por segundo por cada pie de longitud del vertedero,** en pared delgada y sin contracción de las extremidades por la fórmula de Francis : ‖

$$\textbf{Gasto } Q = 3.33\ LH^{3/2} = 3.33\ LH\sqrt{H}.$$

Muy aproximada también, cuando haya contracción de las extremidades, con tal que L sea por lo menos=10 H; y con sólo 6 por ciento de exceso sobre el verdadero valor, si L=4 H. Francis limita la fórmula á cargas H desde .5 pies hasta 2 pies; pero no resultarán errores de importancia del uso de la tabla para cualquiera de las cargas dadas. **Para vertederos de otras longitudes** distintas á 1 pie, multiplíquese el gasto tabular por el largo real en pies. La primera carga de la tabla es .01 pie = .12 pulg = $^1/_8$ pulg escasa = .003 m = 3 milímetros.

---

* Véase esta nota pág. 586.

** Esta tabla es una ampliación de la tabla « original » publicada en la primera edición de 1872. La mayor parte de los valores dados ahora se han tomado (con permiso) de una tabla publicada por los Srs. A. W. Hunking y Frank S. Hart, de Lowell, Mass, en mayo de 1884.

‖ Véase *N. del T.* después de la tabla que sigue.

(*N. del T.* — Por ser la tabla anterior muy minuciosa y precisa y, además, por ser muy fácil utilizarla, empleando medidas métricas, hemos resuelto dejarla.

En efecto, cuando se tenga la longitud del vertedero y la carga en metros, se puede hacer uso de esta tabla, teniendo presente que para convertir metros en pies se multiplican los metros lineales × 3.2809 = pies lineales, y los pies cúbicos que nos da la tabla se convierten en metros cúbicos así : pies cúbicos × .0283 = metros cúbicos.

Ej. Tenemos un vertedero de 2 m de largo y una carga .50 m, es decir, L = 2 m; H = .50 m.

L = 2 × 3.2809 = 6.5618 pies; H = .5 × 3.2809 = 1.6404 pies;

y entrando á la tabla con esta carga de 1.64 pies nos da para un vertedero de 1 pie

de largo solamente 6.994 pies cúbicos por segundo. Pero como el vertedero tiene de largo 6.5618 pies, tendremos el gasto=6.5618×6.994=45.893 pies cúbicos y 45.893 pies cúb×.0283=1.299 metros cúbicos por segundo = 1299 litros por segundo.)

(*n*) **A. Fteley y F. P. Stearns** * hicieron experimentos en Boston, Mass, de 1877 á 79, con vertederos de 5 pies (1.52 m) y 19 pies (5.79 m) de largo, 3 pies 2 pulgs (.96 m) y 6 pies 6 ½ pulgs (1.99 m) de alto y bajo cargas de .8 pulg (.02 m) á 19 pulgs (.49 m). Para vertederos en pared delgada y sin contracción en las extremidades, con un canal de acceso rectangular y uniforme, y bajo cargas mayores que .07 pies (.02 m); (las otras condiciones iguales á las especificadas en (*b*) y (*d*)), la fórmula de ellos es como sigue:

$$\textbf{Gasto, } Q=3.31\,LH^{3}/_{2}+.007\,L \dagger \ldots\ldots\ldots \quad (6).$$

O la siguiente (por el Traductor) aplicable al sistema métrico, y deducida de la anterior:

$$Q=1.82605\times LH^{3}/_{2}+.0006503\,L$$

(*Obs. del Traductor.* — Para que estas fórmulas den resultados exactos deben apreciarse siempre suficiente número de decimales.)

En sus experimentos (los de A. Fteley y P. F. Stearns) las cargas se midieron á 6 pies (1.83 m) detrás del vertedero. La variación total en el valor de los coeficientes obtenidos fué más ó menos de 2½ por ciento.

(*Obs. del Traductor.* — Damos el siguiente ejemplo para que sirva de comparación de las fórmulas: Sea

| | | | |
|---|---|---|---|
| $H=.1$ | (en pies)..... | .0304794 | (en m) |
| $L=.4$ | — ..... | .1219176 (=4 H) | — |
| $H^{3}/_{2}=.03162$ | — ..... | .00532 | — |

tendremos:

En pies... $Q=3.31\times.4\times.03162+.007\times.4=.044664$ pies$^3$ = .001264 m$^3$
En m.... $Q=1.82605\times.1219176\times.00532+.0006503\times.1219176=.001263636$m$^3$)

---

* *Transactions, American Society of Civil Engineers, Jan., Feb. and March,* 1883.
† Véase corrección de la velocidad de acceso, art. 14 (*n*).

(*o*) **M. Bazin** * hizo experimentos en Dijón, Francia, en 1886-88, en vertederos como de .45 m á 1.97 m de largo y de .23 m á 1.14 m de alto, bajo cargas

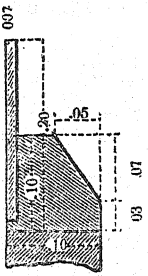

**Fig. 23 *a*.**

pe .063 m á .53 m. La parte superior del vertedero se muestra en la fig. 23 *a*. Los vertederos se pusieron en diferentes puntos de un canal rectangular y regular de 213.35 m de largo revestido con cemento y liso.

Mientras que Francis y Fteley y Stearns previenen el efecto de la velocidad de acceso (véase art. 14 *w* y *v*) modificando la *carga* medida H, Bazin la previene introduciendo el *coeficiente m* en la fórmula $Q = mLH\sqrt{2gH}$.

Sea M = el valor de *m* para el caso en que la velocidad de acceso = 0. Entonces, muy aproximadamente, $M = .405 + \frac{.003}{H\ (\text{metros})}$. Cuando se toma en cuenta la velocidad de acceso, tenemos: $$\mathbf{m} = M\left[1 + .55\left(\frac{H}{H+p}\right)^2\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots\ (7)$$

en la cual H es la carga verdadera medida en el agua corriente, y *p* la altura *ab* del vertedero, fig. 20 H y *p* deben, por supuesto, medirse con la misma unidad, ambos en metros ó ambos en pies, etc.

M. Bazin cree que, excepto en el caso de vertederos muy bajos (lo que debe evitarse), los valores de *m* dados por la fórmula (7) y en la Tabla 14, calculados con ella, se hallarán con 1 por ciento de aproximación para vertederos en pared delgada, sin contracción en las extremidades, si se reproducen exactamente las condiciones de sus experimentos y si se tiene especial cuidado de que la lámina de agua no se esparza lateralmente, después de pasar el copete (art. 14 *d*) y que el aire tenga acceso libre al espacio *w*, fig. 20, por detrás de la caída formada por la lámina de agua al salir del vertedero.

Para cargas comprendidas entre 10 cm y 30 cm, M. Bazin da, como **suficientemente aproximado,**

cuando no hay velocidad de aceso, $M = .425$

y teniendo en cuenta la velocidad de acceso $\mathbf{m} = .425 + .21\left(\frac{H}{H+p}\right)^2$.

---

* *Expériences nouvelles sur l'écoulement en déversoir. Extrait des Annales des Ponts et Chaussées*, oct. 1888, *Paris, Vve Ch. Dunod*, 1888. Traducción de A. Marichal y John. C. Trautwine Jr., presentada al *Club de Ingenieros de Filadelfia* en 1889 para que la publicase en sus trabajos.

**Tabla 14. Valores de m en la fórmula :**

$$Q = mLH\sqrt{2gH} * \ldots\ldots\ldots\ldots 6$$

**Gasto en metros cúbicos** $= m \times$ largo en metros carga medida H, en metros $\times \sqrt{2gH}$, en metros.

*Nota.* El coeficiente $m$ para cualquier caso dado es el mismo, úsese medida inglesa, métrica ú otras; con tal que se tome la carga, el largo y $g$ en la misma unidad y el gasto en el cubo de aquella unidad, porque $m$ es simplemente $\frac{2}{3}ac = \frac{2}{3} \times \frac{\text{gasto real}}{\text{gasto teórico}}$.

Se notará que **bajo las líneas gruesas** de la tabla, la carga H es mayor que la mitad de la altura $p$, y esto excede al límite fijado en (*l*) y (**m**).

Debido á que se ha tomado la carga H y la altura $p$ entre límites más extensos en estos experimentos, encontramos en ellas una **divergencia mayor** en los valores de los coeficientes que los que resultaron de las investigaciones anteriores. Así, el valor más pequeño de $m$ que está de la línea gruesa hacia arriba, es .4092 ó más ó menos $^1/_{10}$ menor que el término medio .4325; y el mayor es .459 ó como $^1/_{10}$ mayor que .4325.

* En estos experimentos la carga H se midió en un punto situado á 5 m detrás de vertedero. La corrección por la velocidad de acceso está incluída en el coeficiente $m$.

† M es el valor de $m$ cuando no hay velocidad de acceso; es decir, cuando la sección transversal del canal de acceso es demasiado grande comparada con la de la corriente del agua que pasa por sobre el vertedero.

(*p*) Comparando un número de datos experimentales, **el autor** ha deducido la siguiente:

**Tabla 15. Valores aproximados del coeficiente** $m$ en la fórmula

$$Q = mLH\sqrt{2gH}$$

para vertederos de diferentes formas y espesores. (Original.)

| **Carga H.** | Arista viva *. | Espesor .05 m. | Espesor .9144 m liso, con inclinación hacia afuera y hacia abajo desde 1 en 12 hasta 1 en 18. | Espesor .9144 m liso y horizontal. |

| .9144 | .37 | .39 | .32 | .30 |

(*Obs. del T.* — A esta tabla, original del autor, le hemos agregado la carga y espesores en metros, para facilitar su uso en el sistema métrico, pues la fórmula $Q = mLH\sqrt{2gH}$, como ya se ha dicho, puede aplicarse en ambos sistemas, con el mismo coeficiente $m$ con tal que se sustituyan en ella los valores en metros de los otros factores.)

(*q*) **Hallar la carga H aproximadamente** teniendo el gasto Q. Según las fórmulas (3) y (4), art. 14 (*l*), tenemos :

$$Q = mLH\sqrt{2gH} = xLH\sqrt{H} = mL\sqrt{2g}\sqrt{H^3} = xL\sqrt{H^3}$$

$$H = \sqrt[3]{\frac{Q^2}{m^2L^2 2g}} = \sqrt[3]{\frac{Q^2}{x^2L^2}} \quad \ldots\ldots\ldots\ldots\ldots \quad (8)$$

ó bien (sistema métrico).

$$\text{Carga H en metros aproximadamente} = \sqrt{\frac{\text{Cuad del gasto de la corriente en metros cúbs por segundo}}{m^2 \times (\text{largo en metros})^2 \times 19.62}}$$

El coeficiente $m$ ó $x$ mismo varía algo con la carga.

(*r*) **Vertederos sumergidos ó ahogados.** fig. 23 *b*, son aquellos en los cuales la superficie del agua del lado *abajo* de la corriente en $h$, es, después de la contracción del vertedero, *más alta* que la arista $a$.

En un vertedero que efectúe la salida del agua libremente al aire como en la fig. 20, Francis halló que con una carga de 30 cm disminuyó el gasto solamente como en una milésima parte, poniendo un piso sólido horizontal como á 15 cm debajo y frente al borde ó arista del vertedero para que el agua cayese sobre dicho piso. También, cuando la carga era de 25 cm y el agua caía libremente á través del aire en aguas de profundidad considerable (como en la fig. 20), el

* Estos valores son menores que los dados en el art. 14 (*m*) y (*n*) y mucho menores que los dados en (*o*).

gasto era el mismo, aunque estuviese la superficie del agua del lado abajo de la corriente, como 7 cm ½ ó 33 cm bajo la cresta *a*.

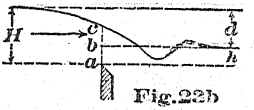

Fig. 23b

En los experimentos hechos por Francis y Fteley y Stearns, dejando entrar libremente el aire por debajo de la caída formada por la lámina de agua, justamente debajo de la cresta *a*, el gasto no se afectó sensiblemente por una sumersión de *h*=desde .017 de H á .023 de H. Cuando el aire sólo penetraba parcialmente, el gasto se afectaba (*aumentando*) en menos de 1 por ciento mientras *h* permanecía menor que .15 H.

**Fórmula de Dubuat para vertederos sumergidos.** Sea :

**H** y *h*=las cargas medidas verticalmente desde la cresta *a* del vertedero á la superficie del agua en reposo * del lado arriba y abajo de la corriente del vertedero respectivamente;

$d = H - h$ =su diferencia=diferencia de nivel de las dos superficies del agua en reposo, * (la sup de arriba y la de abajo del vertedero);

*c* =coeficiente del gasto $= \frac{\text{gasto teórico}}{\text{gasto real}}$.

Entonces tenemos :

$$Q = cL\ (h + {}^2/_3\ d)\ \sqrt{2gd}\ **. \ldots\ldots\ (9)\ \text{ó sea}$$

**Gasto** *real* en mets cúbs por segundo $= c \times$ largo del vertedero en mets $\times 4.43\ \sqrt{d \text{ en mets}} \times (h + {}^2/_3 d)$ en mets.

(*s*) **Fteley y Stearns** † hicieron experimentos en Boston, en 1877, con **vertederos sumergidos** bajo cargas H aguas arriba como de 10 á 25 cm, y **Francis** § en Lowel, 1883, bajo cargas como de 30 á 71 cm.

De estos experimentos deducimos la siguiente **tabla 16** de los valores aproximados del **coeficiente c** en la fórmula del gasto en **vertederos sumergidos.**

$$Q = cL\ (h + {}^2/_3 d)\ \sqrt{2gd}.$$

Deducidos de experimentos hechos por Fteley y Stearns y por J. B. Francis. En los experimentos de Francis, el valor de *c* para un valor dado de $h \div H$, aumentó generalmente en proporción de H.

---

* Para la velocidad de acceso, véase art. 14 (*u*), etc.

** Al deducir esta fórmula, el agua que pasa por el vertedero entre *c* y *b*, se supone que corre como por sobre un vertedero cuya arista es *b* y que efectúa la salida del agua libremente al aire, como por sobre la arista *a* en la fig. 20; y para esta parte, el gasto lo dará la fórmula (2), art. 14 (*l*) :

$$Q_b = cL\ \frac{2}{3}\ d\ \sqrt{2gd}$$

(para pies y metros introduciendo en cada caso los valores respectivos) mientras que el agua que pasa por la parte inferior entre *b* y *a* se considera como saliendo por un *orificio* vertical sumergido, cuya altura es $ba = h$, bajo una carga $= d$. Por consiguiente, para esta parte inferior el gasto sería :

$Q_a = cLh\ \sqrt{2gd}$. (La misma para metros y pies introduciendo para cada caso los valores respectivos.)

Se supone que el coeficiente de gasto *c* sea el mismo para la sección superior *cb* que para la inferior *ab*. Por tanto, sumando estos dos gastos, tendremos para todo el gasto :

$$Q = Q_b + Q_a = c\,L\,(h + \frac{2}{3}\ d)\ \sqrt{2gd}\ \text{(Para metros y pies.)}$$

**(1) Clemens Herschel** *, comparando estos experimentos con algunos anteriores hechos por Francis, da lo siguiente :

Habiendo determinado las profundidades H y $h$ á que se halla la cresta del vertedero bajo el nivel del agua en reposo, aguas arriba y aguas abajo, respectivamente, divídase $h$ por H; búsquese el cociente tan aproximadamente como se pueda en la columna encabezada $h \div H$ de la Tabla 17. Tómese el coeficiente correspondiente $a$, y multiplíqueselo por la carga aguas arriba H**.

El producto $a$H es la carga que haría que un vertedero dado produjese el mismo gasto saliendo el agua al *aire libremente*, como en la fig. 20. Búsquese el gasto ó cantidad de agua que vierte al aire el mismo vertedero con la carga $a$H; y este gasto será aproximadamente el mismo que el del vertedero *sumergido* realmente bajo la carga aguas arriba H, y contra la carga aguas abajo $h$; ó (siendo H la carga efectiva aguas arriba del vertedero *sumergido*) el gasto es :

$$Q = mLa\text{H}\sqrt{2ga\text{H}} = xLa\text{H}\sqrt{a\text{H}} \ldots\ldots \quad (10)$$

(*Obs. del T.* — Tanto la fórmula como la tabla se aplican al sistema métrico, sustituyendo los valores de $g$, $h$ H y L en metros, y teniendo en cuenta que $x = m\sqrt{2g}$.)

*(u)* **Velocidad de acceso.** Véase fig. 24. Generalmente es impracticable la medida de la carga H en el agua perfectamente en reposo, desde $o'$ aguas arriba. La carga se mide generalmente en un punto $o$ situado desde 60 cm ó 1 m hasta 1½ á 2½ m ó más distante del vertedero aguas arriba, según el tamaño de este último. En estos puntos la velocidad es generalmente apreciable, y la superficie por lo tanto un poco más baja que en $o'$. Por consiguiente, una fórmula en que se use la carga más pequeña H, medida de este modo en lugar de la H', y con

* *Transactions, American Society of Civil Engineers, May* 1885, págs. 189, etc.

** La tabla de Herschel, de la cual se ha extractado la nuestra, da el valor de $a$ para cada .01 pie de $h \div H$; pero los valores de $a$, intermedios á los que hemos elegido, pueden deducirse de nuestra tabla con bastante exactitud por una simple proporción. El orden de los coeficientes $a$ de la tabla, correspondientes á cada valor de $h \div H$, es el indicado por las experiencias que variaban de un modo semejante. No sabemos qué escoger entre estos extremos; pero en la mayor parte de los casos los valores *medios* son probablemente exactos.

los coeficientes basados en H', dará un gasto demasiado pequeño. Francis halló que una corriente de .305 m por segundo, ó casi 1,098 m por hora, en el punto, *o*, donde se midió la carga, aumentó el gasto como en un 2 por ciento solamente

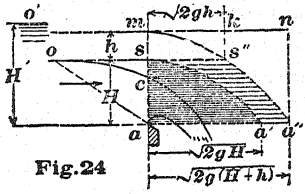

Fig. 24

cuando la carga era de 33 cm; y con una corriente de 15 cm aumentó el gasto en 1 por ciento más ó menos cuando la carga era de 20 cm.

Sin embargo, si la velocidad de acceso es tal que se haga necesario tenerla en cuenta, procédase como sigue : Para obtener la velocidad media de acceso, aproximadamente tenemos :

$$v \text{ en mets} = \frac{\text{gasto aproximado en mets cúbs}}{\text{área total de la sección transversal del arroyo en } o, \text{ en mets cuads}} = \frac{1.838\ \text{LH}^{3/2}}{\text{área en } o \text{ en mets cuads}}$$

y para la carga debida á esta velocdad, $h = \frac{v2}{2g}$.

Luego, para todas las aplicaciones prácticas, podemos decir : $H' = H + h$; ó

$$Q = mL\ (H+h)\ \sqrt{2g\ (H+h)} = xL\ (H+h)^{3/2} \ldots\ldots \quad (11)$$

(para ambos sistemas de medidas, como ya se ha dicho, y recordando que $x = m\sqrt{2g}$; $g = 9.81$ m $= 32.2$ pies).

Sin embargo, hablando estrictamente, la diferencia de nivel entre *o'* y *o* es realmente (como se indica en la fig. 24) algo *mayor* que en *h*, ó que $\frac{v2}{2g}$, porque se pierde alguna carga por el rozamiento entre *o'*, y *o*.

(*y*) **Fteley y Stearns** hacen á $H' = H + 1.5\ h$ para vertederos sin contracción en las extremidades y $H' = H + 2.05\ h$ como término medio, para vertederos en que es completa la contracción en las extremidades; y **Hamilton Smith, Jr.**, después de comparar los experimentos de ellos con otros hechos por Lesbros, Castel y Francis, da $H' = H + 1\frac{1}{3}\ h$, y $H = H' + 1.4\ h$ para los dos casos respectivamente.

(*w*) Por otra parte, la fórmula de Francis, modificada para la velocidad de acceso,

$$Q = xL * (\sqrt{(H+h)^3} - \sqrt{h^3}) = mL * \sqrt{2g} \times (\sqrt{(H+h)^3} - \sqrt{h^3}) ** \ldots \quad (12).$$

(*Obs. del T.* — Esta última fórmula sirve también para medidas métricas.)

---

* Si hay contracciones en el extremo, L se convierte en $\left(L - n\frac{H}{10}\right)$. Véase el art. 14 (*m*).

** Esta fórmula se deduce como sigue : Supongamos que el área del segmento parabólico *asa'* fig. 24, representa el gasto teórico del vertedero en una unidad de longitud (como se ha explicado en la nota § al pie del art. 14 (*l*), bajo la carga medida $H = a\ s$, como si no hubiera corriente alguna en *o*. Sea $ms = h = v^2 \div 2g$. Las velocidades teóricas de las moléculas que atraviesan el plano oblicuo, *oa*, bajo sus cargas efectivas, estarán ahora representadas por líneas horizontales *ss''*, *aa''*, etc., trazadas desde cada punto de *s a* á la curva *exterior* *s'' a''* ; la línea *ss''* representa el valor de $v$ = velocidad de acceso $= \sqrt{2gh}$, y *aa''* representa á $\sqrt{2g\ (H+h)}$.

(*x*) **A. W. Hunking y Frank S. Hart,** ingenieros civiles é hidráulicos, han sustituído por la expresión $(\sqrt{(H+h)^3} - \sqrt{h^3})$ en la fórmula (12), la expresión equivalente $K\sqrt{H^3}$, en la cual K es un coeficiente deducido de la expresión anterior, y por lo tanto dependiente de la relación existente entre H y *h*, ó de la relación entre la sección transversal *as*, fig. 24, en el vertedero y de toda la sección transversal de la corriente en *o*.

Después de hallar el área de la sección transversal en *o*, divídasela por $\left(L - n\frac{H}{10}\right)$, usando cualquiera unidad, que es el largo del vertedero corregido con respecto á la contracción. Véase art. 14 (*m*). Llámese el cociente D §. Divídase la carga medida H por D; búsquese este último cociente en la columna $\frac{H}{D}$ de la tabla. Multiplíquese el gasto aproximado, $Q_1 = 1.838\left(L - n\frac{H}{10}\right)H^{3/2}$, (en m) por el coeficiente correspondiente K; ó sea:

$$\textbf{Gasto real en } \textit{mets cúbicos} = 1.838\ K\left(L - n\frac{H}{10}\right)H^{3/2} \ldots\ldots\ldots (13)$$

(El coeficiente K es el msimo, úsense metros ó pies.)

**Tabla 18. Coeficiente K en la fórmula (13).**

| $\frac{H}{D}$ | K | $\frac{H}{D}$ | K | $\frac{H}{D}$ | K | $\frac{H}{D}$ | K | $\frac{H}{D}$ | K |

K es muy aproximadamente $= 1 + \frac{1}{4}\left(\frac{H}{D}\right)^2$. Por lo tanto,

Q en pies cúbs, es $= 3.33\left[1 + \frac{1}{4}\left(\frac{H}{D}\right)^2\right]\left(L - n\frac{H}{10}\right)H^{3/2} =$

$$\left[3.33 + .83\left(\frac{H}{D}\right)^2\right]\left(L - n\frac{H}{10}\right)H^{3/2} \ldots\ldots\ldots (14)$$

(*Obs. del T.*: Q en mets cúbs $= \left[1.838 + .459\left(\frac{H}{D}\right)^2\right]\left(L - n\frac{H}{10}\right)H^{3/2}$. ....(14)

Véase *Journal of the Franklin Institute Philadelphia, August*, 1884, del cual hemos extractado la tabla arriba mencionada.

(*y*) **M. Bazin,** para la velocidad de acceso, modifica (véase art. 14 *o*) el coeficiente *m* en lugar de la carga H, haciendo $m = .425 + .21\left(\frac{H}{D}\right)^2$; (para pies y metros),

---

Entonces, el área $ss''a''a$ es = área $ma''a$ − área $ms''s = \frac{2}{3}$ área del rectángulo $ais$ $- \frac{2}{3}$ área del rectángulo $sk$

$$= \frac{2}{3}(H + h)\sqrt{2g(H + h)} - \frac{2}{3}h\sqrt{2gh}, = \frac{2}{3}\sqrt{2g}\left(\sqrt{(H + h)^3} - \sqrt{h^3}\right);$$

y el gasto efectivo ó real es:

$$Q = c \times \text{largo del vertedero} \times \text{área } ss''a''a = cL\frac{2}{3}\sqrt{2g}\left(\sqrt{(H + h)^3} - \sqrt{h^3}\right)$$

$= m\,L\sqrt{2g}\left(\sqrt{(H + h)^3} - \sqrt{h^3}\right) = x\,L\left(\sqrt{(H + h)^3} - \sqrt{h^3}\right)$; porque $x = m\sqrt{2g}$

En un vertedero sin contracción en las extremidades, $D = H + p$.

mientras que por el método de Hunking y Hart (basado en los experimentos de Francis), $m$ se hace $= .415 + .10 \left(\frac{H}{D}\right)^2$ (para pies y metros).

**Art. 15. Vertederos inclinados.** Si la cara de un vertedero situada del lado aguas arriba, en lugar de ser vertical, como en la fig. 25, está inclinada como en la fig. 25 *a*, ó hacia aguas abajo como en la fig. 25 *b*, se modifica la forma de la vena y el gasto. Con una inclinación aguas arriba, fig. 25 *a*, la cara inferior de la lámina

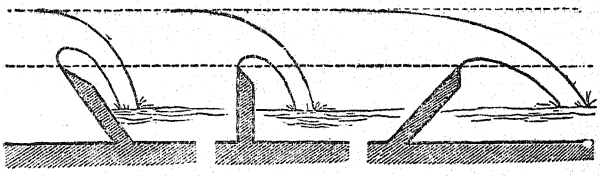

FIG. 25 *a*. Inclinado aguas arriba.

FIG. 25. Vertical.

FIG. 25 *b*. Inclinado aguas abajo.

de agua al pasar por sobre el vertedero salta más alto y su curva interior penetra más hacia aguas arriba cuanto más se aumente la inclinación.

Con una inclinación aguas abajo, fig. 25 *b*, es al contrario: cuando la inclinación aumenta, el salto de la lámina de agua disminuye, su perfil se hace más y más plano y la curva de la superficie superior, debida á la caída, se extiende más, aguas arriba, del borde del vertedero.

Una inclinación aguas arriba, fig. 25 *a*, disminuye el gasto, y una inclinación aguas abajo, fig. 25 *b*, lo aumenta, como lo indican los coeficientes siguientes obtenidos por M. Bazin *.

**Para obtener el gasto suministrado por un vertedero inclinado.** Conociendo el gasto de uno vertical de la misma altura, y bajo condiciones semejantes por otros respectos, multiplíquese el gasto suministrado por el vertical por los coeficientes aproximados que siguen:

| | Inclinación. | | Angulo. | | Coeficientes. |
|---|---|---|---|---|---|
| | Horizontal. | Vertical. | con la horizontal. | con la vertical. | |
| Vertederos inclinados aguas arriba, fig. 25 *a*..... | 1 | 1 | 45° | 45° | .93 |
| | ⅔ | 1 | 56°19′ | 33°41′ | .94 |
| | ½ | 1 | 71°34′ | 18°26′ | .96 |
| Vertederos verticales, fig. 25. | 0 | 1 | 90° | 0° | 1.00 |
| Vertederos inclinados aguas abajo, fig. 25 *b*..... | ¼ | 1 | 71°34′ | 18°26′ | 1.04 |
| | ⅔ | 1 | 56°19′ | 33°41′ | 11.70 |
| | 1 | 1 | 45° | 45° | 1.10 |
| | 2 | 1 | 26°34′ | 63°26′ | 1.12 |

El gasto aumentará también si se redondea la arista interior ó filo del copete de vertedero en lugar de dejarlo con aristas vivas; ó si las paredes del estanque convergen más ó menos á medida que se aproximan al vertedero, de manera que guíen el agua más directamente hacia él; ó si *ab*, fig. 20, es menor que el doble de *am*. Realmente son tantas las circunstancias susceptibles de modificaciones que existen para embarazar los experimentos en ésta, y en materias análogas, que algunos de los ya hechos con gran cuidado han resultado inaplicables, y también otros de aproximaciones tolerables, debido á que por negligencia ó ignorancia no se tomó en consideración alguna peculiaridad local, al tiempo de hacer los ensayos,

* *Expériences Nouvelles sur l'Ecoulement en Déversoir*, 2e article; *Annales des Ponts et Chaussées*, enero 1890, traducido en *Proceedings, Engineers Club of Philadelphia*, vol. IX, 1892.

por no creerse que ejercería un efecto apreciable. A menos que las circunstancias no nos permitan combinar todas las condiciones mencionadas en los arts. 14 (*d*), (*f*) y (*m*), consiguiendo con ello resultados *muy* aproximados, debemos ocurrir ó á una medida directa del gasto en un envase de capacidad conocida, ó conformarnos con reglas que puedan conducir á errores de 5, de 10 ó más por ciento, en proporción á lo que nos desviemos de aquellas condiciones. A menudo hasta un error de 10 por ciento se considera de poca importancia.

*Nota* 1. Cuando el agua después de pasar por un vertedero, fig. 26, en lugar de caer libremente al aire, corre por encima de un canal, T, de poca inclinación, cuyo fondo coincida con el borde ó arista, *a*, del vertedero, entonces el gasto no dismi-

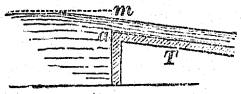

*Fig. 26.*

nuye por eso apreciablemente, cuando la carga *am* es de 38 cm ó más. Pero si la carga *am* es solamente de 30 cm, entonces el gasto calculado debe reducirse más ó menos en una décima parte; si es de 15 cm, dos décimas; si de 6 cm, tres décimas; y si es de 2½ cm, cinco décimas más ó menos.

*Nota* 2. El profesor Thomson, de Dublín, propuso el uso de vertederos triangulares para medir el gasto; porque entonces el perímetro siempre tiene la misma relación con el área del arroyo que fluye por él, lo que no sucede con cualquiera otra forma. Experimentando con una abertura triangular rectangular practicada en una plancha de hierro delgada, fig. 26 A, con cargas desde 5 á 18 cm, medidas

*Fig. 26 A.*

verticalmente del fondo de la abertura *al nivel de la superficie del agua en reposo*, encontró: *gasto* en pies cúbs por seg = 2.54 × $\sqrt{}$ quinta potencia de la carga en pies *.

***Del Traductor.*** — Gasto en mets cúbs = 1.40254 $\sqrt{}$ quinta potencia de la carga en mets ó en general si $m$ es = coeficiente de contracción (art. 9, pág. 576) T = tangente del semiángulo de la escotadura = ½ ancho de la superficie del agua ÷ la profundidad en la abertura; $g$ = la intensidad de la gravedad = digamos 9.81 m por segundo y $h$ = carga, medida como se dijo; y entonces tenemos:

$$\text{Gasto} = \frac{8m}{15}\,\text{T}\sqrt{2gh^5} * = 4.28\,m\text{T}\sqrt{h^5}\text{ en pies }*.$$

(***Obs. del T.*** — $m$ y T tienen el mismo valor en cualquiera unidad que se calcule, por tanto, cuando se de la altura $h$ en metros, la fórmula del gasto en mets cúbs será = 2.363 m T $\sqrt{h^5}$ en mets *.)

*Nota* 3. Al construir el canal de irrigación, Canale Villoresi, cerca de Milán, en 1881-4, el ingeniero italiano, Cesare Cippoletti **, adoptó **una abertura trapezoidal**, con su arista inferior horizontal y sus costados inclinados á razón de 4 vertical : 1 horizontal, para evitar la necesidad de suprimir ó de permitir las contracciones de las extremidades. (Véanse arts 14 *c* y 14 *m* de este mismo capítulo.) Se encontró que la contracción sólo afectaba los espacios triangulares situados encima de los extremos inclinados del vertedero, y el largo efectivo del vertedero permaneció así constante (é igual al largo de la arista del fondo) para todas las cargas. Al usar estos vertederos la contracción es completa tanto á lo largo del fondo como en sus extremidades.

---

Para esta raíces, véanse págs. 69 á 71.

** Véase su obra *Canale Villoresi; Modulo per la Dispensa della Acqua, etc.* Milán, 1886; publicada por la *Società Italiana per Condotte d'Acqua*. Los resultados fueron recopilados por L. G. Carpenter, en el Bulletin n.º 13, *Agricultural Experiment Station, Fort Collins*, Colorado, octubre, 1890.

## DE LA CORRIENTE DEL AGUA POR CANALES DESCUBIERTOS

**Art. 16. La velocidad media de la corriente** es una velocidad imaginaria uniforme con que suponemos animada el agua en cada punto de su sección transversal y que da el *mismo gasto* que el producido por la velocidad real no uniforme. O de otro modo:

$$\text{Velocidad media} = \frac{\text{Gasto}}{\text{área de la sección transversal}}.$$

En los canales de sección transversal uniforme la **velocidad máxima** se halla más ó menos en el medio ó centro entre sus dos orillas, y generalmente á cierta distancia bajo la superficie; esta distancia varía en las diferentes corrientes; pero por término medio parece ser, más ó menos, la tercera parte de la profundidad total. Cuando la profundidad es grande en relación á su ancho (por ejemplo, la mitad del ancho ó más), se ha encontrado que la velocidad máxima se halla como á la mitad de la profundidad de la superficie al fondo, mientras que en arroyos pequeños de poca profundidad parece aproximarse á la superficie hasta una distancia de ella como de .1 á .2 de su profundidad total. Muchos experimentos hechos en ríos ó corrientes de poca profundidad han indicado ciertamente que la velocidad máxima está *en* la superficie.

**La relación entre las velocidades de los diversos puntos de la sección transversal** es sumamente variable en las diferentes corrientes, de modo que hay que fiarse poco en las reglas empleadas para deducir de la velocidad de un punto de la sección, la de otro punto de la misma sección. Con la misma velocidad, los ríos anchos y hondos tienen mayor velocidad media y en el fondo, que los ríos de poca profundidad. Para obtener **una grosera aproximación de la velocidad media** cuando se ha dado la máxima de la superficie, á menudo se supone que la primera es igual á [illegible] (ó .80) de la última. Pero Francis encontró en sus experimentos hechos en Lowell, que los flotadores *superficiales* de cera, de 5 cm de diámetro, que flotaban en el centro de un canal rectangular descubierto de 3.65 m de ancho y 2.44 de hondo, realmente se movían como 6 por ciento *más despacio* que un flotador compuesto por un tubo de hoja de lata de 5 cm de diámetro, que sobresalía pocas pulgadas de la superficie del agua y llegaba hasta 3 ó 4 cm del fondo del canal, provisto por supuesto de plomo en su parte inferior para que se mantuviese próximamente vertical. Mientras que el flotador superficial de cera se movía á razón de 1.14 m por segundo, el tubo se movía (evidentemente con una velocidad casi igual á la del hilo ó filamento líquido *vertical* del centro) á razón de 1.21 m por segundo. Igualmente encontró que en el mismo canal, con velocidades del tubo central que variaban desde .46 m, á 1.22 m, la velocidad del tubo era *menor* que la velocidad media de toda la sección transversal del agua en el canal como .96 á 1 para la velocidad menor y .93 á 1 para la mayor. Mientras que, en otro canal rectangular de 6.10 m de ancho y 2.43 m de profundidad, con velocidades que variaban de .35 m á .56 por seg, la velocidad de los tubos flotadores era *mayor* que la de la masa total del agua, más ó menos como de 1.04 á 1. En un canal de 8.84 de ancho por 2.47 m de hondo, con velocidades de .91 m por seg más ó menos, era como de 1 á .9, y en un canal de 11.12 m de ancho por 2.56 m de hondo con velocidades como de 1.07 m por segundo, era, la del flotador, de 1 á .97 de la de toda la masa.

**Charles Ellet hijo, ing. civil, halló que en el Misisipí**, en diferentes puntos del río á profundidades que variaban de 16 á 30 m, y en corrientes que variaban de 5 á 11 km por hora, más ó menos, la velocidad de un flotador provisto de una cuerda de 15 m de largo, es casi siempre mayor que la de un flotador superficial solo. Los mismos resultados se obtuvieron con cuerdas de 8 y 23 m de largo, siendo el exceso de velocidad de los flotadores de cuerda más ó menos de un 2% mayor que la de los flotadores solos; y M. Ellet dedujo de esto, que la velocidad media de la sección transversal total del Misisipí, en lugar de ser menor, es absolutamente 2% mayor que la *velocidad media de la superficie*. El, sin embargo, toma .8 de la velocidad máxima de la superficie para representar aproximadamente, en su opinión, la velocidad media de toda la sección transversal del agua. En ríos de *poca profundidad* encontró siempre que el flotador superficial corría más ligero que el de cuerda.

Ensayos hechos en Europa sobre la velocidad *media en diferentes verticales de una corriente*, en ríos de profundidad regular, han dado de .85 á .96 de la velo-

cidad de la superficie en cada vertical. Debe tomarse á .90 como término medio de todo.

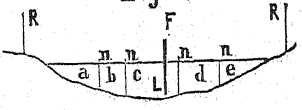
**Velocidad en el fondo.** En ríos ó arroyos de pendiente y sección transversal próximamente uniformes, hay una gran disminución de velocidad cerca del fondo. Como ligera aproximación, la velocidad mensurable más profunda, en ríos de pendiente uniforme, etc., parece ser de ½ á $^{3}/_{4}$ de la velocidad media.

**Art. 17. Para medir la velocidad en la superficie**, elíjase un lugar donde el río sea en alguna distancia (mientras más grande mejor) de una sección transversal aproximadamente uniforme y libre de contracorriente, remolinos, saltos de agua, etc. Obsérvese en un reloj de segundos cuánto tiempo emplea un flotador (como un pedazo pequeño de madera), colocado en el punto más *rápido* de la corriente, en atravesar una distancia determinada y medida previamente. Es suficiente distancia, en los ríos de poca corriente, 15 metros y hasta 50 metros en los rápidos. Esta dist dividida por el número total de segundos que el flotador emplea en recorrerla, dará en metros por segundo, la mayor velocidad de la superficie.

**La velocidad en la superficie debe medirse siempre en tiempo de perfecta calma** para que el viento no perturbe el flotador; y por la misma razón, el flotador no debe sobresalir mucho de la superficie del agua. La medida debe repetirse varias veces para obtener exactitud. En arroyos muy pequeños pueden arreglarse las orillas y el lecho en una distancia corta, de manera que presente un canal uniforme. El flotador debe ponerse en el agua un poco más arriba del punto en donde principia la observación, para que pueda adquirir la velocidad total del agua antes de llegar á dicho punto.

**Art. 18. Aforo de un arroyo por medio de su velocidad.** Elíjase un lugar en que la sección transversal permanezca, en una corta distancia, medianamente uniforme, y libre de contracorrientes, remolinos, aguas muertas ú otras irregularidades. Prepárese con cuidado una sección transversal, como en la fig. 27.

Fig 27



Por medio de jalones ó boyas, *nn*, divídase el arroyo en secciones, *a*, *b*, *c*, etc. Pónganse dos jalones R, R, en el extremo superior, y otros dos en el inferior de la distancia que han de recorrer los flotadores, para observar el tiempo, con un reloj ó péndulo, que emplean en recorrerla. Luego mídase la velocidad *media* de cada sección, *a*, *b*, *c*, etc.; separada y directamente, por medio de flotadores largos, como FL, que lleguen hasta cerca del fondo del río, y que sobresalgan un poco de la superficie. Los flotadores pueden ser tubos de hoja de lata ó reglas de madera, poniéndoles plomo en su extremo inferior hasta que floten casi verticalmente. Deben ser de diferentes longitudes, á fin de que se adapten á las profundidades de las distintas secciones. Por esta razón deben hacerse los flotadores en piezas, con juntas ó articulaciones provistas de tornillos. El área de cada sección separada del arroyo en metros cuadrados, multiplicada por la velocidad media observada del agua en metros, por segundo, dará el gasto de aquella sección en metros cúbicos por segundo. Y los gastos de todas las secciones separadas obtenidos así, darán, sumados, el gasto total del río, y este gasto total, dividido por el área total de la sección transversal del río, dará la velocidad media de *toda* el agua.

*Nota.* **Si el canal es de tierra común**, especialmente si es arenosa, las pérdidas por las infiltraciones y por la evaporación extraen á menudo tanta agua, que el gasto disminuye gradualmente más y más mientras más abajo se haga el aforo de la corriente. Por esta razón, los canales de alimentación muy largos no suministran al canal principal sino una parte pequeña del agua que les entra por su extremo superior.

**El flotador doble** se usa para determinar las velocidades á diferentes profundidades. Se compone de un flotador que descansa sobre la superficie del agua y de un cuerpo más pesado, ó « flotador inferior », que está suspendido del flotador superior por medio de una cuerda. La altura del flotador inferior depende, por supuesto, del largo de la cuerda de suspensión (que puede aumentarse ó dismi-

nuirse según se quiera hasta que se crea que el flotador inferior ha llegado á la profundidad, cuya velocidad se necesita) y de su posición vertical, que es más ó menos modificada por la corriente. Debida á esta última circunstancia es difícil saber si el flotador inferior está realmente á la profundidad deseada. Además, no se sabe hasta dónde llega la acción contraria que los flotadores ejercen en sus movimientos el uno sobre el otro. En aguas profundas la cuerda suele oponer á la corriente una área mayor que el flotador inferior. Por esta razón no se puede fijar con certeza hasta qué grado puede confiarse en la velocidad del flotador superior como indicador de la velocidad del agua á la profundidad donde se halla el flotador inferior.

**Art. 19. El cuadrante de Castelli, ó péndulo hidrométrico,** se compone de una bala metálica suspendida por un hilo del centro de un arco graduado. Se pone el instrumento en la corriente, con el arco paralelo á la dirección del agua, y la velocidad se calcula por el ángulo que forma el hilo con la vertical.

**La placa de presión de Gauthey** era una lámina de metal suspendida de uno de sus extremos, á cuyo alrededor podía girar libremente. Se sumergía la placa en la corriente, colocando su cara en ángulo recto á ella. Se estimaba la velocidad por el peso necesario para que la lámina tomase la posición vertical opuesta á la fuerza de la corriente.

**El tubo de Pitot** era en su origen un simple tubo de vidrio, fig. 27 A, abierto por ambas extremidades y doblado en forma de L. Una rama de la L estaba fija horizontalmente debajo del agua con su extremidad abierta dándole el frente á la corriente, y se medía la velocidad $v$ en el punto $o$ donde estaba colocado, por la altura vertical $h$ $\left(\text{teóricamente} = \frac{v^2}{2g}\right)$ á la cual el agua subía en la otra rama sobre la superficie de la corriente.

Fig. 27A

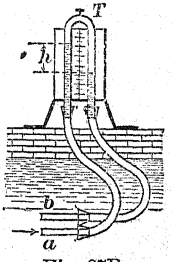


Fig. 27B

**Modificado por M. Darcy y por el profesor S. W. Robinson,** toscamente dibujado en la fig. 27 B, el tubo de Pitot se compone esencialmente de *dos* tubos horizontales de vidrio ó de metal $a$ y $b$ de un diámetro interior muy pequeño, colocados uno al lado del otro en la corriente y dirigidos en contra de ella. El tubo $a$ recibe ésta por su extremo abierto colocado aguas arriba, mientras que el tubo $b$ tiene cerrado el extremo que mira hacia aquel lado y tiene solamente pequeños orificios *laterales*. La otra punta de cada tubo está en comunicación por medio de un pequeño tubo de caucho ó de metal con la rama de un tubo en forma de U invertida, de vidrio y graduado, fijo en un bote ó en la orilla de una corriente. Por conveniencia, los dos tubos flexibles deben unirse entre sí, formando un tubo doble. Por succión hecha en la llave T que está en la parte superior, el agua sube á una altura conveniente en las dos ramas del medidor. Cuando no hay corriente las dos columnas de agua permanecen á la misma altura; pero en una corriente, la diferencia $h$ de sus alturas es tal, que $v = \sqrt{2gh}$ sin necesitarse de coeficiente de corrección. El instrumento es notablemente sencillo y exacto, y puede usarse en corrientes de agua ó gas angostos y poco profundos. Este instrumento aprecia velocidades hasta de .10 m por segundo.

En la práctica, $a$ y $b$ se fijan juntos en una sola pieza y se colocan, para usarlos, en un marco de metal que se desliza verticalmente, ó sobre un alambre que pasa por él provisto de una plomada que descansa en el fondo y mantiene tenso el alambre (ó en corrientes de menos de 6 m de profundidad), se ponen sobre un

bastón vertical de madera cuya punta inferior se fija en el lecho de dicha corriente. En el primer caso, el marco está provisto de una veleta larga, para mantener el instrumento aguas arriba. En uno ú otro caso, se proveen medios para indicar la profundidad á la cual está sumergido el instrumento.

Haciendo que la escala graduada se adapte verticalmente y colocándola (en cada cambio de profundidad del instrumento) con el cero opuesto á la parte superior de la columna, evitamos la necesidad de observar la altura de ambas columnas de agua en cada lectura; porque la lectura de la columna superior sola, da desde luego la carga $h$.

**Art. 20. El medidor ó contador de rueda**, es una rueda que la corriente hace girar y que comunica su movimiento por medio de su eje y engranajes á indicadores que registran el número de revoluciones. Este instrumento puede fijarse en un punto cualquera de una vara larga que llegue hasta el fondo del arroyo, y por lo tanto puede usarse para cualquiera profundidad. El observador, por medio de un alambre, varilla ó cuerda, que llegue hasta el instrumento, engrana primero el aparato de registro y después lo desengrana con la rueda (por medio de un freno que se aplica al primero en el momento de desengranarlo), anotando cuidadosamente la hora á que lo hace. Luego se levanta el instrumento y se lee en los índices el número de revoluciones hechas en el tiempo anotado y con esto se calcula la velocidad. Pero el contador se hace á menudo de **registro automático**; la rueda en cada revolución interrumpe y restablece automáticamente una corriente eléctrica engendrada por una batería. El alambre que conduce esta corriente se hace obrar sobre un aparato registrador eléctrico de Morse, colocado en un bote ó en la orilla. Algunos medidores ó contadores arreglados así, pueden fijarse en diferentes puntos de la vara al mismo tiempo, y por consiguiente registran **observaciones simultáneas de velocidades á diferentes profundidades.**

La mayor parte de sus contadores se hacen de manera que puedan libremente moverse horizontalmente alrededor de una vara larga, á la cual están fijos, y cada uno está provisto de una aspa ó veleta semejante á la de los molinos de viento, para sostener la rueda en la posición que se desee con respecto á la corriente. Generalmente se hacen las ruedas como las de los molinos de viento, es decir, con sus aletas colocadas formando un ángulo tal que presente á la corriente una superficie inclinada, y el eje de la rueda paralelo á la dirección de dicha corriente. El eje se mueve en chumaceras de ágata. Si se quiere se puede proveer á la llanta de la rueda de un receptáculo de aire para equilibrar su peso y suprimir de este modo el rozamiento continuo debido á dicho peso. Los medidores ó contadores provistos de aparatos de registro eléctricos, tienen algunas veces el engranaje y los índices, etc., encerrados en una caja de vidrio para evitar que se emboten con la introducción en ellos de hierbas, sedimentos, etc.

**El contador de ruedas se regula** moviéndolo en el agua tranquila con una velocidad conocida y anotando el efecto producido. Por este medio se obtiene un coeficiente para cada contador, el cual, multiplicado por el número de revoluciones registradas en cada caso, dará la velocidad.

*Nota* 1. **Debe tenerse cuidado de que la velocidad en el fondo no sea tan grande que lo desgaste**; si hay ese temor debe protegerse la superficie del canal artificialmente; ó puede reducirse la altura de caída y aumentar la sección transversal del canal, de manera que se logre el mismo gasto con menos velocidad. También debe tenerse en cuenta, en la construcción de tales canales, lo que sube la corriente al tropezar y levantarse sobre las plantas acuáticas que se forman por los depósitos de lodo traídos en las aguas de lluvia, y á veces por el soplo de vientos fuertes contra la corriente.

*Nota* 2. **El agua que corre en un canal de fondo horizontal no puede tener una velocidad, ni una profundidad uniforme, á lo largo de su curso**, porque se necesita la acción de la gravedad debida al plano inclinado, y el agua puede sólo correr formándose ella misma una *superficie* inclinada, lo que trae una disminución de la profundidad á distancias sucesivas del estanque.

**Para la teoría de la corriente** en tuberías largas y canales, velocidad media, distribución de la velocidad en la sección transversal, fórmula de Chezy, coeficiente de frotamiento, etc., véanse págs. 560, etc.

**Para la fórmula de Kutter**, véanse págs. 558, 603, etc.

**Fórmula de Bazin para la corriente en canales.** Anales de Puentes y Calzadas, 1897, 4.º trim., pág. 40.

En la fórmula de Chezy, $v = c\sqrt{rs}$, donde (pág. 561)

$v$ = velocidad media;

$r$ = radio medio = $\frac{\text{área sección transversal}}{\text{perímetro mojado}}$;

$s$ = pendiente = $\frac{\text{carga de frotamiento}}{\text{longitud}}$.

Bazin considera $c$, independiente de la pendiente, y da:

**Para medidas inglesas,**

$$c = \frac{87}{.552 + \frac{\gamma}{\sqrt{r}}}$$

**Para medidas métricas.**

$$c = \frac{87}{1 + \frac{\gamma}{\sqrt{r}}}$$

donde $\gamma$ tiene los siguientes valores:

| | |
|---|---|
| Superficies muy lisas (cemento, maderas cepilladas, etc.)..... | $\gamma$ = .06 |
| Superficies lisas (tablas, ladrillos, piedras planas, etc.)..... | $\gamma$ = .16 |
| Mampostería..... | $\gamma$ = .46 |
| Tierra muy lisa ó pavimentada con piedras picadas..... | $\gamma$ = .85 |
| — en condiciones ordinarias..... | $\gamma$ = 1.30 |
| — escabrosa..... | $\gamma$ = 1.75 |

« Midiendo la pendiente de un gran río, los errores ordinarios, en la más cuidadosa nivelación, son á veces parte importante de la caída total; la variación de nivel en una sección transversal de la superficie, es á veces tan grande como la pendiente en 10 kilómetros, ó más; el punto preciso, donde debería tomarse el nivel, es á menudo incierto; el flujo y reflujo del agua hace muy difícil decidir cuándo deben tomarse los niveles en los puntos altos y bajos; el oleaje de transporte puede afectar la inclinación en cantidad grande é incierta y hasta darle á la superficie una pendiente contraria á la que tiene. » Genl T. G. Ellis.

## Fórmula de Kutter.

Véase también pág. 558. **Para la teoría de la corriente** en tuberías largas y canales, véase pág. 561.

Ganguillet y Kutter han dado una fórmula para el valor de $c$ en la fórmula de Chezy: $v = c\sqrt{rs}$; donde $v$ = velocidad media; $r$ = radio medio = área ÷ por perímetro mojado; $s$ = pendiente = carga de frotamiento ÷ longitud.

Los hidráulicos antiguos dieron (cada uno según el resultado de sus investigaciones) **valores fijos para el coeficiente c** (generalmente más ó menos de 95 á 100 para canales en tierra ó granzón, como en nuestras primeras ediciones), haciéndolo, en otras palabras, constante é independiente de la forma, tamaño, inclinación y aspereza del canal; pero, según E. Ganguillet y Kutter, ingenieros suizos eminentes, el coeficiente $c$ está afectado por las diferencias en cualquiera de estas circunstancias. Según la fórmula de ellos (llamada por costumbre **Fórmula de Kutter.**)

**Para medidas inglesas.** **Para medidas métricas.**

$$c = \frac{41.6 + \frac{.00281}{\text{pendiente}} + \frac{1.811}{n}}{1 + \frac{\left(41.6 + \frac{.00281}{\text{pendiente}}\right) \times n}{\sqrt{\text{radio medio } \textit{en pies}}}} = \frac{23 + \frac{.00155}{\text{pendiente}} + \frac{1}{n}}{1 + \frac{\left(23 + \frac{.00155}{\text{pendiente}}\right) \times n}{\sqrt{\text{radio medio } \textit{en metros}}}}$$

**Las tablas que dan los valores de c** en sus diferentes pendientes, radio medio y grados de aspereza, están en las págs. 606, etc.

Aquí $n$ es un « **coeficiente de aspereza** » de los lados del canal, como se da más abajo.

Estos valores de $n$ fueron obtenidos después de experimentos en que se tomó el término medio de muchos de éstos, hechos bajo circunstancias muy diferentes. Por consiguiente, abarcan todas las causas perturbadoras debidas á las obstrucciones que existen en el fondo y lados del canal, en todos los casos de las experiencias. En pequeños canales artificiales de secciones transversales y pendientes uniformes, puede decirse que estas obstrucciones sólo consisten en las comparativamente pequeñas debidas á la naturaleza del material, de que está hecho el

fondo del canal. Pero en canales de ríos y tierra, aun en los casos donde la dirección general, inclinación y sección transversal son tolerablemente uniformes (como lo fueron en los casos en que se basa nuestra lista), existen otras muchas irregularidades en los lados y en el fondo, y éstas ejercen sobre la velocidad una acción retardatriz mucho mayor que las asperezas del terreno. Encontramos, por consiguiente, mayor valor dado á $n$ en tales casos, que en los de pequeños y regulares canales artificiales, aunque el material de los lados, etc., fué en muchos casos barro suave; y no debemos aplicar á estos canales comparativamente irregulares los pequeños valores de $n$ obtenidos en corrientes rectas y de sección y pendiente uniforme, aunque supongamos el fondo y lados de los primeros tan lisos como los de los últimos.

No puede aplicarse una fórmula general á los casos de **curvas fuertes** en el curso de una corriente natural, ó de **marcadas irregularidades en la sección transversal**. Tales casos requerirían aún coeficientes $n$ más grandes que los que aquí se dan para ríos y canales; deben ser determinados por experimentos hechos para cada caso y no servirían para otros. Para tales corrientes debemos, por consiguiente, basarnos sobre la medida real de la velocidad, ya directamente, ya por medio del gasto.

Hay mucha latitud para la **elección del adecuado coeficiente n** en un caso determinado, aun en los casos en que se conocen bien las condiciones del canal. Frecuentemente es necesario darle á $n$ un valor intermedio al de los establecidos; porque una mampostería de ladrillo mal hecha puede ser más áspera que una mampostería ordinaria bien acabada; pendientes laterales sobre « un granzón firme » pueden tener grados muy diferentes de asperezas, etc., etc. El ingeniero debe hacer listas de los valores de $n$ y resultados de su propia experiencia, apuntando principalmente las peculiaridades en cada caso.

Una diferencia dada en el grado de aspereza $n$ ejerce un efecto mayor sobre el coeficiente $c$, y por tanto sobre la velocidad, en los canales pequeños que en los más grandes. Por consiguiente es muy necesario que, en los casos de canales pequeños, se tenga mucho cuidado en encontrar (por experimentos, si es necesario) el adecuado valor de $n$; y cuando se desee alcanzar un gasto grande, deben hacerse especialmente muy lisos los lados en los pequeños canales.

### Cuadro del coeficiente, n, de aspereza.

El valor de **n es el mismo si el radio medio se da en medidas inglesas, ó métricas**, etc.

| | n = |
|---|---|
| **Canales artificiales de sección transversal uniforme.** | |
| Lados y fondo del canal construído de madera bien lisa | .009 |
| Cemento puro (se aplica también á tubos barnizados y tubos de hierro muy lisos) | .010 |
| Mezcla de 1 medida de arena y 3 de cemento (ó tubos de hierro liso) | .011 |
| Madera no acepillada (también se aplica á tubos de hierro ordinarios) | .012 |
| Mampostería de ladrillo | .013 |
| Mampostería ordinaria | .017 |
| **Canales sujetos á irregularidades en la sección transversal.** | |
| Canales en cascajo muy firme | .020 |
| Canales y ríos de sección transversal bastante uniforme, pendiente y dirección bastante regular y libres de piedras y hierbas | .025 |
| Canales que tienen ocasionalmente piedras y hierbas | .030 |
| Canales en mal estado y orden, llenos de vegetación y de piedras y detritus | .035 |

**Art. 22. Las siguientes tablas dan los valores del coeficiente c** obtenido por la fórmula de Kutter para diferentes pendientes, radio medio y grados de aspereza ($n$) *.

**1.º Teniendo la pendiente S, el radio medio R y el grado $n$ de aspereza, encontrar el coeficiente c.** Búsquese en la parte del cuadro que corresponde, la

* Es necesario á menudo interpolar valores de S, R, $n$ y $c$ intermedios de los de la tabla; esto puede hacerse mentalmente por una simple proporción.

pendiente dada S. Búsquese en la primera columna el radio medio dado R. En la misma línea de esta R, y bajo la *n* dada, se encuentra el valor de *c* *.

**2.º** Teniendo la pendiente S, el radio medio R y uno de los dos, ó el coeficiente *c* ó la velocidad real ó la requerida *v*, **encontrar el verdadero ó el más próximo valor n de la aspereza** del canal. Si se conoce la velocidad y no *c*, búsquese primero $c = \frac{\text{velocidad}}{\sqrt{\text{pendiente} \times \text{radio medio}}}$. Búsquese la parte de la tabla que corresponde á S dada, y en la primera columna encuéntrese la R dada. En la misma línea encuéntrese el valor dado, ó el obtenido para *c*; sobre e cual se encontrará el valor de *n* *.

**3.º** Teniendo la pendiente S, el grado *n* de aspereza y la velocidad real ó la requerida, **encontrar el radio medio R**. Supóngase un radio medio; y de la parte de la tabla correspondiente á la S dada, tómese el valor de *c* correspondiente á la *n* dada y al supuesto R. Entonces dígase :

$$v' = c \text{ así encontrado} \times \sqrt{\text{supuesto radio medio} \times \text{pendiente}}.$$

Si esta *v'* es la misma que la velocidad dada, ó bastante próxima á ella, tómese la R supuesta como verdadera. O repítase toda la operación, con un nuevo valor de R, *mayor* que el anterior si *v'* es *menor* que la velocidad dada y *viceversa* *.

**4.º** Teniendo las dimensiones de la parte mojada (*abco*, fig. C, pág. 561) del canal, el grado de aspereza *n*, y la velocidad real ó requerida, **hallar la pendiente verdadera ó necesaria, S :**

$$\text{Búsquese el radio medio } R = \frac{\text{Area de la sección transversal mojada}}{\text{Largo } abco, \text{ del perímetro mojado}}.$$

Supongamos que una de las cuatro pendientes de las tablas sea la pendiente propia. De la columna correspondiente de la tabla tómase el valor *c*, correspondiente á los valores de R y *n* dados.

Si R es 1 metro, el valor de *c* hallado así es el valor propio (porque entonces *c*, para cualquier valor dado de *n*, permanece el mismo para todas las pendientes); y la pendiente S, puede hallarse desde luego, así :

$$\text{Pendiente } S = \left( \frac{\text{Velocidad dada}}{c \times \sqrt{\text{radio medio}}} \right)^2$$

Pero si R es mayor ó menor de 1 metro, dígase :

$$v' = c \text{ (así encontrado)} \times \sqrt{\text{radio medio} \times \text{pendiente supuesta}}.$$

Si esta *v'* es bastante próxima á la velocidad dada, tómese la pendiente S supuesta, como la verdadera. Si no es así, elíjase otra S *mayor* que la última, si *v'* es *menor* que la velocidad dada, y *viceversa*, y repítase la operación *.

---

* Á menudo es necesario interpolar valores de S, R, *n* y *c* intermedios á los de la tabla. Esto puede hacerse mentalmente.

**Tabla del coeficiente c, para radios medios** *en metros.*

**Para pendientes mayores de .01** por unidad de longitud, =1 en 100, el coeficiente *c* se hace prácticamente el mismo que en esta pendiente. La *velocidad*, sin embargo, como es $= c \times \sqrt{\text{radio medio} \times \textit{pendiente}}$, continúa aumentando con la pendiente.

(*N. del T.* — Es más claro el método gráfico que damos á continuación que el que trae el autor.)

Diseño gráfico para la fórmula de la velocidad dada para Ganguillet y Kutter. (Véase la hoja págs. 608 *a* y 608 *b*).

En la fórmula de la velocidad media, pág. 558, $v = c\sqrt{\text{radio medio} \times \text{pendiente}}$; llamando R el radio medio y J la pendiente y tomando el valor *c* del coeficiente en la misma página 558, tenemos

$$v = c\sqrt{RJ} = \left[\frac{23 + \frac{1}{n} + \frac{.00155}{J}}{1 + \left(23 + \frac{.00155}{J}\right)\frac{n}{\sqrt{R}}}\right]\sqrt{RJ}$$

Las rectas $n$ dan el coeficiente $c$, en función de la naturaleza del perímetro mojado. Ellas emanan todas del punto que tiene por abscisa, $\sqrt{R} = 1$. Mientras más áspero, rugoso, es el lecho, más se aproximan las rectas $n$ á la horizontal. Las curvas J (curvas de pendiente) muestran la variación del coeficiente $c$, con la variación de la pendiente.

**Siendo dadas R, J, n**, encontrar $c$ : El punto $\sqrt{R}$ tomado como abscisa es el punto de intersección de la curva J con la recta $n$, determinando una recta que corta sobre el eje de las ordenadas un segmento igual á $c$. Ej. : Si $R = 1.7$ (es decir, $\sqrt{R} = 1.3$), $J = .0002$, $n = .025$, se obtiene el punto, $d$, juntando $a$ con $b$, y se lee $c = 45.3$.

**Dadas c, J, n**, encontrar **R** : El punto de intersección de la curva J con la recta $n$ y el punto sobre el eje de las ordenadas determinan una recta que encuentra al eje de las abscisas en un punto que es precisamente $\sqrt{R}$.

**Dadas c, R, n**, encontrar **J** : El punto $\sqrt{R}$ sobre el eje de las abscisas, y el punto $c$ sobre el eje de las ordenadas, determinan una recta que corta á la recta dada $n$ en un punto que corresponde al valor de J que se busca.

**Dadas c, R, J**, encontrar **n** : La recta que une el punto $\sqrt{R}$ sobre el eje de las abscisas y $c$ sobre el de las ordenadas, corta á la curva J dada en un punto que corresponde al valor de $n$, que se busca. »

**Cuando el agua corre á medio caño solamente,** la velocidad será la misma, según la fórmula, que cuando corre á caño lleno; pero no sucede lo mismo en cualquiera otra cantidad mayor ó menor. A profundidades mayores, la velocidad aumenta hasta que aquélla llega á ser próximamente igual á .9 del diámetro, y es entonces como 10 por ciento mayor que la velocidad á caño lleno ó á medio caño. A partir de la profundidad de .9 del diámetro, la velocidad disminuye aunque la profundidad aumente ó disminuya. A una profundidad de .25 del diámetro la velocidad es más ó menos .78 de la que corresponde al caño lleno; y luego disminuye mucho más rápidamente para menores profundidades. Todo esto se aplica igualmente á los tubos.

**Una velocidad de** 1.50 m por segundo más ó menos es la mayor velocidad que puede adoptarse en la práctica para evitar que las partes bajas de la cloaca se gasten demasiado pronto con las horruras que arrastra el agua.

**Art. 23. La proporción en que el agua de lluvia llega á una cloaca** ó alcantarilla puede hallarse aproximadamente por la fórmula siguiente de Burkly-Ziegler, según el admirable informe « *Report on European Sewerage Systems* », *de R. Hering, Civ. and San. Engineers of Philadel.;* véase *Trans. Am. Soc. C. Eng.*, noviembre 1881. (*N. del T.* — La hemos transformado para medidas métricas.)

Metros cúbicos por segundo y *por hectárea* = que llegan á la cloaca

Un coeficiente determinado á juicio según las circunstancias

× Término medio de metros cúb. de lluvia caída **por segundo por hectárea**

× $\sqrt[4]{\dfrac{\text{Pendiente media del terreno en metros por 1,000 metros (ó sea el tanto por mil)}}{\text{Número de hectáreas desaguadas} \times 2.47104}}$

**Los coeficientes** para ambos sistemas de medidas para calles pavimentadas es .75; para casos ordinarios, .625; para los alrededores de poblaciones con jardines, prados y calles macadamizadas .31.

(*N. del T.* — El ejemplo que sigue es análogo al del autor, pero cambiando todas las unidades de acres, pulgs, etc., al sistema métrico.)

**La caída media mayor de lluvia** es de 44 á 70 mm por hora, suponiéndola de 76.2 mm = .0762 m sobre un área de 1254.48 hectáreas con una pendiente, de 5 por 1,000 y adoptando el coeficiente de .5; tendremos para calcular los $m^3$, que llegarán por segundo y por hectárea á la cloaca, en la parte baja de las 1254.48 hectáreas, lo siguiente :

Los 76.2 mm de lluvia por hora equivalen á .2099 metro cúbico por segundo y por hectárea, y usando la fórmula tendremos :

Metros cúbs por seg y por hect que llegan á la cloaca =

$$.5 \times .2099 \times \sqrt[4]{\frac{5}{1254.48 \times 2.471}} = .02130485 \text{ metro cúb.}$$

Para 1254.48 hect llegarán á la cloaca por seg un total de $m^3 = 1254.48 \times .02130485 = 26.726\ m^3$.

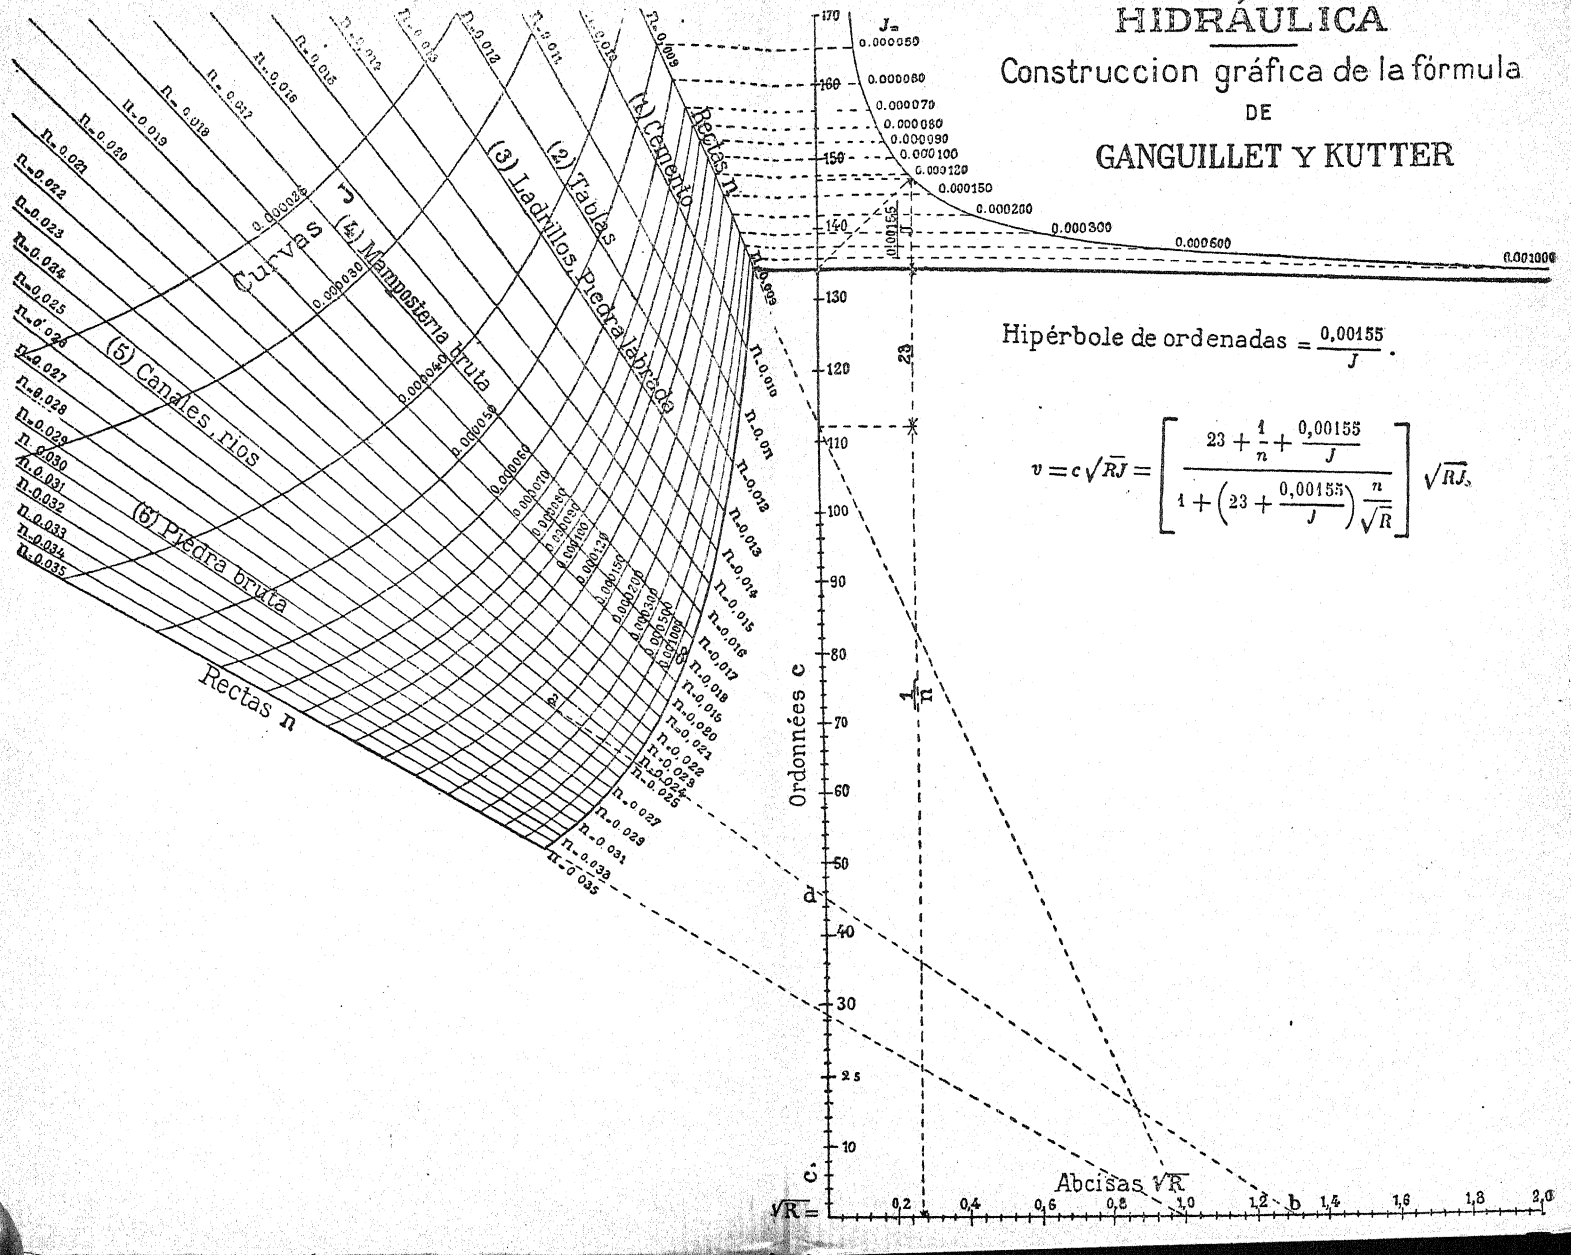
Cuando se tenga la pendiente J, la velocidad $v$ y el coeficiente de aspereza $n$, que corresponde á la especie de material con que se construye la superficie de la cloaca

# HIDRÁULICA

## Construccion gráfica de la fórmula

DE

## GANGUILLET Y KUTTER



en contacto con el agua, entonces, empleando la fórmula de Kutter ó su diagrama, se determina el radio medio R, y por ahí la sección de la cloaca, que dará pase al volumen calculado. »

La sección debe hacerse siempre un poco más amplia que la calculada.

Para una corriente de alguna constancia que arrastre basuras, la velocidad, para que el agua no gaste un fondo de ladrillos, no debe exceder de 1.50 m por segundo.

**Tabla. El Sr. Wicksteed, hidráulico inglés de experiencia, da la tabla siguiente de las velocidades, pendientes ó caídas menores, que deben darse á los tubos de desagües y á las cloacas en las poblaciones,** para que ellas se mantengan en las circunstancias ordinarias, limpias y libres de depósitos.

(*Obs. del T.* — La que sigue está deducida de la « que trae el autor en medidas inglesas »).

Las juntas se cogen con mezcla de cemento, ó, cuando los tubos se usan para desagües solamente, con greda ó arcilla. Los tubos de desagüe de 76 á 300 mm tienen un espesor de 22 mm más ó menos. Un codo ó rama bifurcada cuesta tanto como 1 á 1½ m de tubo ordinario.

Los tubos de 1.22 m de diámetro tienen más ó menos 5 cm de espesor.

**Art. 24. Cuando el área de la sección transversal de un canal está reducida en cualquier punto,** sea por un dique, fig. 33, pág. 610, ó cuando se estrechan sus paredes, fig. 32, ó porque se coloca en él una pila, etc., fig. 34; una parte á lo menos de la gravedad (que de lo contrario comunicaría *velocidad* al agua, aguas arriba del punto en donde se halla el obstáculo) ejerce *presión* contra la represa ú obstáculo. Esta presión mantiene el agua del lado arriba á un nivel más alto del que tendría si esta obstrucción no existiese.

Dicha agua se halla entonces como si estuviera en un estanque, por tener menos velocidad y más presión que antes. Si el estanque no tiene salida, entonces *no* hay velocidad, y *toda* la carga, ó fuerza de la gravedad, actuando sobre el agua

se consúme ó emplea en ejercer *presión*. Pero si hay una salida, sea por encima de la represa ó por el espacio comprendido entre los pilares, etc., una parte *co*, figs. 31, 33 y 34, de esta presión ó carga se gasta en *darle velocidad* (ó aumentársela) al agua que se escapa por aquella salida; después de lo cual sólo se requiere la carga (producida por la pendiente) para vencer las resistencias de las obstrucciones del canal del lado abajo del obstáculo y *mantener así uniforme* la velocidad que le comunicó la carga *co*.

Cuando un gran canal está alimentado por un estanque, como los destinados á la navegación, la caída *co* en metros es aproximadamente

$$= (\text{velocidad media en mets})^2 \times .055777;$$

y en los canales más pequeños, como los que se usan en los molinos,

$$= (\text{velocidad media en mets})^2 \times .06562.$$

(*N. del T.* — Estas son las fórmulas equivalentes á las que trae el autor en pies.)

Lo brusco de la caída puede disminuirse redondeando ó inclinando las orillas de las pilas, ó los ángulos de los lados del canal, fig. 32, ó el acceso á la represa.

La fig. 33 es una sección transversal del **dique de Clegg**, que atraviesa el río Cape Fear, N. C. Está trazada con medidas hechas por Ellwood Morris, I. C., quien dió los datos al autor. El dique se hizo con maderos redondos de apuntalar y el borde superior ó copete horizontal, de 8 pies 5 pulgs (2.57 m) de ancho está cubierto de tablones, sobre los cuales el agua se desliza en una lámina plana de 6 pulgs (.15 m) de profundidad (cuando se midió). En la extremidad aguas arriba de esta lámina, y á una distancia de 2 pies (.61 m) más ó menos, se forma una carga *co* de 9 pulgs (.229 m) como lo indica la figura.

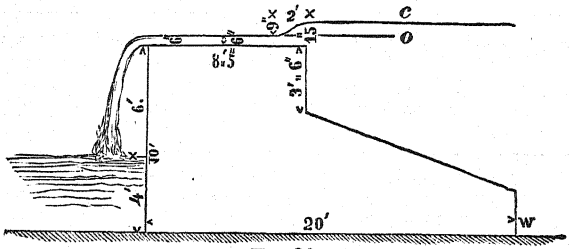

Fig 33

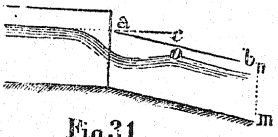

Fig 31

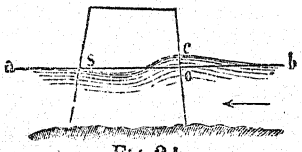

Fig 34

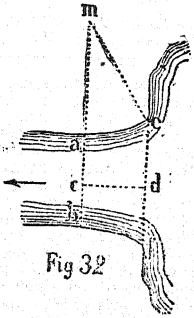

Fig 32

**Las dos tablas siguientes** fueron tomadas (con muchas correcciones) de la *Nicholson's Architecture*, y deben considerárselas meramente como aproximaciones probables. En ellas se supone que las pilas estén bien redondeadas ó que terminen por ángulos agudos en sus caras situadas hacia donde viene la corriente para dejar pasar fácilmente el agua. Nicholson dice que si dichas pilas son de caras cuadradas, la carga aumenta como 50 por ciento. Este asunto es complicado en extremo y no admite solución exacta. Si la velocidad aumentada socava ó degrada el fondo hasta el punto de que el área ó superficie del curso de agua se haga mayor de lo que era antes, la carga desaparece y la velocidad se reduce hasta su primitivo valor.

**Art. 25. Desgaste.** En un canal de pendiente y sección transversal uniforme y constante, la velocidad de las moléculas de agua contiguas al fondo y lados del canal es muy débil, y el desgaste es muy poco. Pero si hay irregularidad en la pendiente ó en la sección transversal, como se ha dicho en el último artículo, el desgaste aumenta en gran manera en sus inmediaciones.

La colocación de una ó dos pilas en una corriente de alguna magnitud produce frecuentemente un increíble deterioro ó erosión, si el fondo es de una substancia que cede á la acción de la corriente del agua. La mayor erosión tiene efecto, naturalmente, durante las crecientes y cerca de las obstrucciones.

**El desgaste se supone proporcional al cuadrado de la velocidad.**

Según Smeaton, una velocidad de 12.870 km por hora no mueve las piedras brutas de cantera que no excedan de 14 litros puestas alrededor de las pilas, etc., á menos que arrastre ó socave el terreno en que se apoyan.

*N. del T.* — Damos la tabla siguiente en sistema métrico deducida de la del autor en pulgs, pies y millas.

## Tabla de cargas producidas por obstrucciones de la corriente.

| Velocidad primitiva del curso de agua. ★ | | Naturaleza del fondo que comienza á desgastarse bajo la acción de velocidades de la corriente en el fondo iguales á las de las primeras tres columnas. | Parte del área primitiva del curso de agua ocupada por las obstrucciones. | | | | | | | | |

| 1.5240 | 5.488 | 1.70685 | 1.76781 | 1.82877 | 1.95068 | 2.13356 | 2.401779 | 3.200342 | 4.26712 | 6.40068 |
| 1.8288 | 6.582 | 2.06651 | 2.12137 | 2.19452 | 2.3042 | 2.56027 | 2.89045 | 3.840417 | 5.120546 | 7.68082 |
| 3.0479 | 9.960 | 3.44418 | 3.53592 | 3.657 3 | 3.84041 | 4.27712 | 4.815756 | 6.40068 | 8.53425 | 12.8014 |

Si son *cuadradas*, estas velocidades deben aumentarse en 1/8 según Nicholson.

**Art. 26. La resistencia que opone el agua al movimiento de una superficie plana colocada perpendicularmente á ella**, es casi como el cuad de su velocidad, y, según Hutton, su valor aproximado en libs por pie cuad es = cuad de la velocidad en pies por segundo.

(*Obs. del T.* — Este valor en kilog por metro cuad = (aproximadamente), al cuad de la velocidad en metros multiplicado por la constante 52.557.

Ej. : Supongamos $v$ = 1 pie = .304794; $v^2$ = 1 pie cuad = .0929 m cuad; luego tendremos :

$$\text{Resistencia en libs por pie cuad aprox} = v^2 = 1 \text{ libra.}$$

$$\text{Resistencia en kilog por m cuad.} = \begin{cases} v^2 \times 52.557 = .0929 \times 52.557 = 4.883 \text{ kilogramos} \\ (= 1 \text{ libra por pie cuad}), \end{cases}$$

**ó lo que es lo mismo, la presión que ejerce una corriente de agua** contra una superficie plana vertical fija, es = al peso de una columna de agua cuya base sea igual á la superficie comprimida y que tenga por altura la carga que corresponda á la velocidad $\sqrt{2gh}$. (En la unidad que se elija.)

La resistencia de una esfera es á la de su círculo máximo como 1 es á 2.9.

Cuando la superficie en movimiento en lugar de formar ángulo recto con la dirección en que se mueve, forma otro ángulo con ella, la resistencia se hace menor (más ó menos) en la relación que sigue. Por lo tanto, cuando la superficie es inclinada, calcúlese primero la resistencia como si estuviera en ángulo recto, y multiplíquese luego por las decimales que siguen situadas frente al ángulo de inclinación en este cuadro :

| | | | |
|---|---|---|---|
| 90° .... 1.00 | 60° .... .88 | 40° .... 58 | 20° .... .16 |
| 80 .... .98 | 55 .... .83 | 35 .... 46 | 15 .... .10 |
| 70 .... .95 | 50 .... .76 | 30 .... 34 | 10 .... .06 |
| 65 .... .92 | 45 .... .68 | 25 .... 24 | 5 .... .02 |

**La fuerza de desgaste del agua corriente** se supone proporcional al cuad de la velocidad.

**Art. 27**. Para calcular en caballos la fuerza de una caída de**

* Véase nota página anterior.

** *N. del T.* — Dejamos este ejemplo en ambos sistemas de medidas, por creer útil para los ingenieros, que respectivamente los usan, practicar esta conversión con unidades de tan frecuente empleo.

**agua.** Sabemos que por caballo de fuerza se entiende la fuerza necesaria para levantar 33,000 libs verticalmente á 1 pie de altura en un minuto. (La fuerza de un caballo ordinario es generalmente la que se necesita para levantar como las $^2/_3$ partes, ó sean 22,000 á un pie de altura en un minuto.) Multipliquense entre sí el número de pies cúbicos de agua que caen por minuto, la altura vertical de caída ó carga en pies y el número 62.3 (peso de un pie cúbico de agua), y divídase el producto por 33,000. O, traduciéndolo á una fórmula :

$$\text{Número de caballos de fuerza} = \frac{\text{Gasto en pies cúb por minuto} \times \text{altura vertical en pies} \times \text{libras que pesa un pie cúb de agua.}}{33{,}000}$$

*Obs. del T.* — Para mayor claridad en la apreciación de ambos sistemas de medidas (inglés y métrico), recordamos aquí que por *potencia de un motor*, se entiende el producto del esfuerzo (peso, presión, etc.) por el camino recorrido en un segundo; la unidad es **el kilográmetro**, por segundo, ó sea la potencia necesaria para elevar un kilogramo á 1 metro de altura en un segundo. **Setenta y cinco kilográmetros** (*potencia necesaria para elevar 75 kilogms á un metro de altura en un seg) es lo que* **se llama caballo de fuerza ó caballo de vapor** (Force de cheval), unidad adoptada en el sistema métrico para medir la potencia de una máquina, caída de agua, etc., etc. En consecuencia, la fórmula que en este sistema corresponde á la del autor es :

$$\text{Potencia en caballos, de una caída de agua} = \frac{\text{gasto en mets cúb por seg} \times \text{caída en metros} \times \text{kilogs que pesa un metro cúb de agua}}{75}.$$

**Ej.:** Sea una cascada de 16 pies (4.87671 m); gasto 800 pies cúbs=22.65225 mets cúbs por minuto=.377537 met cúb por seg). ¿Cuántos caballos de fuerza desarrollará esta caída?

(*Obs. del T.* — Para que sean comparables las fórmulas en medida inglesa con las métricas, tomemos el agua á 4° C; el pie cúbico á esta temperatura pesa 62.4245 libras y el met cúb 1,000 kilogs.)

Por la fórmula en medidas inglesas tenemos entonces :

$$\frac{800 \times 16 \times 62.4245}{33{,}000} = \frac{799{,}033.6}{33{,}000} = 24.21 \text{ caballos (Horse-power),}$$

y por la dada en sistema métrico :

$$\frac{.377537 \times 4.87671 \times 1{,}000}{75} = \frac{1840.86}{75} = 24.5484 \text{ (caballo métrico).}$$

Si multiplicamos este número de caballos obtenido por .9863, relación del caballo de fuerza, inglés al francés, obtendremos el mismo número suministrado por la primera fórmula. Ponemos también aquí la relación que hay entre uno y otro caballo de fuerza :

1 caballo de fuerza (inglés) =1.01385 caballos de fuerza (francés);
1 — — (francés)= .986337 — — (inglés).

**Las ruedas hidráulicas** no producen toda la fuerza que tiene el agua, calculada por esta última regla. Las ruedas que reciben el agua por debajo producen sólo de $^1/_4$ á $^1/_3$; las que les llega por un costado ½; y las que la reciben por arriba de $^2/_3$ á $^3/_4$; las turbinas $^3/_4$ á .85 de la fuerza total del agua; según la disposición de cada rueda, y la perfección de la obra de mano. Aunque giran dentro de una cabidad ó cubierta de fundición apropiada y bien ajustada, los cajones con codos ó en ángulo comunican más potencia que los cajones centrales ó en dirección del radio. De la fuerza real recibida por una rueda, una parte se consume en rozamientos, etc., mientras que la restante realiza el trabajo útil de elevar agua, moler granos, aserrar, etc.

**Las observaciones hechas por el general Haupt**, en 1886, dieron los resultados siguientes con un **ariete hidráulico** pequeño. Carga del ariete= 2.686 m; diámetro del tubo alimentador=38 mm; longitud=4.572 m; diámetro del tubo de salida=19 mm; longitud=60.959 m. Altura vertical á la cual se elevó el agua=19.324 m. Golpes del ariete por minuto 170. Cantidad de agua que actuaba sobre el ariete=.0125846 mets cúbs=12.58 kg.

Cantidad elevada á la altura de 19.324 m por minuto=.0007865 mets cúbs

por min = .78765 kg por min. Por lo tanto la fuerza gastada por minuto = $12.58 \times \frac{\text{kilog agua}}{\text{metros}}$ 2.686 = 33.79 kilográmetros; y efecto útil = .7865 × 19.324 = 15.199 kilogmtros

Por consiguiente la relación es $\frac{15.199}{33.79} = .45$. (*N. del T.* — El ejemplo anterior es el que corresponde al del autor, en medidas inglesas.) Sin embargo, la fuerza real desarrollada por el ariete es mayor que ésta porque aquel tiene que vencer el rozamiento del agua en todo el tubo de salida *.

**Hallar la fuerza (en caballos) de una corriente.** Las ruedas hidráulicas de paletas planas ** (sin cajones), son movidas algunas veces por la sola fuerza de una corriente natural sin caída apreciable. En estos casos debemos buscar la carga *virtual ó teórica* que es la carga capaz de producir la velocidad que la rueda tiene realmente. La carga teórica puede encontrarse de una vez por la fórmula $\sqrt{2gh}$. Así, si un río tiene una velocidad de 1.5 m por segundo, tendremos $h = \frac{v^2}{2g} = \frac{(1.5)^2}{19.62} = .114$. Hallada así la carga, debemos buscar ahora la cantidad de agua que pasa en un minuto por una sección transversa de la corriente. Si suponemos que la parte *sumergida* de una paleta, cuando está vertical, es de 1.524 m de largo, y de .305 m de ancho, entonces el área de esta parte que recibe el empuje de la corriente es 1.524 × .305 = .465 met cuad. Por lo tanto, .465 m² × 1.5 m = = .697 m³ por segundo. Teniendo ahora los metros cúbs por segundo y la altura vertical ó carga, se halla el número de caballos de fuerza de la corriente sobre el área dada por la siguiente fórmula.

$$\text{Fuerza en caballos} = \frac{\text{Gasto en mets cúbs por seg .697} \times \text{altura ó carga en mets .114} \times \text{peso del met cúb de agua 1,000}}{75} = \frac{79.458}{75} = 1.058.$$

Pero en la práctica las *ruedas* no producen sino, más ó menos, $^1/_{10}$ parte de la fuerza de *la corriente*. La velocidad de la corriente no debe medirse en la superficie sino en la mitad de la profundidad á que llegan las paletas. Esto es más necesario aún en los ríos de poca profundidad, donde la parte sumergida de la paleta es una tracción considerable de aquélla.

**La fuerza de una corriente (para cualquier sección transversal dada) aumenta como los cubos de las velocidades**; porque, como hemos visto, la fuerza se encuentra multiplicando entre sí el peso del agua que pasa por la sección transversal y la carga teórica; y como este peso aumenta como la velocidad, y esta carga como el cuadrado de la velocidad, el producto de los dos (ó la fuerza) está como el cubo de la velocidad.

---

* **Un comité del « Franklin Institute »**, en 1830, dió .71 como el coeficiente de un ariete en el Colegio Girard, en el cual el diámetro del tubo alimentador era de 63 $^1/_2$ mm; su largo, 48.77 m; su caída, 4.26 m. Tubo de salida, 25 mm diámetro: 688.84 m de largo; elevación vertical, á la cual se llevó el agua, 28.346 m. No hay detalles del experimento. En Francia algunos arietes grandes dan un *efecto útil* de .60 á .65 de la fuerza total empleada. El ariete *hidráulico* es una máquina excelente en muchos casos, y se usa muchas veces para llenar depósitos de agua en las estaciones de ferrocarriles.

** **Esta especie de ruedas, para molinos flotantes, en Europa**, raras veces tienen un diámetro mayor de 4.572 m. Cualquiera que sea el diámetro, ellas pueden tener de 18 á 20 paletas, las paletas son de 2.44 m á 4.88 m de largo; y profundizan más ó menos 1/8 á 1/10 del diámetro de la rueda. No deben sumergirse en toda su profundidad, y no deben estar en la prolongación de los radios de la rueda; sino inclinados 30° aguas arriba, para producir su efecto total. Todas estas observaciones se refieren á ruedas que se mueven libremente en un canal ó río indefinido; como en el caso de un molino flotante, construído sobre una lancha, y anclado en el río, pero no en ruedas, para las cuales se represa el agua y obra por caída. No puede esperarse gran exactitud de las reglas sobre esta materia. La mejor velocidad para una rueda es más ó menos .4 de la que tiene la corriente.

# DRAGADO

El dragado es hecho, generalmente, por contratistas diestros que poseen las máquinas necesarias, lanchas, etc., y que tienen este trabajo como una especialidad. Es necesario estipular si el material ha de medirse en el lugar donde esté antes de excavarlo ó después de excavado y depositado en la lancha; porque en este último caso hace más volumen. En las extensas excavaciones hechas para profundizar el río San Lorenzo, en el lago de San Pedro, se halló por término medio que, un metro cúbico de fango duro antes de excavarse, equivale á 1.4 m cúb puesto en la lancha, ó bien 1 en la lancha = .715 antes de excavar. También debe estipularse si la extracción de piedras grandes, árboles sumergidos, etc., constituye un trabajo extra ó no. Muchas veces es necesario aserrarlas ó romperlas debajo del agua.

El costo por metro cúbico de dragado varía mucho con la profundidad del agua, la cantidad y calidad del material, la distancia á la cual ha de llevarse éste; si la descarga se hace de una vez con la máquina por medio de canales colocados al lado de ella, ó si se hace en lanchas que puedan llevarse á una pequeña distancia por medio de remos, ó á una distancia mayor por remolcadores de vapor; si se le puede arrojar en aguas profundas por una puerta falsa practicada en el fondo de la lancha, ó si debe palearse de las lanchas para aguas **de poco fondo** (de 7 á 13 centavos por $m^3$), ó echarse á tierra (quizás de 10 á 17 ó 34 centavos por palear solamente, ó palear y transportar en carretillas de mano, según el caso) si hay que gastar mucho tiempo en mover á menudo la máquina hacia adelante como cuando la excavación es angosta y de poca profundidad, por ejem para ahondar un canal, etc.; si hay que levantar muchas piedras grandes ó árboles sumergidos ó que haya interrupciones por causa del oleaje en tiempo de tempestad; si se puede obtener fácilmente carbón ó leña para las máquinas, etc.

Estas consideraciones pueden hacer el costo por m cúb 2 ó 4 veces mayor. El costo real para profundizar el canal de navegación á través del lago San Pedro, á 5.5 m de su profundidad original de 3.3 m y por varias millas de fango moderadamente duro, fué de 18 centavos antes de excavar y 13 centavos en las lanchas; incluyendo la traslación del material á una distancia de 304 m más ó menos por remolcadores de vapor vaciándolo en agua profunda. Esto comprende reparación de instrumentos y material de toda clase; pero sin contar la utilidad. El caso era favorable. Cuando los tobos trabajan en aguas hondas no se llenan tan bien como en aguas de poca profundidad, porque tienen un movimiento más vertical y, por consiguiente, no se arrastran bien á una distancia grande del fondo. Esta es una de las causas por qué el dragado en aguas profundas es más costoso, y además el tener que levantarlo á una altura mayor.

Tal vez la tabla que sigue sea tolerablemente aproximada para grandes trabajos en fangos ordinarios, arena ó granzón, suponiendo los instrumentos pagados por la Compañía, y que el precio de jornal ordinario sea de un dólar.

**Tabla del costo real del dragado en grande escala, incluyendo la echada del material entre las lanchas al costado de la draga, ó en canales laterales á bordo. — Trabajo ordinario $ 1 por día. Se incluye la reparación de los útiles, pero no la utilidad del contratista.** (*N. del T.* — La tabla que sigue es equivalente á la del autor en medidas inglesas.)

| Profundidad en metros. | Centavos por metro cúbico antes de excavar. | Centavos por metro cúbico en la lancha. | Profundidad en metros. | Centavos por metro cúbico antes de excavar. | Centavos por metro cúbico en la lancha. |
|---|---|---|---|---|---|
| Menos de 3 m | 11 | 7.8 | 7.5 á 9 | 23.6 | 16.9 |
| — 3 á 4.5 | 12.8 | 9.1 | 9 á 10.5 | 32.7 | 28.4 |
| — 4.5 á 6 | 14.5 | 10.4 | 10.5 á 12 | 45.5 | 32.5 |
| — 6 á 7.5 | 18.2 | 13 | | | |

Para remolcar las lanchas con vapores á una distancia de 400 m y dejar caer el fango en aguas profundas, agréguese 5 centavos por metro cúb; á 800 m, como 8 centavos; por 1,600 m, como 13 centavos. Agréguese la utilidad del contratista. El trabajo en pequeña escala es menos ventajoso y por consiguiente debe hacerse un aumento en estos precios. También si el contratista mismo suministra la draga y accesorios, debe hacerse otra adición al precio. Es evidente que esta materia no admite gran exactitud. Los trabajos en pequeña escala, aunque el material sea favorable, pero en puntos no convenientes, pueden fácilmente costar dos ó tres veces más que el anterior, y en material muy duro, como granzón y greda compactados, puede costar su dragado cuatro ó cinco veces más. El costo de remolcar, sin embargo, es lo mismo siendo los salarios iguales en ambos casos.

El costo de las dragas, y remolcadores depende de su capacidad, solidez en la construcción, etc.; y además de la comodidad á bordo para vivir la tripulación. Cuando las excavaciones se hacen en agua salada, los fondos de las dragas, lo mismo que los de las lanchas, deben forrarse con cobre para protegerlas contra la acción corrosiva de aquélla; y si algunas veces están expuestas á oleajes, deben ser de construcción más fuerte. Las máquinas de más potencia usadas en el río San Lorenzo costaron más ó menos $45,000 cada una y mudaron en 10 horas de trabajo una cantidad media de 1376 $m^3$ medidos antes de excavar, ó 1927 $m^3$ en las lanchas. Sin embargo, las máquinas buenas, capaces de ejecutar igual trabajo, pueden construirse por $25,000 ó 30,000, más ó menos. Para trasladar esta cantitad de material excavado á una distancia de 800 á 1,600 m, se requieren dos remolcadores de vapor de un costo de $6,000 á $10,000, más ó menos cada uno; y de 4 á 6 lanchas (llenando unas mientras las otras están llevando el material) que carguen de 22 á 44 $m^3$ cada una, y que cuestan de $800 á 1,500 cada una en la fábrica. Las lanchas con dos tolvas son las mejores. Una draga como la descrita aquí, necesitaría, por lo menos, de ocho á diez hombres de tripulación, incluyendo capitán, ingeniero, fogonero y cocinero. Cada remolcador, cuatro ó cinco hombres, y cada lancha, dos. El ingeniero debería ser herrero al mismo tiempo, ó agregar un herrero. En ciertos casos pudiera necesitarse médico, contador, ingeniero auxiliar, etc.

Las dragas se construyen á menudo según el principio del « Excavador Yankee », con una sola tolva de .75 á 1.5 $m^3$. Casco de 7 á 18 m, más ó menos. Calado, 1 m. Cilindro de 18 á 20 cm de diámetro. Carrera de émbolo de 38 á 45 cm : presión de vapor ordinario de 3.5 á 6 kg por cm cuad, según la condición del material. Costo, $8,000 á 12,000. Esta draga extraerá por día de trabajo medio (10 horas) de 150 á 400 $m^3$ de material, medidos antes de la extracción, ó de 200 á 530 $m^3$ puesto en las lanchas, según la profundidad, clase de material, etc. Se requieren por todo de 5 á 7 hombres á bordo, incluyendo el cocinero. Gastos de carbón = ½, ó 1 tonelada por día. Las piedras grandes, de tamaño regular, y los árboles sumergidos pueden sacarse por medio del cucharón (*dipper*) *.

Cuando el material es duro y compacto, los tobos de las dragas deben estar provistos de dientes fuertes de acero que sobresalgan de su arista cortante. Al encontrar esta clase de material, algunas veces se aplican todos estos tobos alternativamente. Si se arreglan los tobos de tal manera que efectúen la excavación á pocos metros delante del casco de la draga, pueden excavarse tiras largas de tierra seca, haciendo la máquina de este modo su propio canal.

El trabajo de un día será en este caso, más ó menos, la mitad del trabajo en terreno húmedo.

En trabajos pequeños, las **dragas maniobradas por dos ó más caballos**, en vez de vapor, dan buen resultado si el material que se excava es blando, ó aun si el material es moderadamente duro, si se reduce el número y tamaño de los tobos. Una máquina de dos caballos puede levantar de 40 á 80 $m^3$ de fango ordinario, medido antes de excavar, ó 50 á 100 puesto en la lancha, por día, y de una profundidad de 3.5 á 4.5 m.

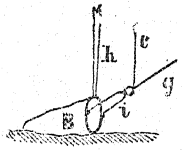
El material blando, á una profundidad moderada, puede sacarse en pequeñas cantidades por el método lento y costoso de **draga de mano**.

Ésta se compone simplemente de un saco B, hecho de lona ó cuero y provisto

---

* El autor ha visto casos en que hubiera sido de gran utilidad la adición á la draga de una sierra circular para aserrar los trozos de madera sumergidos en aguas profundas, maniobrada al vapor y adaptable á diferentes profundidades; su precio sería $ 500 más ó menos.

en su boca de un anillo de hierro, el cual, en su parte inferior, tiene un filo cortante. Contiene un mango fijo *h* y uno giratorio *i*. El modo de usarlo es el siguiente : Un hombre introduce el saco dentro del fango por medio del mango *h*,



y otro hombre lo arrastra con la cuerda *g*, y cuando está lleno otro lo levanta con la cuerda *c* y lo vacía.

Si el saco es grande puede emplearse un cabrestante para izarlo. Los hombres pueden trabajar á bordo de una lancha ó de una balsa anclada convenientemente. Puede emplearse también una especie de cuchara de metal con un mango largo, de la forma de una azada honda y concava, la cual puede ser aplicada por un hombre solo, ó un hombre puede guiar una cuchara, y por medio de un caballo que marche á bordo, alrededor de un círculo, comunicarle movimiento hacia adelante y hacia atrás.

**El peso de un metro cúbico** de fango excavado mojado, arena pura ó granzón, es, por término medio, de 1 $^{3}/_{4}$ toneladas más ó menos; el granzón con lodo=2 ton; la arena pura y el granzón se dragan fácilmente; también las capas de conchas. La greda excavada mojada se desliza por un canal de tablas de una inclinación de 5 en 1, ó de 3 á 1, según se encuentre libre de arena, etc.; pero, la arena mojada ó granzón, no corre aun con una inclinación de 3 en 1, sin una corriente de agua que le ayude á deslizarse, pues de cualquier otro modo hay que empujarla mucho.

# CIMENTACIONES

Esta importante materia podría llenar un volumen. Sólo tenemos espacio para algunas apreciaciones generales, dejando al que estudia que determine hasta dónde pueden ser aplicables en un caso dado. En casos ordinarios, tales como para alcantarillas, muros, etc.; si las excavaciones, pozos, etc., hechos, en las inmediaciones, no han probado que el terreno permite una excavación profunda, será en general suficiente precaución, después de haber excavado y nivelado á una profundidad de 1 á 1.5 m, probar el terreno por medio de una vara de hierro ó un taladro, ó cavando agujeros en diversos puntos á la profundidad de 1 á 2 m (según el peso de la construcción que se pretenda hacer) para averiguar si el terreno continúa firme hasta aquella profundidad. Si así es, rara vez habrá peligro en proceder inmediatamente á construir la mampostería; pues una capa de terreno sólido de 1 á 1.5 m de espesor será firme para casi todos los edificios ordinarios, aun en el caso de que aquélla se apoyara en una capa mucho más blanda. Sin embargo, si la capa firme superior está expuesta á corrientes de agua, como en el caso del estribo de puente sobre un río, deben tomarse precauciones á fin de preservarlo del desgaste gradual por la corriente, ó de que se desmorone ó derrumbe por innundaciones fuertes, especialmente cuando arrastran grandes masas de hielo, árboles y otras materias flotantes. Éstas son detenidas á veces por las pilas y se acumulan de tal modo que forman diques que se extienden hasta el fondo de la corriente, creando con esto un aumento de velocidad y de acción destructora muy peligrosos, tanto para la estabilidad del cimiento como para la de la construcción. Cuando se necesita hacer la prueba á una profundidad considerable, será necesario encajar un tubo de hierro forjado ó fundido para impedir que la tierra caiga en el agujero sin terminar. Este tubo puede ser formado de trozos cortos unidos por empates de tornillo para manejarlos y dirigirlos mejor, y la tierra que se encuentra

en su interior puede removerse por medio de una cuchara pequeña con mango largo *.

**Taladrando en terrenos comunes** ó arcillosos pueden hacerse hasta 30 m de profundidad en un día ó dos por medio de un taladro de madera ordinario de 38 mm de diámetro, con palanca de un metro movida por 2 ó 4 hombres. Esto hará subir muestras del terreno.

Al empezar la mampostería deben, por supuesto, colocarse las piedras más grandes en la parte inferior de la fosa, de manera que se distribuya igualmente la presión lo más posible, y se debe tener cuidado de colocarlas sólidamente en el terreno á fin de que no haya tendencia á oscilar. Algunas de las capas subsiguientes por lo menos, deben ser también de piedras grandes colocadas de manera que sus junturas *no* se correspondan con las de abajo. Los huecos que quedan en las fosas deben rellenarse con tierra tan pronto como lo permita el trabajo de mampostería, á fin de evitar que la lluvia perjudique la argamasa y reblandezca los cimientos. Será conveniente apretar un poco la tierra á proporción que se deposita.

Si las pruebas demuestran que el terreno (no expuesto á corrientes de agua) es demasiado blando para soportar la mampostería, se harán los fosos considerablemente más anchos y profundos y se llenarán luego en toda su extensión (y á una profundidad como de 1 á 2 m ó más (según el peso que deban sostener) con capas pisadas, comprimidas de arena, cascajo ó piedras machacadas, ó con concreto en el cual haya una buena proporción de cemento. Sobre este depósito la mampostería se sostendrá bien. La práctica común, seguida á veces, de colocar planchas ó plataformas de madera en los cimientos para fabricar sobre ellos, es muy mala, porque si las planchas no se mantienen húmedas constantemente, se destruirán en pocos años y producirán grietas y hundimientos en la mampostería.

Algunas de las partes del acueducto de ladrillo ** que suple de agua á Boston presentaron muchos inconvenientes en los lugares en que los fosos pasaban por arena movediza y otros materiales traicioneros. Se empleó el concreto; pero la arena movediza mojada se mezclaba con él y lo destruía. Las armazones de madera, etc., tampoco dieron resultado, y finalmente se venció la dificultad depositando simplemente en los fosos como 60 cm de profundidad de cascajo grueso ***. La arena ó el cascajo, *cuando se evita que se esparza hacia los lados*, constituyen uno de los mejores cimientos. A fin de impedir este esparcimiento, el área donde se va á fabricar debe ser rodeada por un muro ó por estacas cuadradas colocadas, tan unidas, que se toquen unas con otras, y en casos de menos importancia sólo por tablas delgadas. Pero generalmente bastará hacer los fosos y rellenarlos con arena ó cascajo en capas (mejor si están húmedas), teniendo cuidado de compactarlas bien contra los lados del foso.

Los grandes pesos producen algún descenso (un pequeño hundimiento), como sucede en todas las fundaciones, con excepción de las que se hacen en roca. Si la construcción es muy pesada adóptese el sistema de estacas, etc. Véase « Empa-rrillado ».

**Cuando un terreno inseguro descansa sobre uno firme,** pero á tal profundidad que la excavación de los fosos (los cuales evidentemente deben ser más anchos y más profundos) se hace demasiado difícil y costosa, especialmente cuando (como generalmente sucede en estos casos) se filtra el agua rápidamente por las capas adyacentes, tenemos que recurrir á las estacas. Al hacer fosos para cimientos profundos en **arcilla húmeda**, debemos recordar que esta materia, siendo blanda, tiene tendencia á comprimirse hasta cierto punto en todas direcciones. Esto hace que haga barriga, es decir, se combe hacia dentro en los lados, y hacia arriba en el fondo. Las excavaciones para túneles ó para pozos verticales, á menudo se estrechan por todas partes, y se contraen mucho antes que puedan ser revestidas; por consiguiente, deben hacérselas más anchas de lo que sería necesario sin este motivo. La base de las excavaciones de canales y caminos de hierro sobre arcilla húmeda, se levanta generalmente hacia arriba por

* Las cavernas subterráneas en regiones de piedra caliza son fuentes de inconvenientes contra las cuales es difícil adoptar precauciones.

** El acueducto de Cochituate edificado de 1846-1848 : es ovalado de 1.93 m por 1.82 m en semicírculo invertido.

*** Smeaton menciona un puente de piedra construído sobre un lecho natural de arena de cerca de 60 cm de espesor solamente, colocado sobre un fango profundo tan blando, que una vara de hierro de 12 m de largo se hundió toda por su propio peso. Una de las pilas se hundió mientras echaban los arcos y fué repuesta por Smeaton. A pesar de este desgraciado precedente, este ejemplo demuestra el poder de resistencia d una capa gruesa de arena bien compacta.

el peso de los lados. La **arcilla seca** absorbe rápidamente la humedad y se hincha, produciendo efectos parecidos á los ya indicados. Su expansión produce grandes presiones, de tal modo que los muros que sostienen arcilla comprimida estarán en peligro de combarse si la arcilla se humedece. Es una substancia muy traicionera para trabajar en ella. Sobre cimientos de concreto, véase « Concreto ».

**Respecto al mayor peso** que se puede confiar con seguridad á fundaciones de tierra, Rankine aconseja no excederse de 10 á 16 toneladas por metro cuadrado; pero la experiencia prueba que en cascajo bueno y compacto, en arena ó marga, y á una profundidad fuera de la influencia atmosférica, puede llegarse sin riesgo, de 20 á 30 toneladas, y hasta de 40 á 60 si se conceden algunos centímetros de descenso para el asiento de la mampostería, como puede hacerse á menudo en edificios aislados, exentos de vibraciones. Pasarán años antes de que la construcción se asiente enteramente.

La arcilla pura, especialmente si es húmeda, es más susceptible de compresión y no se la debe cargar con más de 10 á 16 toneladas por $m^2$, según el caso. Todo cimiento en tierra cede algo. La **igualdad de presión** es un punto esencial y al cual debemos aspirar. Las vibraciones aumentan los hundimientos ó descensos y hacen que continúen por largo tiempo, especialmente en terrenos débiles, y se debe tener mucho cuidado en no exagerar la carga en dichos casos, aun cuando haya estacada. **Las cimentaciones en terrenos fangosos** descienden probablemente en años á razón de 7 á 30 cm por 10 toneladas (hasta 20 ton) por metro cuadrado, de carga *quieta*, si no está sobre estacas.

La fig. 2 enseña un modo fácil de obtener un cimiento en ciertos casos. Es el « **pierre perdue** » de los franceses, y en inglés el « **random stone** » ó « **riprap** ».

Es simplemente un depósito de piedras angulares de cantera que se arrojan al agua haciendo que queden las más grandes arriba á fin de que resistan el choque de las aguas, del hielo, y árboles flotantes, etc. Una parte del interior puede ser de piedras pequeñas, ripios de cantera, con algún cascajo, arena, arcilla, etc. Cuando la base es de roca imperfecta este procedimiento economiza el gasto de aplanarla para recibir la mampostería. Desde .60 á 1 m debajo de la superficie del agua las piedras deben ser colocadas á la mano de modo que queden juntas y firmes. Deben colocarse pequeños fragmentos de piedra entre las grandes para que el bloque sea más uniforme y menos propenso á ser removido. Se usan á veces lañas, grapas, ó cadenas de hierro para unir algunas de las grandes piedras y darles mayor estabilidad. **Este sistema, sin embargo, es propenso á hundimientos.**

**Si la base del cimiento es floja ó deleznable hasta el punto de que puede ser arrastrada ó socavada por inundaciones,** puede además protegérsela, como se ve en la fig. 2, por medio de una cubierta de la misma clase de piedras como en *c*, que se extienda completamente alrededor de la construcción. O bien el montón principal de piedras puede extenderse como lo indica la línea

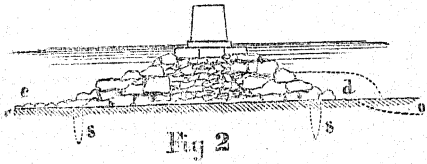


Fig 2

de puntos *d*, de manera que si la parte inferior fuese socavada como lo indica la línea de puntos *o*, las piedras en *d* caerán en la cavidad impidiendo así mayores daños. Se pueden colocar estacas delgadas como precaución adicional. Para mayor seguridad debe dragarse el lecho del río en todo el espacio que ha de ser cubierto por el depósito principal, como se ve en la fig. 3, y á tan gran profundidad que esté fuera del alcance de la acción corrosiva. Esta excavación debe ser rellenada también con piedras. Estas fundaciones, evidentemente, se adaptan más á aguas tranquilas. La mampostería debe descansar sobre una fuerte plataforma.

Grandes depósitos de piedra, como se ven en estas dos figuras, aumentan muchísimo la velocidad y la acción de la corriente alrededor de ellos, especialmente en las inundaciones, á menos que el fondo de cada lado del depósito sea excavado

de tal modo que el área primitiva del agua no se reduzca. Si el fondo es engañoso, esto debe hacerse antes de depositar las piedras de protección *c*, fig. 2.

Son muy necesarios en esta materia el buen juicio y la experiencia, como en toda otra que se relacione con la ingeniería. El mero estudio no nos preservará de constantes errores. La teoría y la práctica deben ayudarse mutuamente.

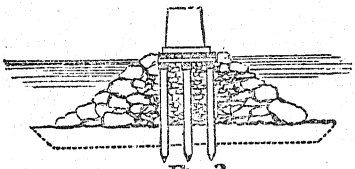

Fig 3

La fig. 3 indica otro método simple, muy eficaz, y cuando no se opone demasiado obstáculo al movimiento de la corriente ó al escape de las aguas en tiempos de inundaciones. En este caso, las estacas se clavan primero en el fondo del río para que sirvan de soporte á la pila; entonces se depositan las piedras para apoyar y proteger las estacas é impedir que se doblen bajo el peso que sostienen, y defenderlas contra los choques de los cuerpos flotantes. Luego que se hayan cortado las estacas á un mismo nivel, se colocará sobre ellas una fuerte plataforma de madera que servirá de base para la mampostería. La parte superior de la plataforma no debe tener menos de 30 á 40 cm debajo de las más bajas aguas para impedir que se deteriore. La estaca de tornillo de hierro de Mitchell ó las estacas huecas de hierro fundido se deben usar en lugar de las de madera.

La fig. 4 enseña un método muy conveniente para construir cimientos en el agua, por medio de una **caja de madera, AA, sin fondo**. Se construye con trozos de madera cuadrados, *escopleados en sus intersecciones* como en la fig. 5. Cada escopleadura debe ser ¼ del espesor de la madera. De este modo cada viga está sostenida en toda su extensión por la que está debajo, y resiste el empuje en ambas direcciones. Se le atraviesan también pernos en las intersecciones, por lo menos en los bordes de la caja, á fin de evitar que una parte sea arrastrada y separada de la otra. La caja se divide, pues, en celdas cuadradas ó rectangulares de .60 á 1.20, ó 1.5 m en cada lado, de acuerdo con las exigencias del caso. Las divisiones de las celdas se unen de la misma manera que las de los bordes de la caja, y por consiguiente forman, como las últimas, sólidos costados de madera.

La caja se armará á flote en el mismo sitio, en cualquier punto conveniente, y cuando esté terminada se llevará á su lugar, donde se anclará y hundirá cuidadosamente, depositando piedras en las celdas. Para esto se les pondrá fondo como se ve en *cc*. Estos fondos ó plataformas deben colocarse un poco más arriba del borde inferior de las celdas, á fin de no impedir que la caja penetre en el terreno, y de este modo llegue á fijarse perfectamente sobre el suelo.

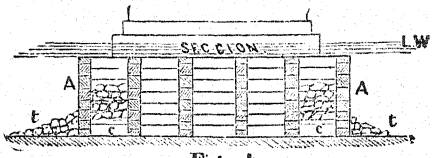
Después de hundir la caja se llenarán todas las celdas con piedras. Se agregará ó no, según el caso, una fuerte plataforma superior y también una defensa de piedras regadas para evitar el socavamiento que produce la corriente. Si los costados están expuestos á la abrasión ó desgaste producido por el hielo, etc., deben ser cubiertos todos ó en parte por tablones de madera ó por planchas de hierro y los ángulos deben ser guarnecidos por medio de láminas de hierro. En aguas profundas, el cimiento puede fabricarse en parte de piedras regadas, como en las figs. 2 y 3, y sobre éstas se hundirá una caja, cuya parte superior debe quedar como á .60 m bajo las aguas más bajas, sirviendo de base para la mampostería. Esto ofrece más seguridad que las piedras regadas solamente.

**En base ó fondo de roca desigual** es necesario ensamblar la parte inferior de la caja á fin de que calce en la roca, y la caja debe ser sumergida primero por medio de una plataforma cargada que se colocará sobre ella, ó llenando algunas de las celdas hasta que sus planchas inferiores se encuentren á una pequeña distancia del fondo. Conservándola así en una posición horizontal, se arrojarán piedras pequeñas en las celdas, las cuales, pasando á través de ellas, formarán una base igual donde podrá descansar la jaula. Entonces se llenarán

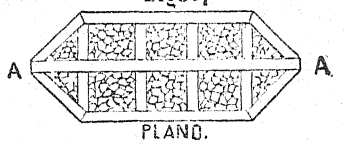
las celdas y se depositarán piedras grandes (*rip-rap*) alrededor de la caja para evitar que las pequeñas se salgan fuera de su sitio.

Se puede construir **una jaula que sólo tenga una hilera exterior de celdas**, y la cámara ó recinto interior puede llenarse de concreto debajo del agua. La mampostería puede descansar entonces sobre el concreto solamente. Si la jaula se apoya sobre cimiento de piedra picada, los intersticios de estas piedras deben rellenarse con piedras pequeñas ó cascajo para recibir entonces el concreto de la cámara.

**Ó se puede sumergir una jaula como la de la fig. 4**, clavar las estacas en las celdas y luego llenar éstas de piedra picada ó concreto. La mampostería descansará entonces solamente sobre las estacas, las cuales á su vez estarán pro-



Figs 4.



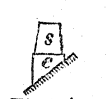


Fig. 5 *a*.

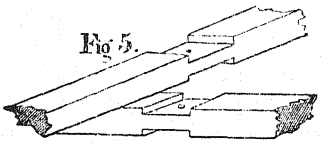
Fig 5.



tegidas por la jaula. Si el fondo ó suelo es susceptible de ser socavado, se colocarán estacas ó piedras sueltas alrededor de la base de la jaula.

**Se debe evitar por todos los medios** una jaula como la que representa *e* en la fig. 5½, con un lado mucho más alto que el otro, *si la construcción s* ha de descansar sobre el maderaje de la jaula ó cajón en lugar de apoyarse sobre las estacas, ó sobre concreto independiente del maderaje; pues que la parte alta de la jaula comprimiría más bajo su peso que la parte baja y esto haría que la construcción se inclinase y se desplomase.

Una jaula terminada por caras ya sea rectas ó circulares con sólo una hilera exterior de celdas para echar el concreto ó argamasa, puede usarse como un ataguía. (Véase « Ataguía », pág. 624.) Las ensambladuras exteriores de las vigas deben calafatearse bien y se debe tener cuidado de que el agua no se filtre por debajo, para lo cual se emplearán estacas, cascajo, etc.

**En el puente de hierro fundido que atraviesa el Schuylkill en la calle Chestnut, en Filadelfia**, el señor ingeniero Strickland Kneass nos presenta un ejemplo sorprendente de fundaciones con cajas. El estribo central descansa en una jaula de figura oblonga octógona de 9.45 × 26.53 m en la base, 7.32 × 24.40 m en la parte superior, y (con su plataforma) 9.15 m de alto. Las piezas de madera son de pino amarillo, de 30 cm en cuadro y construídas como en la fig. 5. Las maderas inferiores se labraron cuidadosamente á fin de adaptarlas á las irregularidades de la roca, medianamente á nivel, sobre la cual descansa. Ésta se encontró (después de haber dragado 2.4 m de profundidad de arena) de la manera acostumbrada. Luego se amarró sobre el lugar una plataforma de madera grande y flotante, compuesta de vigas que correspondían en posición con todas las de la jaula ó cajón que se ejecuta, tanto longitudinal como trans-

versalmente y se echaron las sondas á lo largo de esas líneas de vigas. Casi todas las celdas tienen como de 1 ¼ á 1.20 en sus lados, algunas de ellas tienen plataformas al nivel de la segunda serie para recibir piedras que hundan la jaula, y las otras están abiertas hacia abajo.

La jaula se construyó en el agua y se conservó flotante durante su construcción y, con la parte superior, no terminada, constantemente á flor de agua para llenarla gradualmente con piedras á proporción que se le agregaban vigas. La piedra que se empleó con este objeto solamente alcanzó á 300 toneladas. Al llevar la jaula á su posición y asegurarla, se le agregaron 150 toneladas para hundirla. Después se llenaron todas las celdas de piedra seca y escorias ordinarias de carbón, haciendo un total de 1,666 toneladas. Una plataforma de madera de vigas de 30 × 40 cm, cubría el todo y su parte superior estaba á 75 cm debajo del nivel más bajo de las aguas. El solo estribo que descansa sobre esta jaula pesa 3255 toneladas, y durante su construcción comprimió la caja 16 cm. El peso de la construcción que descansa sobre el estribo se puede calcular aproximadamente en 1000 toneladas más.

**Un cajón ordinario para construcciones bajo el agua es simplemente un lanchón fuerte, ó una caja sin tapa,** cuyas caras pueden abrirse ó separarse de su parte inferior, si se quiere. Se construye en tierra y luego se echa al agua. La mampostería puede ser construída en todo ó en parte, al estar á flote, y el todo, después de haber sido remolcado y fijado en su lugar, se sumerge hasta el fondo del río, y se apoya sobre un cimiento que ha sido preparado previamente por medio de estacas si es necesario, ó meramente rebajando y nivelando la superficie natural, etc.

El fondo del cajón constituye una fuerte plataforma de madera sobre la cual descansa la mampostería, y está preparada de tal modo, que después que ha sido sumergido se pueden desunir y quitarse sus lados para aplicarlos en la construcción de otra pila ó estribo. Esta separación puede efectuarse por medio del mecanismo indicado en la fig. 6, en que *PPw* es la base del cajón al cual están

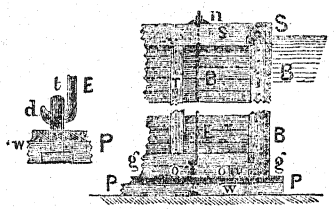


**Fig. 6.**

firmemente adheridas, á intervalos, fuertes argollas de hierro *t*, en las cuales se insertan los garfios de que están provistos los extremos inferiores de los pernos, E *n* que llegan hasta las vigas *s* superiores de la jaula, donde están fijos por medio de tuercas de tornillo *n*. Aflojando las tuercas, los garfios se separan de las argollas *t*, y de este modo puede quitárseles las piezas laterales del fondo. Los garfios y argollas se colocan generalmente en la parte exterior del cajón y las tuercas de los tornillos están sostenidas por los extremos prolongados de las piezas transversales *tt*, fig. 9. La impropia posición que les damos en nuestra figura fué debida simplemente á la conveniencia de ilustrar el principio. Sería necesario algunas veces tener un lado más sobresaliente que otros con el objeto de que el cajón flote libremente al separarse del estribo ya terminado, á menos que sea separado antes porque la mampostería se haya elevado ya á tal altura que haga innecesaria la precaución. La fig. 6 indica uno de los muchos modos de construir un cajón con caras formadas de postes verticales en las esquinas; piezas de tope y cabezales S en la parte superior y vigas de apoyo en la base, que descansan en la plataforma inferior *PPw;* postes intermedios T ensamblados á las vigas de tope y de apoyo, y todo cubierto exteriormente por uno ó dos espesores de tablón B, los cuales, así como la plataforma, deben ser calefateados para impedir que haga agua el cajón. Con el fin de contribuir á este objeto pueden clavarse también encurados por fuera. Donde más molestan las filtraciones es donde las caras del cajón se unen á la plataforma. En la parte superior de la plataforma está fuertemente fija una viga *oo* que se extiende alrededor de ella, justamente

del lado interior de la arista inferior de las caras del cajón. El objeto de esto es impedir que dichas caras sean comprimidas hacia adentro por la presión del agua. Los detalles de construcción variarán, naturalmente, según las exigencias del caso. A los cajones profundos es necesario aplicarles abrazaderas transversales interiores ó puntales *cc*, de una cara á otra, fig. 7, á fin de impedir que la presión del agua comprima las caras hacia adentro á medida que la balsa se sumerge gradualmente, á proporción que se construye la mampostería. A medida que la mampostería se eleva se quitan los puntales. Cuando el cajón es poco profundo sólo se necesitarán las abrazaderas superiores. Éstas sostendrán también una plataforma para los trabajadores y sus materiales. En cajones profundos, el entablado exterior puede, en parte, ser ejecutado gradualmente á proporción que la mampostería hace progresos, á fin de no estorbar á los albañiles.

Puede ser conveniente, algunas veces, hacer la mampostería hueca al principio, con tabiques interiores de poco espesor, para reforzarla, si es necesario, y rellenar el interior después de sumergir el cajón. En este caso, la mampostería descansa en la plataforma, formando así los lados del cajón; ó bien éstos se forman con una cubierta de hierro impermeable ó de madera de la forma del estribo ó pila que se ejecuta. Esta cubierta, limitada en la plataforma, viene á ser un molde en el cual se conforma la pila ó estribo, y se sumerge al mismo tiempo, llenándolo con concreto hidráulico. **Sobre cimentaciones de concreto,** véase « Concreto ».

**En suelos de roca** las vigas inferiores de la plataforma pueden labrarse de modo que se adapten á las irregularidades de la roca, como ya se ha dicho, ó puede emparejarse el fondo colocando primero grandes piedras alrededor del área sobre la cual debe descansar el cajón, y luego rellenar los intersticios con piedras pequeñas y cascajo, tanteando la profundidad por medio de la sonda; ó puede colocarse con cuidado en el agua una capa de concreto á nivel. Si la roca tiene grietas angostas y profundas, por medio de las cuales pueda escaparse el concreto, deben ser éstas cubiertas antes con tela encerada. Las campanas de buzo se usan á menudo con ventaja en dichas operaciones; pero cuando las rocas son muy irregulares será mejor recurrir á los cajones. Se aplican comúnmente válvulas de admisión de agua para sumergir el cajón. Si después de haberle sumergido fuese necesario elevarlo de nuevo, sólo se necesitará cerrar las válvulas y extraer el agua por medio de una bomba. Se pueden clavar estacas de guía y atarlas alrededor del cajón para efectuar su hundimiento verticalmente y en el lugar conveniente, ó puede hacerse descender por medio de tornillos sostenidos por un fuerte andamio provisional.

Suponiendo que los postes I, T, fig. 6, estén suficientemente sujetos como en *cc*, fig. 7, la siguiente tabla indicará el espesor de los tablones para diferentes distancias de un poste al otro para obtener un coeficiente de seguridad 6 contra la presión del agua á diferentes profundidades, y al mismo tiempo que no se encorve hacia adentro bajo dicha presión en una cantidad mayor de $^1/_{150}$ parte de la distancia á que se halla un poste de otro. Dicha tabla puede ser útil para cualquier otro problema análogo.

**Tabla de los espesores que han de tener los tablones de pino blanco para que no se encorven más de $^1/_{150}$ parte de su longitud horizontal bajo diferentes cargas de agua.** (Original.)

| Extensión en metros. | CARGA Ó ALTURA DEL AGUA EN METROS | | | | |
|---|---|---|---|---|---|
| | 12 | 9 | 6 | 3 | 1.5 |
| | Espesor en centímetros. | | | | |
| .90 | 9 | 7½ | 6½ | 5½ | 4½ |
| 1.20 | 11 | 10 | 8½ | 7 | 5½ |
| 1.80 | 17 | 15 | 13 | 10½ | 8 |
| 2.40 | 23 | 20 | 17½ | 13½ | 11 |
| 3.00 | 28½ | 25 | 22 | 18 | 14 |
| 3.60 | 34 | 31 | 27 | 21 | 17 |
| 4.50 | 42½ | 38 | 33 | 27 | 21 |
| 6.00 | 56 | 50 | 44 | 35 | 28 |

*N. del T.* — Esta es la tabla equivalente á la que trae el autor, pero apreciando sólo ½ cm en los espesores, pues eso es suficiente en la práctica.

**Las ataguías** (*coffer-dams*) son recintos de los cuales puede ser extraída el agua de manera que pueda hacerse el trabajo sin estorbo. En agua mansa y baja dará un resultado satisfactorio un simple terraplén bien construído con arcilla y cascajo, y cuando haya mucha corriente, sacos casi llenos de esas mismas materias, ó (según la profundidad) una hilera doble ó sencilla de estacas chatas ó de estacas cuadradas de grandes dimensiones clavadas de modo que se toquen una á otra, con sus extremos inferiores enterrados algunos pies dentro de la tierra y los superiores un poco más arriba del nivel de las altas aguas, y protegidas exteriormente por montones de tierra cascajosa ó lodazal (como en P, fig. 7) para impedir la filtración. Las estacas pueden ser de madera ó de hierro fundido de una forma fuerte.

**Está demostrada la suficiencia de un simple dique de tierra bien compactada** en aguas tranquilas, por los terraplenes y diques levantados en todos los países para impedir las inundaciones de los ríos en terrenos bajos. La altura media general de los diques que se extienden en un espacio de 1,026 kilómetros en el Misisipí, es de 1.83 m, sólo .90 m de ancho en la parte superior, é inclinados los lados de 1½ en 1. En las inundaciones el río sube cerca de .30 m ó menos en la parte superior, y frecuentemente rompe y se abre paso por en medio de ellos causando muchos perjuicios. Son demasiado débiles.

El sistema de una sola hilera de estacas cuadradas de 30 × 30 cm, clavadas juntas unas de otras, y resguardadas simplemente por un depósito exterior de terreno impenetrable, es muy eficaz, y con la adición de abrazaderas interiores transversales, semejantes á *cc*, fig. 7 (para impedir que se inclinen hacia adentro por la presión externa del agua y el relleno al extraer el agua con la bomba), se ha empleado con éxito en aguas de 6 á 7.5 m de profundidad, sin corriente suficiente para arrastrar el relleno. Las abrazaderas se intercalan sucesivamente á medida que se extrae el agua, comenzando, por supuesto, por las de arriba. Las puntas de estas abrazaderas deben rematar en las vigas longitudinales clavadas en las estacas con este objeto.

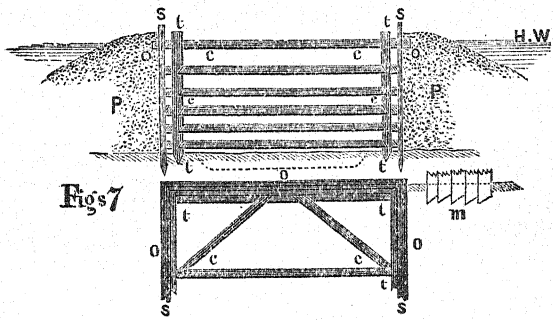
Hay otro método que consiste en una **caja fuerte** compuesta de postes fijos por sus extremos superior e inferior á piezas de madera que sirven de vigas de tope y de apoyo, forradas exteriormente con planchas de madera en contacto unas con otras, y bien calafateadas como en el cajón que indica la fig. 6, pero sin fondo. Entre los pares opuestos de postes, hay colocados fuertes puntales interiores como *cc*, fig. 7, que pasan de un lado al otro para impedir el hundimiento hacia adentro. Las series superiores de estos puntales generalmente sostienen una plataforma para los obreros, grúas, etc. Después de construída la jaula en tierra, se arrojará al agua, se colocará en su lugar definitivo, y se sumergirá amontonando piedras en una plataforma provisional que descansa sobre los puntales, habiendo preparado previamente para su recepción el fondo del río.

Para evitar la filtración por debajo de la caja ó jaula, se clavarán estacas de tablas á su alrededor, con las cabezas que sobresalgan del fondo, ó puede colocarse un depósito pequeño de escorias alrededor de ella, como se ve en los depósitos de piedras *tt*, fig. 4. O bien se clavará fuertemente alrededor, y un poquito hacia arriba de la arista inferior de la jaula, una tira ancha de encerado, arreglada de tal modo que pueda extenderse libremente en el fondo del río á una distancia de pocos metros alrededor de toda la parte exterior de la jaula; el relleno de escorias se pondrá sobre ella. Dichos encerados son también muy útiles en los casos en que el fondo del río es hasta cierto punto irregular, y no puede ser excavado sin grandes gastos, en cuyo caso la jaula no puede descansar perfectamente sobre él, y por consiguiente el agua filtraría ó correría libremente por debajo. Son adaptables especialmente á las rocas desiguales donde no es posible clavar estacas de madera. Sin embargo, puede depositarse sobre una roca lisa una capa impermeable, en cuyo caso el hundimiento de la jaula y las subsiguientes operaciones serán las mismas que sobre una capa natural. Estos medios son más ó menos aplicables en otros casos, los cuales no se mencionan especialmente para evitar repeticiones.

**La fig. 7 representa otra forma de ataguía** cuyas caras, en lugar de ser entabladas longitudinalmente como en el último ejemplo, están forradas con estacas de tablones, tablas verticales S, clavadas después de sumergir la jaula. Ésta es muy inferior á la última, debido á la facilidad con que puede filtrarse.

Se han usado con éxito en 5 m de agua con dimensiones de 10.27 × 24.40 m. En cada una de sus largas caras había 7 postes de 5.7 m de largo, 30 cm en cuadro,

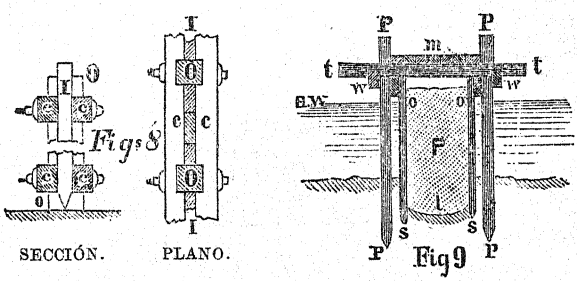
y á 3.88 m de distancia unos de otros. En cada par opuesto de éstos había escopleadas y sujetas por garfios de hierro abrazaderas de 30 cm en cuadro. La distancia entre las dos de encima era de .91 cm, disminuyendo gradualmente hasta .45 cm, que era la separación de las dos últimas. Así se hizo á causa del aumento de presión del agua al descender. En la parte exterior de los postes y opuestas á las abrazaderas extremas había vigas longitudinales atornilladas para soportar la presión exterior contra las estacas de los tablones *ss*. Otras piezas longitudinales *oo*



fijan las puntas de las estacas de tablas á la parte superior de la jaula, después que están clavadas. Las puntas inferiores se cortan en ángulos como en *m*, á fin de que al clavarse se unan y cierren bien el fondo.

Dichas estacas se clavarán de una manera mucho más regular y satisfactoria siguiendo la disposición adoptada en la fig. 8. En ella *oo* son los postes; *ee* son pares de piezas longitudinales escopleadas y ensambladas á los postes cerca de sus extremos superiores é inferiores, y en tantos puntos intermedios como se desee. Las estacas de tablas I están intercaladas entre éstas, y por tanto guiadas durante su descenso mucho más perfectamente que en la fig. 7.

Cuando la corriente es demasiado fuerte para permitir el uso del relleno exterior P, fig 7, se usa generalmente el tipo de caja de la fig. 9, en el cual ambos lados del relleno están protegidos contra el arrastre de las aguas. El espacio que debe



ocupar el dique está rodeado por dos hileras de estacas principales firmemente clavadas, *pp*, de las que depende principalmente la resistencia del aparato. Deben ser redondas. Al determinar el número de ellas debe recordarse que tienen que resistir la acción del hielo flotante ó choques accidentales de buques, etc.; contra esto, deben clavarse, además, estacas de defensa. Un poquito más abajo de las puntas superiores de las estacas principales están atornilladas dos piezas exteriores longitudinales *ww*, llamadas cintas, y opuestas á éstas dos interiores como se ve en la figura. Las exteriores sirven para sostener las vigas *tt* que unen cada par de estacas

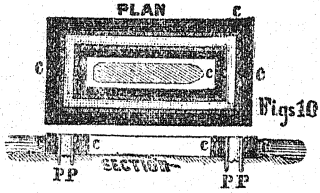
opuestas, haciéndolas inmovibles é impidiendo que se desunan con la presión del relleno P. Las interiores hacen el oficio de guías de las estacas *ss* mientras se encajan, después de lo cual las cabezas de las estacas de tablas se sujetan á ellas, En aguas profundas estas estacas deben ser muy gruesas, como de 30 cm en cuadro, para resistir la presión del relleno.

**Un pasamano, m**, se coloca á menudo sobre las piezas cruzadas *tt*, para el uso de los obreros al rodar el material, etc. El relleno se deposita en el agua en los espacios entre las estacas. Deben depositarse en capas compactadas, tan bien como se pueda, sin pandear las estacas, lo que ocasionaría la abertura de sus juntas.

El fondo del foso, donde se deposita el relleno, debe cavarse, como se ve en la figura, caso de que esté formado, como generalmente sucede, de materias sueltas, porosas, las cuales permitirían al agua filtrarse por debajo de él y de las estacas. Esta filtración por debajo del dique es á menudo fuente de muchos gastos y dificultades. El agua se abrirá paso prontamente á cualquier profundidad y á través de cualquier fondo pedragoso ó cascajoso que no esté mezclado con tierra. La arena es algo molesta también, y si se presenta una capa de cualquiera de estas dos especies que se extienda á gran profundidad, será un buen recurso apelar ó á una simple jaula, fig. 4, ó á cajones con estacas ó sin ellas, según las circunstancias. Pero si dicho cascajo, ó cualquiera otro material permeable ó movedizo, como barro blando, arena movediza, etc., se presenta en una capa de poco espesor, sobre arcilla resistente ú otra materia firme, se puede impedir la filtración, ó por lo menos reducirla mucho enterrando las estacas en este último á 60 ó 90 cm, y cavando el foso donde se va á echar el relleno á la misma profundidad. Es algunas veces mejor dragar toda la materia mala del espacio rodeado por el dique y á alguna distancia comenzar la construcción de éste.

Si la represa que indica la fig. 9 está provista (como debe estarlo) de abrazaderas transversales, como las *cc*, fig. 7, colocadas á través del recinto interior, el espesor ó ancho *oo* del relleno no es necesario que sea de más de 1.20 á 1.50 m para profundidades bajas, ó de 1.5 á 3 m para las grandes; porque su aplicación entonces es simplemente evitar la filtración. Pero si no hay abrazaderas debe hacerse más ancho, de modo que resista al volcamiento transversal, y entonces con un buen material de relleno puede adoptarse como regla empírica para dicho espesor $^3/_4$ partes de la profundidad vertical *o l* bajo la marea alta, excepto cuando ésta tenga menos de 1.20 m, en cuyo caso se hará dicho espesor de 1.20 m, á menos que se necesite más para el tráfico de los obreros, depósito de materiales, etc. Si la excavación para la mampostería penetra más profundamente que la masa del relleno, la represa debe ser más ancha, ó de otro modo caería dentro del pozo que ha sido excavado. **La tierra excavada** puede extraerse en baldes por medio de grúas, ó á mano por medio de andamios sucesivos. Las bombas pueden ser maniobradas á mano ó á vapor, según lo requiera el caso, lo mismo que las grúas que necesitan generalmente para descender el mortero, piedras, etc. Se debe contar siempre con que habrá más ó menos filtración, á pesar de todas las precauciones que se tomen.

Cuando una caja-dique ó ataguía está expuesta á corrientes violentas y á grandes peligros por el hielo, etc., se hace necesario adoptar el costoso sistema de la fig.



Figs 10.

Los dos rectángulos negros *cc* representan dos filas de jaulas ordinarias llenas de piedras y sumergidas, estando inscrita una en la otra con pocos metros de separación. Luego se clavarán estacas *pp* alrededor de las caras opuestas de las dos jaulas, y el relleno se depositará entre las dos, como se ve en la figura.

Donde la corriente no sea bastante fuerte para arrastrar el relleno, podemos, especialmente sobre roca, aislar el espacio donde se intenta construir, por simples cuadros formados con cajones, sumergidos por medio de piedras, y hacer el re-

lleno después de tomar precauciones, á fin de impedir que por la presión, el cascajo se introduzca por debajo de los cajones *.

Las figuras 10½ muestran el plano, visto lateralmente y la sección transversal en una escala de $^1/_{240}$, de un cajón colocado sobre roca á 2.4, ó 2.7 m de agua, empleado con éxito en el *Schuylkill Navigation*.

**Ataguías colocadas sobre roca.** Los postes *b*, como de 30 cm en cuadro, y á 3 m de distancia de centro á centro á lo largo de los costados del dique, y con 3 m en el espacio transversal de éste, sostienen dos cintas formadas de los largueros horizontales *ii*, en el interior de los cuales están las dos filas de estacas *ss*, conteniendo entre ellas una capa de relleno de cascajo con espesor de 2.1 m. Dos barras planas de hierro (*tt* de la sección transversal) unen los postes *bb* de

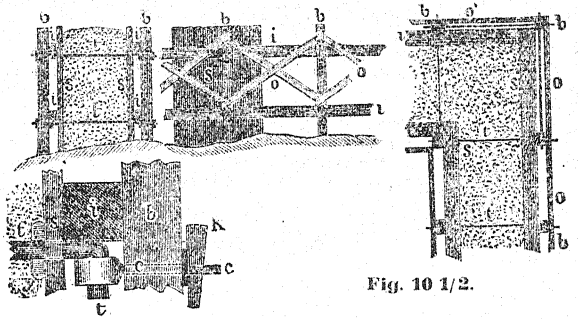


Fig. 10 1/2.

dos en dos. Estas barras son de 12 mm de grueso y 2.7 m de largo. Sus puntas encorvadas calzan en los huecos de los pernos *c* que atraviesan los postes *b*, y fijos en la parte exterior por clavijas (véase el diseño detallado). Entre las clavijas y *b* hay arandelas. En los ángulos del dique (véase el plano) hay tirantes adicionales. Una faja pequeña de paja como se ve en *y*, arrollada alrededor de las barras, justamente en la parte interior de las tablas, y mantenida en su lugar por el relleno, impide eficazmente la filtración, que es generalmente tan molesta. Los gruesos travesaños oblicuos *oo*, estaban simplemente sujetos á las caras exteriores de los postes *b*. No están indicados en la sección transversal. Este dique fué construído en tierra por secciones de 9 á 12 m de largo, las cuales fueron llevadas á flote á su lugar y rellenas con cascajo. El dique tenía compuertas, por medio de las cuales se introducía agua cuando era necesario, para impedir que la parte exterior excediese de 2.7 m. La longitud de los postes *oo* fué determinada de antemano por medio de cuidadosos sondeos.

**El anclaje de grandes cajones** es algunas veces difícil, particularmente en fuertes corrientes. A veces se necesita clavar grupos de estacas, ó sumergir temporalmente algunos cajones ordinarios, llenos de piedra, á los cuales se atan largas cuerdas de guía, por medio de las cuales se coloca en su posición. Frecuentemente se dejan sin sacar los diques después que el trabajo se ha hecho, si éste no queda en la vía de la navegación ó de modo que ofrezca obstáculos, pues que los materiales rara vez compensan el gasto de su remoción. Pero si se remueven, las estacas no deben arrancarse del suelo, sino recortarse cerca del fondo del río, porque si se arrancan, el agua que entra en los agujeros puede ablandar el terreno debajo de la mampostería. A menudo es conveniente clavar dos hileras de estacas desde la represa hasta la orilla para sostener un pasadizo para los obreros y aun para caballos y carros ó para rieles que faciliten la conducción de piedras grandes, etc.

**Estas ataguías pueden pasar á través de un suelo blando á uno firme**, gracias á su forma de cajón rectangular (y á veces circular) y sin fondo. Después de haberlos unido fuertemente y provisto de abrazaderas ó travesaños interiores temporales (para ser gradualmente removidos á proporción que se fabrica la mampostería) se dejan flotar en su lugar, y después de cargarlos de modo

* El cascajo ordinario, puro y limpio, es enteramente inútil para este objeto. — Se necesita una considerable proporción de tierra para impedir la filtración.

que descansen en el fondo blando, se sumergirán dragando el material blando del interior. Algunas veces es necesario agregar una carga adicional para vencer el frotamiento del terreno contra la parte exterior, ó puede hacerse necesario dragar también un poco el exterior. **Sobre roca** puede ser conveniente algunas veces taladrar hoyos bajo aguas profundas para meter las puntas de las estacas ó de barras de hierro, etc. Esto puede hacerse por medio de grandes barras de taladrar que trabajan dentro de un tubo de hierro ó conducto sumergido, como una guía para la barra, con su extremo inferior colocado en el punto donde se va á taladrar. Puede emplearse también una campana de buzo, ó **un cilindro** sin fondo de 10 á 30 cm de espesor suficientemente largo para que llegue á la superficie y provisto de una ancha orilla ó borde de tela alquitranada alrededor de su contorno inferior, que se cubrirá con cascajo para impedir la filtración; se podrá sumergir y extraer el agua con una bomba á fin de que pueda descender un obrero y trabajar al aire.

**Cuando las estacas** se clavan unidas como en la fig. 11, para impedir la filtración, para aislar la masa que constituye el relleno en una caja-dique, ó para cercar un pedazo de terreno blando ó arenoso, á fin de impedir que se esparza, ó si

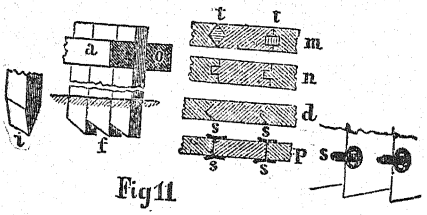

Fig 11

el suelo exterior que las rodea es socavado, etc., se llaman **estacas machihembras**. Son generalmente más delgadas que anchas, pero frecuentemente son cuadradas y tan largas como las estacas de sostén, y se llaman entonces estacas de cerca. A fin de poderlas clavar estrechamente juntas en el pie, se cortan oblicuamente como en *f*. Algunas veces, cuando se clavan en una roca por entre un terreno blando, sus puntas se labran además en filo como en *i*, de manera que estén un poco machacadas cuando lleguen á la roca, y de esta manera se adhieran mejor á su superficie. Sus cabezas se mantienen en fila mientras se clavan, por medio de una ó dos piezas longitudinales llamadas cintas. Estas cintas están sujetas por **estacas directrices** ó estacas de guía clavadas con anticipación en el alineamiento requerido y á alguna distancia con este objeto. Véase la figura 8.

**Un (dog iron) gancho, d,** de hierro redondo puede usarse también para mantener las puntas de las estacas unidas por las cabezas á las clavadas previamente, antes y después de clavarlas. Sus afiladas puntas *cc*, clavadas en las caras superiores de las cintas (como se ve en el plano), mantienen en su lugar la estaca descendente *o*. En *n*, *d*, *p*, fig. 11, se ven otros medios usados, algunas veces, para mantener en línea conveniente *las estacas*. En *p*, las letras *ss* indican pequeñas piezas de hierro bien atornilladas á las estacas un poquito más arriba de sus puntas inferiores, para que funcionen como guías. Se usan rara vez; *m* representa espigas

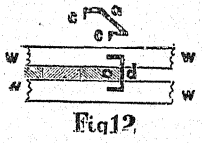

Fig 12

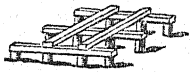
de madera *tt* que algunas veces se clavan entre las estacas después que éstas han sido clavadas, para ayudar ó impedir la filtración. En algunos casos se usan estacas de tablas ensambladas. Se cava un pozo primero á la profundidad á que han de ser enterradas, se colocan dentro las estacas, y entonces se rellena. Así se obtienen

juntas más cerradas que clavándolas. Se llaman estacas de cimiento cuando tienen que sostener pesos, sea enterrándolas completamente, ó en parte, como en la fig. 3. Son generalmente redondas, de 22 á 45 cm de diámetro en la parte superior, y deben ser derechas; pero no es necesario quitarles la corteza. El pino blanco, el abeto y hasta la cicuta son buenos para terrenos blandos, el pino amarillo, para terrenos más firmes y sólidos; la caoba, el olmo, etc., para los más compactos. Generalmente se entierran de .75 á 1.20 m de distancia unas de otras y de centro á centro; sin embargo su disposición depende de la clase de terreno y del peso que deben sostener. Es más económico, para suspender la maza ó martillo, emplear una rueda de escalones en vez de un torno, cuando el trabajo es hecho por hombres. Morin encontró que el trabajo de hombres trabajando 8 horas por día fué de .12 de caballo por hombre y por minuto con la rueda de escalones, y solamente de .08 por medio de cabria.

**Después que las estacas han sido enterradas** y sus cabezas cortadas á nivel cuidadosamente, si no están debajo del agua, se rellenan (en los casos de importancia, hasta el nivel de sus cabezas), los espacios que hay entre ellas, con cascajo bien apelmazado, fragmentos de piedra ó concreto, con el fin de comunicar



mayor resistencia al terreno que se encuentra entre las estacas. Serán atadas ó clavadas á las cabezas de éstas, como se ve en la figura, formando lo que se llama emparrillado, dos hileras de vigas gruesas de 20 á 30 cm en cuadro, según el peso que tengan que sostener. Sobre éste se clavará un tablado ó plataforma de tablas gruesas que sirva de soporte á la mampostería. Se pueden colocar juntas las vigas de la hilera superior del **emparrillado**. El espacio que queda debajo de la plataforma debe también ser macizado en casos de importancia con cascajo, fragmentos de piedra ó concreto. **Si es debajo del agua**, las estacas serán aserradas por un buzo ó por medio de una sierra circular movida por la máquina del martinete, y se omite el emparrillado. En lugar de dicho emparrillado puede fabricarse la mampostería al aire libre, en un cajón; y este se irá sumergiendo gradualmente, á proporción que se va llenando; o bien construir aquella en una fuerte plataforma que se hace descender sobre las estacas por medio de tornillos, á medida que progresa el trabajo. También se puede sumergir primero, enteramente debajo del agua, un cajón fuerte y llenarlo luego de concreto hasta cerca del nivel de las bajas aguas, dejando el cajón dentro del agua. Puede hacerse también del cajón una ataguía que se sumerja primero, y luego se extrae el agua con bombas. Si el terreno es susceptible de ser socavado por el agua alrededor de las estacas, como sucede en las pilas de los puentes, etc., se debe proteger por medio de estacas de tablas ensambladas, ó con piedras echadas, ó de ambos modos.

**El costo de los martinetes flotantes de vapor**, en Filadelfia, con lanchones de 7×15 m, de 45 cm de calado, con una máquina para clavar y otra (para economizar tiempo) para preparar la estaca que se va á clavar, con un martillo, de una tonelada, es como de $6,000, y con $500 más se obtendrá una sierra circular, para aserrar las estacas á cualquiera profundidad. Se necesita un maquinista, un fogonero y 4 ó 5 personas más; consume, más ó menos, media tonelada de carbón por día.

Por término medio se clavan de 15 á 20 estacas por día de 10 horas, enterrándolas á 6 m con cascajo, y aserrándolas luego. En fango, el doble; en tierra, la mitad.

**El martinete con motor de pólvora** inventado por el Sr. Thomas Shaw, el bien conocido ingeniero mecánico de Filadelfia, es máquina de mucho mérito. El martillo se mueve por medio de pequeños cartuchos de pólvora, colocados, uno á uno, en un receptáculo en la parte superior de la estaca, y que hace explosión por medio del martillo mismo. Puede fácilmente ejecutar de 30 á 40 golpes, de 1.5 á 3 m, por minuto, y como el martillo no se pone en contacto directo con las estacas, no maltrata sus cabezas, y no es necesario usar los aros de hierro, etc., para preservarlas. Cuando sólo se necesita un golpe suave se usará un cartucho más pequeño. Para clavar una estaca á 6 m dentro del fango se usa, poco más ó menos, ¼ libra de pólvora; dentro de cascajo, cuatro veces más. Esta máquina no ayuda á elevar la estaca y colocarla en su posición, como se hace por medio de los ordinarios martinetes comunes de vapor; éstos, sin embargo, sólo dan de 6 á 14 golpes por minuto.

**Se han clavado estacas por medio de explosiones** de pequeñas cargas de dinamita colocadas sobre sus cabezas, las cuales están protegidas por planchas de hierro.

**Los martinetes de vapor** que funcionaron bajo el principio indicado por **Nasmyth**, son económicos para clavar á grandes profundidades y en difíciles terrenos, donde haya como 200 ó más estacas en grupos ó hileras, de manera que la máquina pueda moverse fácilmente de estaca á estaca.

**El cilindro** de vapor es vertical y está encerrado entre las partes superiores de dos vigas verticales y paralelas en I, ó acanaladas, como de 1.8 á 3.6 m de largo, separadas 45 cm, cuyas extremidades inferiores sujetan un casquete hueco, cónico, de hierro fundido, el cual ajusta sobre la cabeza de la estaca. Este casquete está abierto en la parte superior, y á través de él el martillo, que está adherido á la varilla del émbolo, golpea la cabeza de la estaca. Cada una de las vigas verticales contiene una de las dos vigas de guía directrices del martinete, entre las cuales el aparato clavador descrito anteriormente puede deslizarse hacia arriba ó hacia abajo.

Cuando ha sido colocada una estaca en su posición y está lista para ser clavada, se le colocará sobre la cabeza el casquete de hierro haciendo actuar de este modo, el peso del volante, cilindro, martillo y casquete sobre la estaca. Este peso se apoya sobre la estaca á través del martinete, y el aparato se desliza hacia abajo por entre las guías ó directrices á proporción que desciende la estaca.

El vapor pasa de la caldera al cilindro por medio de un tubo flexible. Cuando entra en el cilindro, el martillo se levanta como .75 á 1 m, y al escaparse, cae golpeando la cabeza de la estaca. Se dan como 60 golpes por minuto. El martillo está provisto de una (*trip-piece*) pieza giratoria que permite automáticamente la entrada del vapor en el cilindro después de cada golpe y abre una válvula para su escape al fin del movimiento ascendente del émbolo. Alterando el ajuste de esta pieza (*trip-piece*), la longitud de caída para el golpe (y por consiguiente la fuerza de los golpes), puede aumentarse ó disminuirse. La entrada y escape del vapor en el cilindro puede también controlarse directamente por un empleado auxiliar. El número de golpes por minuto se aumenta ó disminuye regularizando el suministro de vapor.

Al hacer el movimiento ascendente del émbolo, el vapor comprimiendo la cabeza inferior del cilindro, comprime, por supuesto, la estaca y ayuda á su descenso.

**La ventaja principal de estas máquinas** consiste en la gran rapidez con la cual se suceden los golpes, no dando tiempo á la tierra movida á que se compacte de nuevo alrededor de los lados y bajo el pie de las estacas. Esto permite á la máquina hacer trabajos que no sería posible ejecutar con martinetes ordinarios. Se han clavado estacas de pino de Noruega á 12.60 m dentro de arena. Estas máquinas rajan ó desfloran menos las estacas, de manera que éstas pueden ser de madera más blanda y más barata. El casquete mantiene la cabeza de la estaca constantemente en su lugar, de manera que las estacas no se salen de línea. A veces se han incendiado las cabezas de las estacas á consecuencia de la rápida sucesión de golpes.

**Estas máquinas consumen** de 1 á 2 toneladas de **carbón** en 10 horas y **requieren una dotación** de 5 hombres. Trabajan con una presión de caldera de 3½ á 5¼ atmósferas.

## Reglas para calcular la resistencia de las estacas como soportes.

Hay grandes diferencias. No hay regla que pueda aplicarse bien en todas las circunstancias. El terreno mismo que está entre las estacas, sostiene, en la mayor parte de los casos, parte del peso, á pesar de que todo él está conflado á las estacas. Al mismo tiempo, en terrenos muy arcillosos hay mayor propensión á hundirse con el tiempo, á consecuencia de la introducción de agua entre las estacas y la arcilla, disminuyendo de este modo el frotamiento entre ellas. Mientras menos firme sea el terreno más daño hacen las trepidaciones, las que causan también hundimientos. En algunos casos este hundimento no será producido por el descenso de las estacas dentro del terreno que las rodea, sino por el de toda la masa compacta de estacas y tierra en las cuales fueron clavadas, que desciende á causa de alguna capa menos densa que se encuentre debajo de ellas; á veces se atribuye á las estacas el descenso que realmente se debe al aplastamiento de las vigas que descansan sobre sus cabezas.

En el hermoso **puente de Londres**, cada estaca debajo de algunos de los estribos sostiene el inmenso peso de 80 toneladas. Están enterradas 6 m solamente entre la fuerte arcilla azul de Londres y colocadas próximamente á 1.20 m de distancia de centro á centro, lo que es demasiado para tales estribos y arcos. A .90 m escasos de distancia hubieran tenido que sostener sólo 45 toneladas. Son de .30 m de diámetro en el medio de su longitud. Han ocurrido serios descensos, algunos de ellos de .30 m más ó menos, bajo estos estribos. El **puente de Blackfriars**, en aquellas mismas inmediaciones, muestra el mismo defecto. Algunas personas atribuyen esto en ambos casos á la penetración gradual del agua entre la arcilla y las estacas, quizás por la acción capilar de las mismas estacas ó por filtración directa. Puede ser debido, en parte al aplastamiento de las plataformas que están encima de las estacas ó á un descenso de la masa entera de arcilla y estaca entre la arcilla sin estaquear que está debajo, todo debido al inmenso peso que soportan. Este peso alcanza en este caso á 59 toneladas por m cuadrado de área cubierta por un estribo, y esto es quizás demasiado para arcilla húmeda cuando el más mínimo hundimiento es perjudicial.

**El mayor J. Sanders**, ingeniero de los Estados Unidos, hizo grandes experimentos en el fuerte Delaware con el fango del río y suministró lo siguiente al «Jour. Franklin Inst.» (nov. de 1851). Para obtener la carga de seguridad de una estaca común de madera enterrada hasta que se hunda sólo por cantidades pequeñas y casi iguales, bajo golpes sucesivos, divídase la altura de caída en metros por el pequeño hundimiento en metros producido por cada golpe; multipliquese el cociente por el peso del martillo, y divídase el producto por 8. El no establece un coeficiente especial de seguridad.

Ej.: En el puente de la calle Chesnut, en Filadelfia, el mayor peso sobre cualquiera de las estacas es de 18 toneladas; el Sr. Kneass hizo enterrar las estacas hasta que penetraron 19 mm (= .019 m) bajo cada golpe de un martillo de 547 kilogramos, enterrándolo hasta 6.10 m. ¿En esto procedía él sobre seguro? Aquí tenemos, aplicando la regla, $6.10 \div .019 = 321$ y $321 \times 547 = 175{,}587$ y $175{,}587 \div 8 = 21{,}948$ k, ó sean 21.95 toneladas como carga de seguridad según la regla del mayor Sanders. El terreno era fango de río. (*Obs. del T.* — Este ejemplo equivale al que trae el autor en medidas inglesas.)

**Nuestra regla** es la siguiente: multipliquense entre sí la raíz cúbica de la caída en pies, el peso del martillo en libras y la decimal .023. Divídase el producto por el último hundimiento de la estaca en pulgadas + 1. El cociente será la **carga extrema** que estará justamente á punto de causar más hundimiento. Para la carga de seguridad tómese de $^1/_{12}$ á $^1/_2$, de acuerdo con las circunstancias. Expresado en una fórmula métrica que equivalga á la regla del autor, resulta:

$$\text{Carga extrema en toneladas} = \frac{\text{Raíz cúb de la caída en metros} \times \text{peso del martillo en kg} \times 0.0019}{\text{Ultimo hundimiento en metros} + 0.0254}$$

Pongamos, como el autor, el mismo ejemplo anterior del puente, y tendremos:

$$\text{Carga extrema en toneladas} = \frac{\sqrt[3]{6.10} \times 547 \times 0.0019}{.019 + 0.0254} = \text{como } 42.8)$$

O digamos, la mitad de esto ó sea 21.4 toneladas, el peso, para un coeficiente 2 de seguridad. La regla del mayor Sanders da por carga de seguridad 21.95. La carga efectiva es 18 toneladas. Un coeficiente 2 de seguridad no es suficiente para fango de río. Pero no obstante que la regla del mayor Sanders y la nuestra están perfectamente de acuerdo en este caso, si se toma para cada uno un coeficiente 2 de seguridad, difieren muchísimo en otros. Así, en el puente Neuilly, Francia, el martillo más pesado tenía 912 kg, caída 1.52 m, hundimiento .006 m en los últimos 16 golpes, ó sean .00038 m por golpe. Las estacas sostienen 47 toneladas cada una. Nuestra regla da 40.6 toneladas para coeficiente 2 de seguridad, mientras que la regla de Sanders da 515 toneladas como carga de seguridad! Si como creemos probable no hubo hundimiento en el último golpe, entonces nuestra regla da 41.2 toneladas para una seguridad de 2, mientras que Sanders da el *infinito*. En los Hull Docks de Inglaterra, estacas de 25 cm en cuadro enterradas á 4.88 m en lecho de aluvión por un martillo de 675 kg á 7.32 m de caída con hundimiento, .05 m por golpe al fin de la clavada sostienen por lo menos 20 toneladas cada una ó, según algunos .25 toneladas. Nuestra regla da 33 toneladas como carga extrema, ó 16.

para un coeficiente 2 de seguridad. Sanders da como carga de seguridad 12.6 toneladas. Como hemos dicho antes, 2 no es coeficiente de seguridad suficiente para el fango. En el fango no son las estacas sino el terreno estacado el que desciende realmente con los años. En el puente Royal Border, Inglaterra, se clavaron firmemente estacas de 9.10 á 12.2 m en arena y cascajo húmedos en algunos casos. Se ensayó primero con pino, pero se resbalaban y se desfloraban tanto bajo el pesado martillo, que fué sustituído con éxito por el olmo americano. Fueron enterradas las estacas hasta que solamente se hundían .0012 m por golpe, bajo un martillo de 765 ks cayendo de 4.88 m de altura. Soportan 70 toneladas cada una. Nuestra regla da 47 toneladas para un coeficiente 2 de seguridad, mientras que Sanders da 364 de carga de seguridad. Sin embargo opinamos que no se hundieron realmente como supusieron los observadores, sino que fueron simplemente comprimidas ó parcialmente machacadas por clavarlas demasiado. La mayor parte de las estacas fueron clavadas hasta que se hundieron solamente 25 mm bajo 150 golpes. Pero dudamos si ofrecían seguridad ó si habían penetrado más en el terreno que recibiendo uno solo de los golpes. Consideramos peor que inútil esta precaución extrema. En algunos experimentos hechos (1873) en Filadelfia fué entetrada una estaca de prueba á 4.5 m en fango blando de río por un martillo de 720 kg, habiendo sido su último hundimiento .45 m. Bajo una caída 10.98 m. Solamente á las 5 horas después de haber sido clavada se cargó con un peso de 6.5 toneladas, que causó solamente un hundimiento de una fracción muy pequeña de pulgada. Nuestra regla da 6.1 toneladas como carga extrema. Bajo 9 toneladas se hundió 19 mm y bajo 15 toneladas 1.5 m. Según la regla del mayor Sanders, su carga de seguridad sería 2.14 notadas.

**Una estaca de prueba del Gobierno de los Estados Unidos** de cerca de .30 m en cuadro, enterrada á 8.84 m, á través de capas de fango, arena y arcilla, con un martillo de 409.5 kg, caída 1.5 m, último hundimiento .0094 m, soportó 26.6 toneladas; pero se hundió lentamente, bajo 27.9 toneladas. Nuestra regla da como 26 toneladas, carga extrema.

**Los ingenieros franceses** consideran que una estaca ofrece seguridad suficiente para un peso de 25 toneladas cuando rechaza el peso de 609 kg, cayendo de 1.22 m de altura. Nuestra regla da 24.2 toneladas para un coeficiente 2 de seguridad. Ellos estiman como peso rechazado el de un martillo que bajo 30 golpes no produce un hundimiento mayor de 1 cm. En muchos puentes importantes, etc., clavan las estacas hasta que cesa el hundimiento, bajo un martillo de 362 kg, cayendo de 1.5 m de altura. Nuestra regla da en este caso 31 toneladas por carga extrema, ó 15.5 para un coeficiente 2 de seguridad.

**Respecto á la carga propia de seguridad**, creemos que sólo debe tomarse la mitad del peso extremo que da nuestra regla para estacas enterradas perfectamente en *terrenos firmes*, no más de una *sexta* parte cuando sean clavadas en fango de río ó en pantano, suponiendo, como hemos hecho anteriormente, que sus puntas no descansan sobre roca.

**Si puede haber trepidaciones**, tómese solamente **la mitad** de estas cargas.

**Las estacas pueden hacerse de cualquier dimensión que se quiera,** sea respecto á longitud ó á sección transversal, atornillando ó empalmando latera, y longitudinalmente un número de vigas cuadradas.

**Estacas con puntas embotadas.** En el puente de la calle South Filadelfial fueron enterradas 1,200 estacas gruesas de abeto de Nueva Escocia, con las puntas embotadas, de 4.5 á 10.67 m, parte en fango sólido, por medio de un martinete común de vapor. Coste total (estaca y enterrada) de 7 á 8 dólares cada una. En el puente de Wilmington, California, el Sr. C. B. Scars, del ejército de los Estados Unidos (Diario Americano, Sociedad C. E., diciembre 1876), descubrió que en arena húmeda, firme y compacta, después de algunos primeros golpes, las estacas no penetran más de 12 á 37 mm á cada golpe, sea cual fuere la altura de la caída del martillo de 1087 kg. Las estacas sin puntas, de las cuales había muchos miles, se enterraron con la misma facilidad que las provistas de puntas, á una profundidad media de 4.5 m en esta arena, y con mucha menos tendencia á inclinarse. Como una gran caída no tenía otro efecto que desflorar las cabezas de las estacas, se redujo aquélla á 3 m, con lo cual se clavaban, por término medio, como 18 mm á cada golpe.

Para que las estacas puedan entrar rectamente deben hacerse ó cortarse sus puntas en ángulo recto á su longitud. En lugar de clavar las estacas, cuando la profundidad es mediana, es mejor, algunas veces, introducirlas simplemente en

hoyos practicados con taladros semejantes al taladro perforador de pozos.

El frotamiento máximo de estacas con su corteza, clavadas á .90 m, más ó menos, de distancia de centro á centro, probablemente nunca excederá mucho de 10.76 toneladas por m cuadrado en arena húmeda densa ó en cascajo arcilloso, ni más de 5 á 8 toneladas en terrenos y arcilla comunes, ó más de $1^1/_2$ á 2 toneladas en fango ó barro húmedo de río, dependiendo todo de la profundidad y densidad. **El frotamiento de los cilindros de hierro fundido** parece ser como de .3 del de las estacas.

**Hay gran diferencia en la penetrabilidad** de las diferentes arenas. Así, en el puente Lary no se encontró dificultad especial para enterrar estacas á 10.67 m en arena debajo del agua, mientras que en otras localidades, dentro del agua, estacas de muy buena madera, bien guarnecidas con hierro, no se pueden enterrar á 1.8 m de profundidad en arena sin que se rompan en pedazos. La misma dificultad se ha encontrado cuando las estacas son de tornillo. En el faro Brandywine no pudieron hacerse penetrar á más de 3 m en arena debajo del agua. La arcilla dura, entre el agua y el cascajo limpio, difieren también muchísimo en este respecto. Generalmente son penetrables á cualquiera profundidad que se desee con facilidad relativa; pero hemos visto estacas fuertes de cicuta hechas pedazos al tratar de enterrarlas á 1.80 m en cascajo entre el agua, y el Sr. Rendel en Plymouth « no pudo, con ninguna clase de fuerza, clavar estacas á más de 1.5 m en la arcilla, no siendo tan dura como la arcilla de Londres », sobre la cual los ya mencionados puentes nuevos de Londres y Blackfriars fueron cimentados y en cuya arcilla se enterraron estacas de madera á 6 m, sin ninguna dificultad.

La mezcla de barro y arena facilita muchísimo la enterrada de las estacas; pero antes de empezar un extenso sistema de estacado deben clavarse unas pocas por vía de experimento, á fin de conocer las dificultades y gastos que deban prevenirse. Simples perforaciones serán á menudo insuficientes.

Por regla general un martillo pesado á poca altura de caída, clava mucho mejor que uno liviano á gran altura. Cuando un martillo de $^2/_3$ de tonelada con caída de 7.5 m, en un terreno duro, destroza las estacas, uno de 2 toneladas con 2.10 m de caída, las clavará satisfactoriamente. Pueden darse mayor número de golpes en el mismo tiempo con poca caída, y de este modo se da menos tiempo á la tierra para compactarse alrededor de las estacas entre golpe y golpe. A veces una estaca puede resistirse al martillo después de haber penetrado algo, pero continuar penetrando después de un pequeño descanso; suelen rechazar un martillo pesado y funcionar bajo uno más liviano; ó penetrar lentamente al principio y más rápidamente después por causas difíciles de descubrir. Sucede muchas veces que la clavada de una estaca es causa de que algunas adyacentes, clavadas anteriormente, salten algunos decímetros hacia arriba. Una estaca se encuentra en la posición más favorable cuando su punta inferior se apoya sobre la roca después de haber atravesado por entre un terreno firme que la cubre y protege perfectamente, para que no se doble como una columna demasiado cargada, y al mismo tiempo desarrolla gran frotamiento contra sus caras, ayudándola así á sostener la carga, y por tanto relevándola de la presión sobre la extremidad inferior. Una estaca puede descansar sobre roca y ofrecer sin embargo muy poca resistencia, pues que si pasa á través de un terreno blando, la extremidad puntiaguda inferior soporta todo el peso, y viene á ser la estaca simplemente una columna, en peor condición que un pilar con una extremidad redondeada. En dichos terrenos las estacas requieren muy poca punta, y, en verdad, sería mejor clavarlas sin ninguna.

La clavada de una estaca en terreno blando á barro, generalmente hace que ana de las adyacentes que ha sido clavada anteriormente, se incline hacia fueru, á menos que se tomen precauciones para impedirlo.

Al estaquear una área de terreno firme, es mejor comenzar del centro hacia fuera, pues de otro modo el terreno se consolidará de tal manera en el centro, que no será posible le clavar las estacas.

Se ha visto que **la reacción elástica del terreno** ha levantado áreas enteras estacadas con las est casa, antes de que se hubiere fabricado sobre ellas.

En terrenos muy sólidos, especialmente si son de piedra, ó aun en terrenos blandos, si las estacas tienen punta y han de ser enterradas hasta la roca, deben protegerse sus puntas inferiores por zapatas de hierro forjado *a*, *s*, y *b*, fig. 13, fijas á la estaca por medio de piezas de hierro en ellas forjadas; ó de hierro fundid,o como en *c*, en que el casquillo es un cono sólido invertido, cuya ancha y chata base suministra un buen apoyo á la base plana del extremo de la estaca. La línea de puntos representa un perno fuerte de hierro, bien fijo al cono; éste sujeta el casquillo á la estaca. Los casquillos medianos de hierro forjadc generalmente pesan de

8 á 12 kg, pero se empleará hierro laminado cuando el terreno es sólo medianamente compacto; hierro batido cuando lo sea más, y hierro sólido ó puntas de acero de 5 á 10 cm en cuadro en su parte inferior cuando es muy compacto y pedregoso.

Fig. 13

Para impedir que las estacas se resbalen **se deben practicar agujeros en las rocas** é introducir sus puntas, lo cual se hará clavando primero tubos que sirvan de guía al barreno, después que se haya extraído la tierra del tubo.

**A fin de preservar las cabezas**, se rodean generalmente con un aro *h*, fig. *d*, de 1 á 2½ cm de espesor y de 4 á 8 cm de alto. Éstos son, á veces, ineficaces, pues cuando se clava fuertemente, la cabeza se machaca y se raja en todos los lados, frecuentemente varios decímetrosde bajo del aro, y por otra parte los aros se abren á menudo. Por lo tanto las cabezas tienen que ser recortadas repetidas veces antes de clavarlas del todo; al pedir estacas para cualquier trabajo debe tenerse en cuenta estas pérdidas, especialmente si el terreno es duro. El capitán Turnbull, ingeniero de los Estados Unidos, dice que en el acueducto del Potomac las cabezas de las estacas fueron preservadas dándole á la superficie cierta forma cóncava, ahondándola como 3 cm, y cubriéndolas con una lámina de palastro floja, como se ve en la sección *e*, fig. 13. Uñ ligero desflecamiento ó trituración de la cabeza disminuye sensiblemente la fuerza del empuje. Las estacas pueden ser clavadas á través de ripios sueltos sin mucho trabajo. La clavada con pisón de madera maltrata menos las cabezas de las estacas. Las que apoyan sus extremos inferiores sobre rocas inclinadas pueden resbalarse cuando estén cargadas.

**Para clavar una estaca debajo del agua**, se empleará un embutidor, *p*, fig. 13. El extremo de este embutidor calza en la parte superior de un molde *ff*, redondo ó cuadrado, según la forma de la estaca, que tiene una división *oo*. La parte inferior del molde se ajustará á la cabeza de la estaca, y el martillo caerá sobre la superior. Cuando se clavan estacas verticalmente en un suelo blando para soportar muros de sostenimiento ú otras construcciones expuestas á fuerzas horizontales ó inclinadas, se debe tener cuidado de que estas fuerzas no compriman las estacas mismas, pues que en dichos terrenos las estacas están dispuestas para resistir fuerzas verticales solamente, á menos que sean clavadas con una inclinación que corresponda á la fuerza oblicua.

**Una estaca rota puede arrancarse** ó, por lo menos, ser desencajada, si no está clavada muy firmemente, atándola á lanchones cuando la marea está baja, y dejar á cargo de la alta marea el aflojarla. O se puede usar una viga grande como palanca y tomar por punto de apoyo la cabeza de una estaca contigua, ó por medio de una grúa movida por la máquina del martinete. En casos muy difíciles se podrá usar el método aconsejado por el ingeniero civil Sr. J. Monroe. Un tubo de gas de 10 cm de diámetro y de 4.5 m de largo, calzado con una punta sólida de acero, y provisto de un reborde exterior para sostener un embutidor circular, fué clavado cerca y á 60 ó 90 cm más bajo que dos estacas que estaban enterradas hasta 3.60 m en 11 m de agua y rotas por el hielo. Luego se depositaron en el extremo nferior del tubo dos kg de pólvora, cuya explosión sacó las estacas completamente de su lugar. A menudo es mejor dejar en su sitio la estaca rota y clavar otra cerca de ella. Puede ser arrancada por presión hidráulica.

**El hielo se adhiere á las estacas** con una fuerza como de 2 á 3 kg por cm cuadrado, y al subir el agua puede arrancarlas si no han sido suficientemente clavadas.

Pilotes ó **estacas de hierro y cilindros**. En Europa se ha empleado el hierro fundido para estacas, y en diversas formas, particularmente cuando se dejan que permanezcan como una cubierta para proteger las obras de concreto, rellenas por detrás y apoyando el relleno *.

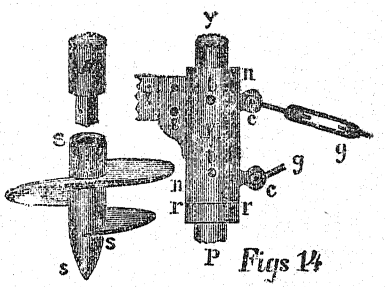
* El hierro fundido destinado á resistir el agua del mar debe ser de grano compacto,

Pueden emplearse como estacas de sostén cilindros de hierro fundido, abiertos en los dos extremos, y pueden limpiarse y llenarse de concreto si es preciso. El frotamiento que se produce al clavarlas es mayor que en las estacas sólidas, puesto que se desarrolla en las superficies interior y exterior. Puede disminuirse extrayendo gradualmente la tierra del interior á proporción que penetren. Se requiere mucho cuidado, debe emplearse un martillo más liviano ó menor caída que con las de madera para impedir que se rompan. Debería interponerse entre el martillo y la estaca una pieza de madera, ó el martillo puede ser de madera. Pero es mejor usarlos en la forma de cilindros de tornillo, los cuales tienen además la ventaja de una ancha base (véase fig.).

**Procedimiento de Brunel.** Experimentó con un cilindro abierto de hierro fundido de .90 cm de diámetro exterior, 37 mm de grueso en trozos de 3 m enchufados y con encajes internos y ensambladuras dentadas sujetas con tornillos y soldadas con plomo. Tenía un aro afilado ó cortador en el fondo, y un poquito más arriba de éste una vuelta de tornillo con un paso de 17½ cm y un vuelo de 30 cm en todo el contorno exterior del cilindro. Por medio de barras y de un cabrestante atornilló éste á través de greda dura y arena á 18 m hasta encontrar la roca. Para descender esta distancia el cilindro hizo 142 revoluciones, penetrando por término medio como 12½ cm en cada una. El tiempo verdaderamente empleado para atornillarlo fué de 48¼ horas ó como 36 cm por hora. Sin embargo hubo intervalos largos de reposo para sacar la tierra del interior. Después de descansar no hubo gran dificultad en comenzar de nuevo. Las próximas figuras darán una idea de la disposición dada al tornillo.

**El pilote de roca** de Alexandre Mitchel, de Belfast, consiste generalmente en una espiga de hierro laminado A, fig. 14, de 7½ á 20 cm de diámetro, provista por debajo de un tornillo de hierro fundido SSS con una espira cortante de .45 cm á 1.5 m de diámetro. Los tornillos que se usan para lugares expuestos á mares mansos son ordinariamente de .90 m de diámetro más ó menos y de 1½ vueltas ó pasos: pesan como 270 kg. Los mangos ó espigas redondos laminados tienen de 12 á 20 cm de diámetro. El tornillo penetra de 3 á 6 m en greda, arena ó coral por el impulso de 30 ó 40 hombres comunicado á 6 ú 8 barras del cabrestante, cuyos extremos describen un círculo como de 9 á 12 m de diámetro.

Con este objeto se prepara frecuentemente una plataforma sobre estacas. En agua mansa se sostiene sobre lanchones. Puede emplearse una balsa bien amarrada cuando la clavada es fácil; ó el puente de una balsa grande, con un hueco en el centro, para que pase el pilote ó estaca. Jaulas y cajones hechos ordinaria y temporalmente rellenos de piedras, y sumergidos, pueden sostener una plataforma en



Figs 14

ciertas posiciones. La plataforma debe de ser, evidentemente, capaz de resistir los movimientos de rotación horizontales comunicados por la gran fuerza de empuje de los hombres que maniobran en las barras del cabrestante; por este motivo no es

---

blanco y duro. La pequeña cantidad de carbón contenida está químicamente combinada con el metal; pero en el más obscuro está mecánicamente combinado, y dicho hierro pronto se vuelve dúctil (más ó menos, como la plombagina) cuando se expone al agua del mar. El hierro blanco duro se ha probado que resiste por lo menos 40 años, sin deteriorarse, esté constantemente debajo del agua ó alternativamente mojado y seco.

Al cobre y al bronce los afecta sólo ligera y superficialmente; pero tiene efecto la acción destructiva galvánica si entran en contacto metales diferentes.

difícil clavar tornillos á una profundidad suficiente en arena compacta por medio de una plataforma flotante. Los extremos inferiores de las estacas deben estar sujetos á los tornillos para impedir que sean separados de ellos por la fuerza de las olas contra la parte superior de la construcción. En *y p*, fig. 14, se ve un modo de empalmar ó unir diferentes puntos ó secciones de una estaca. El punto de unión es *v; rr* es un anillo fuerte de hierro forjado en la estaca baja *p* como 30 ó 45 cm debajo de su parte superior. Un manguito *nn* fuerte, cilíndrico, de fundición, que envuelve los extremos de las secciones, descansa en este anillo y se une á los pilotes por medio de clavijas *tt*. En estos manguitos también hay piezas salientes de fundición *ccc*, para fijar barras *gg*, y vigas, etc., necesarios para ligar la construcción de estaca á estaca. El tiempo que realmente se necesita para enterrar un tornillo es de 2 á 10 horas, bajo favorables circunstancias.

En el faro Brandywine, en un banco de arena muy pura, cubierta de 1.8 á 2.4 m por la baja marea y de 3.30 á 3.90 m por la alta, no pudieron hundirse más de 3 m desde una plataforma fija. En otros lugares se llega á 6 m en arena, sin mucha dificultad, cuando la arena contiene una buena cantidad de barro; pero entonces su resistencia como soporte es menor. Esta (última) varía como de 10 á 60 toneladas por metro cuadrado, según la fuerza, profundidad, compactibilidad, etc., de la arena. En casos de importancia debe probarse su resistencia.

Los pilotes de Mitchell han sido atornillados cerca de 12 m en una mezcla de greda y arena, con tornillos de 1.20 m de diámetro. Atraviesan, sin mucha dificultad, por entre piedras picadas y roca de coral y echan á un lado las piedras de tamaño mediano. Ordinariamente la greda ó la arena no oponen mucha resistencia; pero accidentalmente cualquiera de las dos pueden oponerla. Como regla general la arena pura es la que presenta mayores dificultades. En el bajo de Brandywine la hinca fué ayudada con un espolón (*spur*) y un piñón colocados tan bajo como lo permitió el agua; manejaron las palancas 30 hombres. El peligro de que se fuerza el árbol es lo que limita la línea del tornillo. Son muy usadas para asegurar cadenas, amarrar boyas, etc. En tierra, pequeños tornillos huecos con ejes ó espigas, constituyen un soporte bueno y durable para pilares de almacenes de depósito, para postes de madera, para telégrafos, estaciones de señales en la marina, etc. Se podrán emplear caballos ó bueyes para clavar grandes tornillos. El faro Brandywine descansa sobre 9 pilotes, los cuales están rodeados por otros 30 de 12½ cm de diámetro que le sirven de defensa. Tienen que resistir no solamente mares moderados, sino también inmensas cantidades de hielo flotante que tienen millas de extensión. Un edificio no terminado fué destruído por el hielo, el cual perjudica de tiempo en tiempo al que hoy existe.

**Deben practicarse reconocimientos con los barrenos para asegurarse** de que los tornillos no se apoyan precisamente sobre una capa muy débil, que perjudique su resistencia. Esto para cualquiera estaca.

**Por medio de un chorro de agua** lanzado fuertemente por una bomba impelente, se afloja la más resistente arena (pero no la arcilla dura ni el cascajo compactado) y se facilitará muchísimo la hinca de los pilotes de rosca de madera, y hasta los cilindros más grandes. Pueden desatornillarse fácilmente cuando se quieran quitar. En un muelle del Gobierno, en el cabo Henlopen, en arena muy compacta, se rompieron 6 de 7, antes de haber penetrado 3 m y se descubrió que el uso del chorro les quitaba más de las tres cuartas partes de la resistencia *.

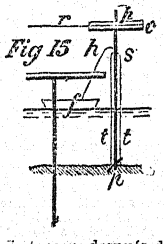


Fig 15

Para clavar la estaca *p*, después de haberla colocado en su puesto, como en la

* Informe de la Sección de guerra.

fig. 15, se apoyan los extremos inferiores abiertos *tt*, de un tubo de hierro *tst*, de 31 mm de diámetro, sostenido por la parte superior del disco del tornillo, y allí se mantenía firme por tres ó cuatro hombres, mientras la estaca se atornillaba por medio del cabrestante *c*, el cual era movido por una cuerda *r*. Desde la curvatura *s* del tubo, una manguera *h*, de 5 cm de diámetro conducía á la bomba impelente, cuyo cilindro tenía 12½ cm de diámetro, una carrera de émbolo de 23 cm, y daba como 80 golpes de émbolo completos por minuto, por medio de una rueda movida por una mula en una plataforma flotante *t*. Entonces no había trabajo en atornillar las estacas á cualquiera profundidad.

**En Mobile Bay** fueron clavadas de 3 á 6 m de profundidad, por medio de un chorro, algunos miles de estacas de madera desde .45 hasta 1.20 m de diámetro en arena con un hundimiento medio de .30 m por segundo. Aquel era impelido por una bomba de vapor, de incendio, colocada sobre un bote de vapor y usando la misma manguera de la bomba con una boca de 31 mm. Durante el descenso la boca *nn* de la manguera se mantuvo sujeta flojamente en su lugar cerca del pie de la estaca, por medio de dos grapas *ss* y por una cuerda *t* que llegaba á la superficie. Las estacas estaban suspendddas por sus cabezas por medio de tijeras con un aparejo para regular su descenso. La arena se asentó firmemente alrededor de las estacas pocos minutos después de haber sido enterradas.

En el río Tensas (Alabama), para cilindros de hierro de 1.80 m de diámetro en profunda y ligera arena movediza, el chorro fué arrojado por una bomba giratoria de 200 á 300 revoluciones por minuto, por medio de una manguera de 7½ cm de diámetro dentro de una cubeta cónica central de hierro fundido de 25 cm de diámetro, de la cual irradiaban 12 tubos de gas de 2½ cm de diámetro y como 75 cm de largo. En el extremo exterior de cada uno de estos radios había un codo, al cual estaba adherido un tubo largo vertical que penetraba dentro del cilindro, compuesto de trozos de 3 m de longitud y terminados en tornillos para prolongarlo á proporción que descendía el cilindro. Este aparato se levantaba y bajaba por medio de una pieza liviana de madera y un cordel: con esto sólo se hizo penetrar cada cilindro como 48 m, en pocas horas, dentro de una arena movediza *.

**En el viaducto Levan, el Sr. James Brunlee**, Inglaterra, en una marga ligera y arenosa de gran profundidad, enterró cilindros huecos de hierro fundido de 25 cm de diámetro exterior, á una profundidad de 6 m, por medio de un tubo surtidor de 5 cm de diámetro que pasaba por debajo, dentro del cilindro y á través de un hueco en su base, la cual era un disco de hierro fundido de 75 cm de diámetro y 2½ de espesor, reforzado por bordes exteriores. Los bordes de conexión de los trozos del cilindro eran exteriores, impidiendo así el descenso, como lo hacía también el disco ancho del fondo. Hasta 3 ó 4 horas bastaban, comúnmente, para sumergir cada uno á la profundidad de 6 m. Ensayos practicados prueban que su resistencia segura como soporte era de 50 toneladas por m cuadrado del disco de la base.

**En el viaducto de Lock Ken** cada estribo constaba de dos cilindros de hierro fundido abiertos en ambos extremos, de 240 cm de diámetro, y 28 mm de espesor, en trozos ó secciones de 1.80 m de longitud con peso de 4 toneladas cada uno, unidos por medio de bordes interiores con soldaduras de hierro entre ellos. Los cilindros tienen una separación de 2.40 m y se encuentran en 11 m de agua. Se erigió un fuerte andamio y fueron clavadas cuatro estacas de guía para cada cilindro. Habiendo sido previamente unidas las diferentes porciones de cilindro, fueron descendidos á sus puestos. Cada cilindro penetró por su propio peso de 30 á 60 cm á través del barro superficial y luego se asentó sobre la arena y el cascajo que forman el lecho, de gran espesor. En este último se hundieron después como 2.40 ó 2.70 m más, extrayendo la tierra interior debajo del agua por medio de una *vasija de tornillo*, cónica é invertida, ó draga, de planchas de palastro de 6 mm. Su diámetro mayor era de .60 m y .30 m de profundidad, y tenía adherido á su fondo un tornillo como de .30 m de largo para ayudar á atornillarla en la tierra. Estaba provista de aberturas en sus costados para que entrara la tierra, y de válvulas de cuero abiertas hacia adentro para impedir que se escape aquélla. A los lados opuestos de la vasija ó paila había tres barras de 19 mm de diám, prolongadas hacia arriba 1.20 m, y allí juntas forjadas y conectadas por medio de una ranura y un perno, unidos á una larga barra ó árbol, en cuyo extremo superior había una cruceta transversal de 4 brazos, por medio de la cual 4 hombres montados en un andamio atornillaban la vasija.

« Cuando una vasija estaba llena, se la subía por medio de una polea. Traía como 27 litros de un golpe, una menor de sólo 30 cm de diám por 30 cm de alto,

* Gabriel Jordan, I. C. Trans. Am. Soc. C. E., febrero 1874.

traía la cuarta parte, y se empleaba cuando el material era muy duro. Así se vaciaba el cilindro á razón de 5 á 45 cm por día. El trabajo lento de 5 cm por día, se debía á las piedras, algunas de 23 kg. Éstas se aflojaban con un pico en forma de barra de .90 de largo con brazos de 30 cm. Después de aflojarlas se subían con el aparato. El costo de estos aparatos era de poca importancia, y la excavación se hizo fácil y barata. Después que se terminó la excavación y se vació el cilindro, antes de bombear afuera el agua se echó concreto (2 volúmenes de granzón, 1 de cemento hidráulico) en una profundidad de 3.60 m, con baldes de fondo movible y quedó aquél 12 días para que fraguara. Entonces se bombeó el agua hacia afuera y se mamposteó al aire. Sin embargo, en algunos de los cilindros el agua ascendía tan pronto, á pesar de los 3.60 m de concreto, que las bombas no pudieron agotarla y hubo que agregar 1.80 m de concreto. Finalmente se echaron piedras sueltas y ripio alrededor de los cilindros para preservarlos de los golpes y evitar que se socaven.* » La mampostería llega á 6 m sobre los cilindros y sobre el agua.

**Procedimientos por el vacío y por aire comprimido.** Apenas podemos aludir á los principios generales de estos dos modos de sumergir grandes cilindros huecos. Por el método del vacío, del Dr. Holher Potts, de Londres, el cilindro *c*, fig. 16, durante la inmersión, está cerrado herméticamente en su parte superior por una puerta falsa, que se abre hacia arriba. Un tubo de caucho flexible *p*, suficientemente largo para adoptarse á la sumersión del cilindro, y provisto de una

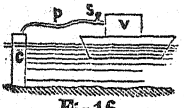

Fig 16

llave *s*, comunica el cilindro con el envase *v*, que puede colocarse sobre una balsa, ó lancha, ó estar en tierra, según convenga.

Después de haber colocado el cilindro en su posición, como en la figura, se saca por medio de una bomba el agua y el lodo ú otro material suelto que se encuentre en su interior si se ha sumergido alguna cantidad por su propio peso. Entonces se cierra la llave *s*, y se saca el aire del envase *v* por medio de una bomba de aire. Abriendo entonces la llave, la mayor parte del aire del cilindro se precipita al envase vacío *v*; dejando de este modo al cilindro comparativamente vacío, y por consiguiente menos capaz de resistir la presión hacia abajo del aire exterior sobre su parte superior. Esta presión, como es bien sabido, es cerca de 1 kg por cm cuadrado, ó diez toneladas por m. En consecuencia, el cilindro está impelido hacia el fondo del río, por esta presión, más su propio peso. Al mismo tiempo, la presión del aire sobre la superficie del agua, se transmite por ésta al terreno, alrededor de la parte inferior abierto del cilindro, de manera que si el terreno está blando ó en un estado semifluido, habrá una presión hacia arriba en el interior del cilindro, donde no existe presión hacia abajo que se oponga á ella. El descenso del cilindro varía desde algunos cm hasta 1.20 ó 1.50 m en cada vez. Luego se repite el procedimiento admitiendo nuevamente aire en el cilindro, abriendo la puerta falsa, sacando el agua y la tierra, etc., etc. Pueden agregarse otros cilindros sobre el primero, por medio de rebordes interiores y pernos.

**Este método se adapta sólo á terrenos blandos**, como también á terrenos arenosos mojados; pero no tiene suficiente fuerza para los muy compactos; ni se puede aplicar donde hay obstáculos como piedras grandes, trozos de madera, etc., cuya remoción requiere que los hombres desciendan dentro del cilindro, lo que no pueden hacer en el aire rarificado. El tubo *p* debe ser de un diámetro suficientemente grande para permitir la salida del aire con rapidez, de modo

---

* **Los pilotes de hierro, huecos**, sean fundidos ó forjados, están provistos en su pie de puntas sólidas, para clavarlos por medio de un martinete que cae en su *interior* y golpea contra la parte superior del pie sólido; son de gran utilidad en muchos casos. Se fabrican en secciones ó partes que pueden unirse gradualmente para llegar á la profundidad necesaria. Así en secciones se evita el peligro de que se doblen, peligro que siempre existe cuando se golpea sobre la parte superior. La base sólida de hierro es un poco más grande que el diámetro del pilote, para disminuir el frotamiento del terreno contra dicho pilote en el resto de su parte superior.

que la presión exterior pueda actuar lo más rápidamente posible sobre la tapa del cilindro.

En el faro de los Goodwin Sands, Inglaterra, se han sumergido cilindros huecos de .75 m de diámetro por este método hasta la profundidad de 10.2 m en 6 horas más ó menos, en lugares donde una barra de acero no se podía hacer entrar á fuerza de martillo sino á 2.4 m de profundidad. Otros cilindros de 30 cm de diámetro se han sumergido 4.8 m en menos de una hora. En este último caso la bomba de aire tenía dos cuerpos de bomba de 11 cm de diámetro, 40 cm de carrera de émbolo, movida por 4 hombres. El tubo *p* era de plomo y solamente de 12 mm de diámetro.

**El procedimiento por el aire comprimido**, inventado por el Sr. Triger, de Francia, consiste en introducir aire en el cilindro CC, fig. 17, hasta una presión suficiente para hacer salir el agua obligándola á escapar por debajo del extremo abierto del cilindro, y á través de la que lo circunda. Estando de esta manera seco el fondo dentro del cilindro, pueden bajar los trabajadores y sacar el material en su base y debajo de ella. Hecho esto, salen, y se deja escapar el aire comprimido, y el cilindro, no sostenido ya por la presión del aire comprimido que se ejerce de abajo hacia arriba, se sumerge en la cavidad ó entre el material aflojado en su pie. La fig. 17 enseña una disposición sencilla para que los trabajadores puedan entrar ó salir del cilindro sin dejar escapar el aire comprimido y también demuestra el principio general del método. LL es una pequeña cámara separada, la **cámara de extracción** (**air-lock**), la cual se quita cuando se agrega otro pedazo de tubo; después se vuelve á poner y se asegura firmemente. Esta cámara tiene una pequeña puerta *d* que puede cerrarse herméticamente y por la cual puede entrarse. Tiene otra puerta *o* que se abre hacia el cilindro. Esta cámara tiene también dos llaves de retención, una, *a*, en un piso comunicando con el cilindro; y otra, *e*, arriba comunicando con el aire libre. En *s* hay un tubo doblado, también con su llave que pasa herméticamente por el lado y el fondo de la cámara de extracción. Por esta llave entra el aire comprimido al cilindro por medio de una bomba impelente y por esta misma llave se le deja después escapar. En *nnn* se ve un sifón. Se emplea un torno *w* para izar el material excavado del fondo del cilindro á la cámara de extracción; los ejes *ii* del torno pasan por cajas de estopas situadas en los costados de la cámara de extracción; el material se iza por trabajadores colocados del lado afuera de dicha cámara. Esta es la disposición generalmente adoptada por el Sr. W. J. Mc Alpine, I. C. de Nueva York, en el puente de Harlem. Nuestra descripción condensa la de este señor. Los cilindros eran de 1.8 m de diámetro, de 30 mm de grueso y en secciones de 2.70 m de largo, unidos por pernos en bordes interiores *f*, á medida que se iba efectuando la inmersión de ellos. La caja de extracción tiene 1.8 m de diámetro por casi 1.8 m de alto, con sus caras construídas con planchas de hierro de calderas y su parte superior y fondo de hierro fundido.

Ahora bien; suponiendo sumergido el cilindro CC y fijo en la posición de la figura, y la caja de aire LL ajustada en la parte superior del cilindro, lo que se hace en seguida es impeler el aire por el tubo doblado *s*, habiéndose cerrado previamente a válvula *t* de la puerta inferior *o* y la llave *a*. Cuando el aire comprimido se acumula

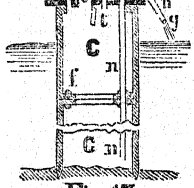

Fig 17

en el cilindro, hace salir el agua que en parte se escapa por debajo del fondo del cilindro y en parte sube por el sifón *nn* y sale por *g*. Como la puerta *o* está cerrada y

la puerta *d* abierta, el aire en la cámara de extracción se halla en la misma condición que el aire exterior, de modo que los trabajadores pueden entrar fácilmente en la caja. Ya adentro, ellos cierran la puerta *d* y la llave *e* y abren la llave *n*, por la cual se precipita el aire comprimido del cilindro hacia arriba, llenando prontamente la caja de extracción. Hecho esto, se abre la válvula *t*, y los hombres descienden al fondo por la puerta *o*, por medio de una escalera de mano ó en un tobo que se maneja con el torno *w*. Una vez en el fondo, aflojan y excavan el material hasta la profundidad que pueden; y llenando el tobo ó saco con el material, avisan por una señal á los trabajadores de afuera, que izan el tobo á la cámara de extracción. Hecho esto, ascienden á dicha cámara, cierran la puerta *o* y la llave *n*, y abren la llave *e*, por la cual se escapa el aire comprimido dentro de ella dejando el aire interior lo mismo que el exterior. Entonces se abre la puerta *d*, los tobos del material se sacan y los trabajadores salen. Finalmente, se abre la llave en *s*, el aire condensado del cilindro se escapa por ella al exterior y el cilindro se sumerge por su propio peso en la cavidad y terreno aflojado y preparado al efecto en su base para este fin. Dicho terreno es de nuevo impelido dentro del cilindro por el agua que se precipita otra vez en él. Luego se repite el mismo procedimiento.

La inmersión varía algunas veces de 0 á 3 m ó más en una sola operación. La mayor parte de los hombres pueden soportar el aire comprimido hasta una profundidad de 12 á 15 m; pero si aumenta ésta, se hace más difícil y hasta positivamente peligrosa. Se han sumergido de este modo cilindros de hierro fundido de 4.5 m de diámetro y grandes cajones, fig. 18; pero muchas veces con mucho costo y trabajo. El cilindro debería guiarse en su descenso por medio de un andamio fuerte que pueda apoyarse sobre estacas. De lo contrario está expuesto á inclinarse hacia un lado y es muy trabajoso hacerle llegar á su puesto otra vez. Estos cilindros han sido sumergidos en aguas profundas por buzos empleados en socavar interiormente el terreno.

**Procedimiento por aire comprimido.** El que se aplicó en el puente de South Street, en Filadelfia, por Mr. John W. Murphy, ingeniero contratista, difiere esencialmente del descrito arriba; y además merece atención por la gran sencillez y eficacia de su aparejo. Consiste éste, en parte, de dos lanchas, cada una de 30 m de largo, 5.2 m de ancho y 2.4 m de profundidad. Se anclaron paralelas una á otra á una distancia de 4.5 m. En dicha distancia ó espacio, y apoyada sobre ambas lanchas, estaba levantada una cabria fuerte de cuatro patas, de 15 m de altura más ó menos, y en cuya parte superior estaba sujeto un aparejo para manejar los cilindros de hierro fundido. En la bodega de una de las lanchas se colocó un **compresor de aire Burleigh** provisto de dos émbolos de 25 cm de diámetro y 23 cm de carrera, junto con su caldera de vapor. Sobre la cubierta de la misma lancha había un **depósito ó regulador de aire vertical** de 6.60 m de alto por .60 m diámetro, hecho de planchas de hierro de 6 mm de grueso. Este regulador servía para mantener un gran refuerzo de aire comprimido en el cilindro sumergido en el caso de una parada accidental del compresor de aire, que de otro modo hubiera quizás sido muy fatal para los trabajadores dentro del cilindro. El aire comprimido pasaba de este depósito á la cámara de extracción del cilindro por un tubo de 10 cm de diámetro, hecho de goma y lona, y colocado de tal manera que se extendía por sí mismo á medida que se sumergía el cilindro, manteniendo así la comunicación en todo tiempo.

A través de las dos lanchas se extienden dos durmientes ó travesaños de madera, de .90 m de ancho por .45 m de alto cada uno, compuestos de tres piezas de madera de .30×.45 m, unidas fuertemente por pernos. Estos travesaños tenían en el centro sus dos caras interiores verticales cóncavas hasta la profundidad de .30 m, correspondiendo estas concavidades al diámetro exterior de los cilindros. La distancia de los dos travesaños se fijaba por dos barras fuertes de hierro provistas con tal fin de tornillos y tuercas en sus extremidades.

De manera que cuando una sección del cilindro se izaba en su posición, por medio de la cabria situada entre las dos lanchas, las dos caras cóncavas se ponían en contacto con los lados del cilindro, y apretando luego los tornillos, el cilindro quedaba fijo en su lugar. Entonces se podía colocar otra sección de cilindro encima de la primera por medio de la cabria y unirlos con los pernos. Repitiendo esta maniobra, la altura del cilindro sería pronto demasiado grande é impediría poner otra sección encima por medio de la cabria, en cuyo caso, aflojando ligeramente las tuercas de los tornillos, se permitía al cilindro deslizarse suavemente en el agua hasta que su parte superior sobresaliera muy poco de la superficie del agua. Apretando nuevamente los tornillos, el cilindro estaba sujeto hasta que se unieran otras secciones encima de él, aseguradas por pernos. Cuando había temor

de que la presión hacia arriba del aire comprimido pudiera levantar un cilindro, entonces se levantaban los travesaños, por medio de la cabria, fuera de las lanchas y se colocaba sobre el cilindro una plataforma cargada de piedras.

**La cámara de extracción** estaba arreglada de tal manera que no era necesario quitarla cuando se ponía una sección nueva del cilindro. Esto se efectuaba del modo siguiente: Se unían las secciones del cilindro, como se ha descrito, hasta que el pie descansaba en el fondo del río, con su parte superior algunos decímetros sobre la superficie de la marea alta. Un diafragma pesado, de hierro fundido, de 30 mm de grueso, se ponía entonces sobre el cilindro para formar el piso de la cámara de extracción. Luego se arreglaba otra sección de 3 m del cilindro para formar la caja de la cámara de extracción. Éstas se unían por medio de pernos, y entonces se ponía otro diafragma en la parte superior para formar el techo de dicha cámara de extracción. Estos diafragmas estaban provistos de aperturas y puertas y válvulas correspondientes á las ya descritas en la fig. 17, y se dejaban en el cilindro cuando el trabajo estaba concluído. Si la profundidad del suelo que debía atravesarse para llegar á la roca firme, era tan grande que se hacía necesario añadir otras secciones de cilindro más arriba de la cámara de extracción, podía hacerse hasta donde fuera necesario, tanto más cuanto que no es esencial que la caja de extracción esté debajo del agua ó no. **Para impedir que ni el agua ni el aire puedan penetrar en el cilindro**, las caras de los rebordes se unen con una mezcla de minio y albayalde con fibras de algodón, antes de asegurarlas por medio de los pernos.

**En el puente de South Street**, los cilindros eran de 1.20, 1.80 y 2.40 m de diámetro, en secciones de 3 m de largo; de un espesor de 30 mm. Rebordes interiores de 70 mm de ancho y 30 mm de grueso, con pernos de 30 mm diámetro á distancia de 12½ cm entre sí de centro á centro. La arista de la sección inferior no tenía reborde. Una sección de cilindro de 3 m y de 2.4 de diámetro pesa 6,570 kg; de 1.8 m diám, 4,860 kg, y de 1.2 m, 3,060 kg. Un diafragma de 2.4 m, 1,260 kg; de 1.80 m, 720 kg; de 1.2 m, 352 kg. La roca debajo del suelo era desigual en algunos lugares; pero se nivelaba á medida que bajaban los cilindros, y éstos se aseguraban entonces á la roca firme por medio de abrazaderas y pernos.

**El trabajo se hizo día y noche**, verano é invierno, sin ninguna interrupción por las mareas, crecientes ó hielo flotante; las trece columnas fueron sumergidas rellenas de concreto, y el trabajo acabado en 11 meses; una gran parte del tiempo se gastó nivelando la roca y asegurando las abrazaderas. La falta de guías para la inmersión de los cilindros ocasionó mucho trabajo y dilación.

La diferencia entre la marea alta y baja era de 2.10 m más ó menos. La obra se hizo bajo la inspección del Sr. John Anderson, muy entendido y enérgico en esta clase de trabajos. **El costo total neto** de los cilindros colocados en su lugar, y rellenos de concreto hidráulico, fué aproximadamente de $302 por m de los de 2.4 m; $310 por los de 1.8 m, y $131 por los de 1.2 m de diámetro. Había tres cuadrillas de trabajadores, y cada cuadrilla trabajaba cuatro horas seguidas. La casa del Sr. Anderson (*Anderson and Barr; Tribune Building, N. Y.*), ha sumergido desde entonces con mucho éxito un número de estos cilindros, incluyendo (1884-5) cuatro de ellos de hierro forjado de 2.40 m de diámetro y 20 m de largo; inclinado 45° y colocados como puntales para impedir el movimiento de uno de los estribos del puente de la calle de Chesnut, Filadelfia.

**Se han reventado** varios cilindros de hierro fundido en varios puntos de su circunferencia en muchos puntos de los E. U. y en tiempo muy frío, debido á la diferencia de contracción del hierro y del relleno de concreto.

La ignorancia al usarlos puede traer grandes peligros.

La parte sombreada de la fig. 18 muestra una sección transversal de un **cajón de madera de pino amarillo** y cemento, para la torre del puente colgante sobre el **East River, en Brooklin** (N. Y.), de una abertura neta de 488 m. El cajón tiene un largo de 51.24 m en el fondo, y 31.11 m de ancho. La sección longitudinal se parece á la transversal con la diferencia de que es más larga y exhibe más tubos verticales J. De estos tubos hay 6, arreglados en pares para el trabajo rápido y como una precaución contra los accidentes. Es decir, 2 conductos de agua J, cada uno de $2.10 \times 1.95$ m, para sacar por medio de tinas y del aparato de suspensión el material excavado debajo del cajón, junto con el agua que pueda acumularse en *oo;* dos conductos de aire de 53 cm de diámetro, por los cuales se impele el aire de arriba hacia abajo para expulsar el agua de la parte CSSD debajo del cajón, y permitir que los trabajadores puedan minar por debajo, escapándose el agua debajo del pie CD del cajón al río; y dos conductos de suministro de 1.05 m de diámetro, para que puedan penetrar trabajadores, herramienta, etc. Todos estos

conductos tienen depósitos de aire en su parte superior, bajo el mismo principio que en la fig. 17, para evitar que el aire comprimido se escape por *ss*.

Los conductos son de planchas de hierro de calderas de 6 mm de grueso. El pie CD, de una altura igual á nueve espesores de trozos de madera, es continuo y se extiende alrededor del cajón; su parte inferior está calzada con hierro fundido; y

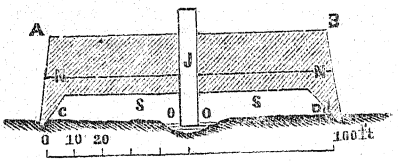

Fig 18

sus 4 esquinas reforzadas interiormente con ángulos de madera de 6 m de largo.

Desde el fondo hasta la línea NN, á 4.20 m, el cajón está construído de capas horizontales de maderas de 30 cm en cuadro cruzándose en ángulo recto, y las maderas de cada capa en contacto unas y otras bien unidas entre sí por pernos; todas las juntas cogidas con brea. Para impedir la filtración del agua, las tuercas y las cabezas de los tornillos tienen arandelas de goma elástica; también todas las juntas del lado exterior, lo mismo que las capas de madera NN, están bien calafateadas; y además un forro de hojalata, intercalado entre dos capas de fieltro, está colocado sobre cada junta del lado exterior, lo mismo que sobre la parte superior de la capa que está debajo de NN.

Cuando el cajón estaba concluído hasta NN, sobre la tierra, se echó á flote en su lugar y se fijó por medio de anclas; después de esto se agregaron, para sumergirlo quince capas de madera de 30×30 cm, colocadas á distancia de 30 cm entre sí, llenando los intersticios con concreto. La capa superior AB, es de madera sólida, para que sirva de sostén á las maquinarias, etc. Se sumergió pocos metros más bajo que el mismo fondo del río, para evitar el daño que podía producir la broma. Se sumergían á los lados cajas abiertas de madera para que sirvieran de muelles provisionales á las lanchas cargadoras del material excavado y á las embarcaciones que traían piedras, etc.

Después de sumergido el cajón, y expelida el agua del espacio CSSD, los trabajadores principiaron á excavar uniformemente el área cercada del fondo del río, para que de este manera el cajón pudiese descender hasta una capa inferior ó lecho firme. Después se construyó una ataguía sobre la parte superior del cajón, y en éste se principió la mampostería de la torre. La altura total de esta torre, incluyendo el cajón, es de 91.50 m más ó menos. Con respecto á los detalles, véase el informe de W. A. Roebling, ingeniero en jefe (1873).

**Los cilindros huecos, ú otras formas de obras de ladrillo ó mampostería, provistos en su parte inferior** de un brocal fuerte ó anillo de madera ó hierro, pueden sumergirse gradualmente, minando y excavando por debajo de ellos en su interior, y entonces forman cimientos muy estables. Debajo del agua puede hacerse esto en medio de excavadoras de forma adecuada, con ó sin el auxilio de campanas de buzos, según la profundidad, etc. En tierra este método es mucha veces el más económico y satisfactorio, especialmente en terrenos duros. Puede ayudarse su descenso colocando una carga sobre ellas, si el frotamiento de sus lados contra la tierra exterior impide que se sumerja por su peso solo, como sucede algunas veces. Un cilindro de mampostería de ladrillos de 14 m de diámetro exterior con sus muros de .9 m de espesor, se ha sumergido hasta una profundidad de 12 m en arena seca y granzón sin dificultad alguna. Se construyó de 4 m de alto (sobre un brocal de madera de 53 cm de grueso), y pesaba 300 toneladas cuando se principió la inmersión. La tierra interior se excavaba lentamente, de manera que el descenso era, más ó menos, de 30 cm por día, levantándose los muros á medida que descendía el cilindro. Conductos verticales para túneles se construyen algunas veces de esto modo.

**En las orillas del Rhin** para construir un pozo vertical de una mina de carbón, se sumergió primero de este modo y por su peso propio, á una profundidad de 23.18 m, un cilindro de mampostería de ladrillos de 7.5 m de diámetro por entre arena y granzón; luego un cilindro interior de 4.5 m de diámetro se sumergió del

mismo modo á una profundidad de 78 m debajo de la superficie, de cuya profundidad los primeros 55 m debajo del primer cilindro fueron de una arena movediza. A 78 m de profundidad el frotamiento era tan grande que el cilindro quedó inmóvil. La arena movediza se excavó por medio de taladros : no se extrajo el agua con la bomba sino que se dejó lleno el cilindro.

Los cimientos enteros de una pila grande de mampostería se han sumergido de este modo en un solo bloque, dejando un numero suficiente de aberturas verticales para el descenso de los trabajadores ó para la herramienta. Ésta es, generalmente, una operación muy lenta y tardía, especialmente debajo del agua. Muchas veces puede hacerse más expedita por medio de campanas de buzos. Es preferible, generalmente, hacer el bloque de mampostería más ancho en el pie que sobre él, para disminuir así el frotamiento contra el terreno exterior. Cuando se trabaja en tierra se emplea de vez en cuando agua para humedecer el fondo. Conservando seco el interior de esta mampostería hueca, se puede **construir de la superficie hacia abajo**, socavando solamente una parte de su circunferencia, llenando dicha parte de mampostería, y luego minando y llenando la otra porción, y así sucesivamente 60 ó 90 cm á la vez. Puede adoptarse este método cuando el frotamiento ha detenido el descenso de la masa de mampostería por su peso propio, estando socavada por debajo.

**La bomba de arena**, como se usó en el puente de San Luis, puede ser de utilidad algunas veces para sacar arena de los cilindros, mientras se están sumergiendo en agua. Con un tubo de bomba de 9 cm de diámetro, y un chorro de agua bajo una presión de 10 kg por cm cuad, se sacaron 15 metros cúbicos de arena por hora á una altura de 38 m. También se usó con éxito un chorro de aire como en el puente colgante de Brooklyn.

**Fajinas.** Sobre terrenos cenagosos ó de arena movediza mojada pueden hacerse los cimientos depositando primero capas de fajinas ó ramos pequeños ó varillas gruesas, amarradas firmemente en líos de 1.8 á 3.6 m de largo, y de 15 á 60 cm de diámetro. Las capas de los líos deben cruzarse. Se hace primeramente una especie de balsa flotante ó colchón, y ésta se sumerge cargándola con tierra, piedras, granzón, etc. De este modo se hicieron (1852) los cimientos para los estribos y pilares del gran puente colgante de Kieff, en Rusia, con aberturas de 134 m y sobre una arena movediza. En este caso las balsas de fajinas se extienden 30 m más allá de las bases de la mampostería que descansa sobre ellas.

Pueden usarse la fajinas del mismo modo para sostener terraplenes de ferrocarriles, etc., en terrenos cenagosos; pero bajan considerablemente.

**Pilotes de arena.** Hemos aludido ya al uso de la arena bien pisada en capas dentro de zanjas ó excavaciones de cimientos; pero también puede usarse en terrenos blandos en la forma de estacas. Primero se entierra una estaca corta y gruesa á la profundidad de 1.5 ó 3 m ó más según el caso; luego se saca ésta y se llena el agujero de arena bien mojada y bien pisada. Entonces se entierra la estaca en otro lugar y se repite la operación. Los espacios de una á otra pueden ser de 30 á 90 cm. Sobre estas estacas ó pilotes de arena pueden ponerse plataformas lo mismo que sobre estacas de madera. Si se echa arena seca y no mojada, en los pozos, hay peligro de que baje mucho después con el agua de lluvia ó de manantial. En este caso, lo mismo que en las fajinas, es bueno probar los cimientos por medio de una carga de prueba. Algún descenso debe efectuarse inevitablemente mientras todo se sitúa en su posición definitiva; pero será relativamente de poca importancia. Lo mismo ocurre hasta cierto grado en toda construcción de cierta magnitud : como en los techos ó arcos de gran abertura, sean de madera, hierro ó mampostería; lo mismo que en pilas, muros elevados, etc. Los cimientos en terrenos arenosos debajo del agua debían estar cerrados por pilotes de palastro para impedir que salga la arena en caso de que la exterior fuera arrastrada por el agua y también debían estar defendidos por un depósito de piedras colocadas alrededor. Sobre fondos malos debajo del agua se han depositado ó formado pequeñas islas artificiales de buen terreno para servir de cimientos á la mampostería. Pueden construirse algunas veces y ventajosamente por este sistema esclusas de canales y otras obras en tierras cenagosas. Si fuere necesario pueden dragarse pocos m de profundidad antes de depositar el material más firme, y este último puede cargarse primero para probar su estabilidad. Se ha empleado últimamente con buen éxito, en aguas profundas, el sistema de construir cimientos bajo el agua construyendo la mampostería sobre una plataforma de madera colocada sobre el agua, sostenida por tornillos y sumergida en el agua á medida que se termina al aire libre una hilada. Sin embargo esto no es nuevo. Fué deado por Belidor hace más de un siglo. Se entierran estacas ó pilotes á distancia de 1.8 á 3 m unas de otras alrededor del lugar que debe ocupar el pilar ó estribo,

unidas sus cabezas por fuertes piezas. Estas últimas sostienen los tornillos que trabajan á través de ellas. La construcción entera tiene ligazones contra el movimiento lateral. Un grupo de estacas bien enterradas y encerradas después por un cilindro de hierro sumergido hasta un fondo duro y lleno de concreto, constituye un cimiento excelente. Las estacas pueden llegar hasta la parte superior del cilindro y de este modo entrar en el concreto. Un sistema como éste ha sido patentado por S. B. Cushing, I. C. El cilindro y el concreto sirven para proteger las estacas de la broma é impedir que se pique la porción que queda fuera de la baja marea, pero no están puestos con la idea de soportar carga alguna.

# TRABAJO EN PIEDRA*

En los lugares donde se hacen obras en grande escala, la extracción de piedras por medio de explosivos puede hacerse algunas veces al precio de 13 á 27 centavos menos por m cúbico **taladrando á máquina y con dinamita** que usando taladros de mano y pólvora. Sin embargo, ordinariamente **el costo es más ó menos lo mismo** y la ventaja de los métodos más modernos consiste más bien en la economía del tiempo y en la conveniencia de tener el trabajo mejor inspeccionado. En trabajos ordinarios de ferrocarriles sobre roca, medianamente dura, y con jornal común de $1 por día de 10 horas, el costo por m cúbico de aflojar la piedra, es, generalmente, de 40 á 80 centavos, incluyendo herramienta, perforaciones, pólvora, etc.

**Las perforaciones para los barrenos, hechas á mano**, son generalmente de .75 á 1.20 de profundidad, y de 37 á 50 mm de diámetro. La perforación con chompa** grande es mucho más ligera y económica que la ejecutada con chompín, á martillo. La chompa es una barra redonda de hierro, generalmente de 1.8 á 2.40 m de largo, con un filo cortante de acero, que es un poco más ancho que el diámetro de la barra. Un hombre la levanta unos cm, ó, más bien, la agarra cuando rebota, la hace girar parcialmente, y la deja caer de nuevo. De este modo puede taladrar un agujero de 1.5 á 4.5 m de profundidad de cerca de 5 cm de diámetro en un día de 10 horas de trabajo, según la clase de la roca. La ejecución de 2.10 á 2.40 m de barreno de 37 mm de diámetro, es, más ó menos, la tarea regular de un día en *gneis* duro, granito ó piedra cálcarea compacta; de .9 á 1.5 en cuarzo sólido; de 2.4 á 2.70 m en mármol común ó piedra cálcarea, y de 2.70 á 3 m en piedra arenisca; pero todo esto puede variar dentro de los límites expresados. Cuando la perforación tiene más de 1.2 m, dos hombres trabajan al mismo tiempo con la misma barra.

La chompa *(jumper)*, como se usa ahora es mucho más corta ***. Un hombre (el *sostenedor*) sentado la levanta un poco, y la da vueltas parcialmente durante los intervalos entre cada dos golpes de un martillo de 3 á 5 kg de peso más ó menos, manejado por otro. Este barreno puede aplicarse á perforaciones de un diámetro menor que el que puede hacerse con una chompa. También es mejor en rocas conglomeradas, en las cuales los guijarros duros silíceos hacen salir el barreno grande de su dirección vertical, de modo que el agujero sale torcido y la barra se atraca dentro de él. Los conglomerados de carbón pueden perforarse fácilmente con la chompa. Anteriormente se empleaba la chompa también para perforaciones profundas, antes de que se reconociera la superioridad del taladro giratorio (*churn-drill*); es necesario sacarle nuevo filo cuando se ha perforado de 15 á 45 cm, y el desgaste del filo de acero obliga á renovarlo cada dos á cuatro días. En los *chompines* de hierro la parte superior se destruye prontamente. A medida que la perfo-

* *N. del T.* — Aunque en otros países los cálculos de valor del material y costo de las obras varían con los diversos jornales, cualidades del obrero, etc., dejamos esta clase de ejemplos porque siempre serán de utilidad para el cálculo de obras y presupuesto. Como el autor los trae todos en medidas inglesas: pies cuadrados, yardas cúbicas, etc., hemos reemplazado los ejemplos y presupuestos por los análogos y equivalentes, en sist metr con suficiente exactitud para cada caso.

** *N. del T.* — El término chompa, aunque no es castizo, es muy corriente en Venezuela.

*** *N. del T.* — Esta chompa más corta se llama en Venezuela *chompín*.

ración se hace más honda, se emplean frecuentemente barrenos más largos que al principio. Mientras más pequeño sea el diámetro de la perforación, tanto más profundo puede hacerse en un tiempo dado; están en razón inversa. Bajo circunstancias análogas, tres obreros, con una chompa, harán, más ó menos, la misma perforación que un hombre con un taladro giratorio.

**El taladro de mano**, en el cual el mismo hombre maneja el martillo y la barra, se usa principalmente para perforaciones de poca profundidad y de poco diámetro. Con él un obrero puede hacer tantos metros de perforación de 15 á 30 cm de hondo cada una y 18 mm de diámetro, como los que pueda hacer otro obrero con perforaciones de 90 cm de profundidad, más ó menos, y de 50 mm de diámetro, en el mismo tiempo, pero con un taladro giratorio (*churn-drill*).

Solamente la chompa y el taladro de mano son prácticos para hacer perforaciones horizontales, ó muy inclinadas.

**Costo de la piedra de cantera.** Después de los gastos preliminares para comprar el sitio de una buena cantera, limpiar la tierra de la superficie y despejar la roca superior; y después de proveer las herramientas, carros, grúas, etc., necesarios, los gastos netos totales para *extraer* la piedra bruta para albañilería, por metro cúbico, lista para entregarla, pueden calcularse aproximadamente así: piedras de tamaños tales que dos hombres puedan fácilmente levantarlas, medidas *en montones*, costarán, poco más ó menos, tanto como de $^1/_3$ á $^2/_3$ del jornal de un obrero de cantera. Grandes piedras, que varíen desde ½ á $^1/_4$ metro cúbico cada una, extraídas por explosión, de 1 $^1/_2$ á 2 $^1/_2$ jornales por metro cúbico. Grandes piedras, que varíen desde 1 á 1½ metros cúbicos cada una, en las cuales la mayor parte del trabajo se haya hecho con cuñas, á fin de que cada piedra salga en forma tolerablemente regular, y conforme á dimensiones estipuladas, desde 3 á 5 jornales por metro cúbico. Los precios más pequeños son bajos para el asperón, mientras que los más altos son altos para el granito. En circunstancias ordinarias, cosa de 1 $^1/_2$ de metro cúbico de buen asperón puede extraerse al mismo costo que 1 de granito; ó, en otros términos, fijando el costo del granito en 1, el del asperón será $^2/_3$; de modo que los promedios de los límites precedentes pueden considerarse más bien como precios completos para asperón; escasos para granito, y casi regulares para piedra caliza ó mármol.

**Costo de la labrada de piedra.** En primer lugar hay que hacer una concesión liberal por desperdicio. Aun cuando la piedra se saque bonita por todos lados de la cantera, en grandes bloques de casi la forma y tamaño requeridos, de $^1/_4$ á $^1/_4$ del bloque bruto, se gasta generalmente en desperdicios cuando está bien labrado. En bloques de tamaño moderado (digamos de un tamaño medio de ½ metro cúbico cada uno), y extraídos por explosión, una pérdida de $^1/_4$ á $^1/_3$ no será exagerada para piedras que tienen mediana facilidad para henderse derecho. Por este motivo hay también que calcular mucha pérdida para las piedras pequeñas bien desbastadas. Mientras más pequeñas sean las piedras, mayor debe ser la concesión por desperdicio en el labrado. En grandes trabajos, es bueno hacer labrar las piedras lo más posible en la cantera, á fin de disminuir el costo del transporte, pues cuando la distancia es grande, y especialmente por tierra, y por caminos comunes, el transporte constituye un gasto importante.

**Un cantero** labrará cómodamente con martillo adecuado cosa de $^1/_3$ á 1 metro cuadrado de cara lisa en granito duro en 8 horas de trabajo; ó el doble de un labrado inferior que ordinariamente se ejecuta en los lechos y cerca de las juntas; y también en las caras de piedras para puentes, etc., cuando no se requiere un acabado muy perfecto. En buen asperón, ó mármol, se puede hacer como $^1/_4$ más que en granito. Del **más perfecto** acabado á martillo, en **granito**, se hace ½ metro cuadrado, más ó menos.

**Costo de la mampostería.** Todos los elementos del costo total son susceptibles de mucha variación; en consecuencia, sólo podemos dar un ejemplo tratando el asunto desde un punto de vista muy general, para que sobre esto pueda hacerse un cálculo más aproximado. Supondremos que el salario de un obrero sea $2.00 por día de 8 horas de trabajo; y $3.50 para un albañil. El monopolio de las canteras afecta mucho * los precios.

---

* Los bloques de granito para el **monumento de Bunker Hill**, por término medio de 1½ metros cúbicos cada uno, fueron trabajados á cuña y entregados por la Asociación del Monumento en el sitio mismo, á un costo líquido de $7.03 por metro cúbico, y de una cantera abierta con ese fin. La Asociación no obtuvo ninguna utilidad; sus servicios fueron gratuitos. Las ofertas medias de contrato para ellos fueron de $32 metro cúbico. El costo de los bloques brutos en la cantera fué de $3.50. La cargada en carros en la cantera, cosa de 20 centavos. Transporte de 13 kilómetros por ferrocarril y camino

**Costo de la mampostería de piedra labrada** *. Tamaño medio de las piedras, digamos 1.50 m de largo, .60 m de ancho y .42 m de alto; entran casi tres piedras en metro cúbico. Entonces, suponiendo que la piedra sea granito ó *gneis*, el costo por métro cúbico de mampostería **con tales salarios**, será :

| | |
|---|---|
| Obtención de la piedra de la cantera por explosión, concediendo $^1/_4$ por desperdicio en el labrado; $1^1/_2$ metros cúbicos, á $4.00 por metro | $5.33 |
| Labrado de 1½ m cuadrados de cara exterior á $3.5 | 5.25 |
| — de 6 m cuadrados de lechos y juntas á $1.8 | 10.80 |
| Costo neto de la piedra labrada en la cantera | 21.38 |
| Acarreo, digamos 1 milla; carga y descarga | 1.56 |
| Mortero, digamos | .52 |
| Colocación, inclusive andamios, máquina de elevar pesos, superintendencia, etc. | 2.60 |
| Costo neto | 26.06 |
| Utilidad del contratista, digamos 15 por ciento | 3.90 |
| Costo total | 29.96 |

El labrado costará más, si las caras han de ser redondeadas ó moldeadas. Si las piedras son más pequeñas que las que hemos supuesto, habrá que labrar mayor superficie por metro cúbico.

Si en el caso precedente, las piedras han de labrarse *perfectamente* bien en todos los lados, inclusive la parte posterior, el costo por metro cúbico aumentará cosa de $13; y, si algunos de los lados fueren encorvados, como en las piedras de arco, calcúlese $15 ó $18 de aumento; y si los bloques han de ser cuidadosamente trabajados con cuña y con dimensiones dadas, $21 ó $24; llegando así el costo neto de la piedra labrada *en la cantera* á $34, $36 ó $39 por metro cúbico.

El gasto de colocación se aumentará mucho, si la piedra ha de levantarse á grandes alturas, ó si ha de ser muy movida, como cuando se lleva en lanchones para ser depositada en muelles, etc. Casi todo gran trabajo presenta ciertas peculiaridades que alteran los cálculos y que deben dejarse al juicio del ingeniero y del contratista. El tanto por ciento de la utilidad del contratista es ordinariamente menos en grandes trabajos que en pequeños.

**Costo de la mampostería de piedra labrada.** Si la piedra es asperón con buenos lechos naturales, la obtención puede fijarse en $4.00 por metro cúbico. El labrado de las caras exteriores á $2.86 por metro cúbico. Lechos y juntas á $1.40 por metro cuadrado; digamos $8.40 por metro cúbico. El costo neto, colocado, como $22.

Y el **costo total de mampostería de grandes asperones bien desbastados con argamasa** puede apreciarse en cosa de $13 por metro cúbico.

**Costo de piedras gruesas de granito desbastadas**, como se usan de ordinario para rellenar el sillar precedente; piedras que tienen por término medio cosa de ½ metro cúbico cada una :

| **Trabajo á $1 por día.** | Costo por metro cúbico de albañilería. |
|---|---|
| Obtención de la piedra de la cantera por explosión, concediendo $^1/_5$ por desperdicio en el desbaste; $1^1/_7$ m cúbico á $4.00 | 4.57 |
| Acarreo 1600 m, carga y descarga | 1.56 |
| Mezcla (73 litros de cal viva, en terrón ó en polvo; y 365 litros de arena ó cascajo; y la mezclada) | 1.95 |
| Desbaste; colocación, inclusive andamios, máquinas para levantar, etc. | 3.25 |
| Costo neto | 11.33 |
| Utilidad del contratista, digamos 15 por ciento | 1.70 |
| Costo total | 13.03 |

**Las piedras pequeñas** **, que puedan manejar dos hombres, cuesta

ordinario, $3.32. Total, $7.02. En 1825 á 1845 el trabajo de un obrero inhábil, común, valía por término medio $1 por día.

* Véase *N. del T.* * pág. 644. Los $ son dólares.

** Véase *N. del T.* * pág. 644.

extraerlas de la cantera cosa de 1.04 por metro cúbico en montón; ó calculando desperdicio, digamos $1.30. Acarreo 1 milla, $1.30. Pueden ser desbastadas toscamente y colocadas por $1.56 más; mezcla como queda dicho, $1.95. Costo neto total, $6.11; y, con 15 por ciento de utilidad, $7.03 *con los salarios dichos.*

**Con piedras más pequeñas,** como las que puede manejar un hombre, podemos calcular: piedra 90 centavos; acarreo, $1.30; colocación, andamios, herramientas, etc., $1.30; mezcla, $1.95. Resultando el costo neto, $5.45; ó, con 15 por ciento de utilidad, $6.27. El trabajo de ordenación mediana nitidamente desbastaba, cuesta de $2.6 á $4 más por metro que con ripio ó piedras sueltas, según la naturaleza de la piedra, etc. El levantamiento de paredes delgadas cuesta relativamente más que el de paredes gruesas.

**El costo de revestimientos de sillería lisos de 20 cm de espesor** para habitaciones, etc., en Filadelfia, en 1888, es próximamente como sigue por metro cuadrado de paramento exterior, todo incluído. Asperón, $16 á $24.30; mármol de Pensilvania, $27; mármol de Nueva Inglaterra, $30 á $35; granito, $24 á $30. Si es de 15 cm de espesor, hay que deducir la octava parte. *Con piedra artificial de primera clase* podía hacerse por la tercera parte del precio. **Baldosas de piedra azul de North River,** de 7½ cm de espesor, para aceras, colocadas, inclusive arena gruesa, etc., $7.50 por metro cuadrado. **Pavimento belga para calles,** con arena gruesa, completo, $4.55 por metro cuadrado en las ciudades del Este.

Cuando el revestimiento de piedra labrada está respaldado por ripio, el gasto por metro cúbico de la masa entera variará por supuesto según las proporciones de los dos. Así, si la piedra labrada cuesta $15.5 por metro y está respaldada por igual espesor de ripio á $6.5, el costo medio será ($15.5+6.5) ÷ 2=$11; ó si el ripio es dos veces tan ancho como el sillar, entonces, (15.5+6.5+6.5) ÷ 3=9.5. **Tales paredes compuestas son débiles** y susceptibles de separarse con el tiempo, como también las paredes de piedra tallada respaldadas por concreto, ó por ladrillo, á causa de que no se asientan lo mismo las dos partes. A veces al contratista deben hacérsele concesiones extraordinarias cuando tiene que abrir nuevas canteras, ó construir caminos ó abrir cimientos, ó por tener que bombearlos, estaquearlos, etc., cuando inesperadamente se encuentran manantiales; para las cimbras, para arcos, etc., á menos que estas partidas estén incluídas en el contrato.

# MUROS DE SOSTENIMIENTO

**Art. 1. Muro de sostenimiento** es el destinado á soportar la presión de las tierras, arenas ú otros *rellenos* que se depositen detrás de él, después de construído, para distinguirlo de los **muros de revestimiento,** que es una construcción semejante, erigida para evitar la caída de las tierras, que permanecen inmóviles en posición natural, á las cuales se ha excavado una cara vertical ó inclinada. La tierra, en este caso, está tan consolidada que no ejerce ninguna, ó muy poca, presión lateral, y por lo tanto, el muro puede, generalmente, ser más delgado que el de sostenimiento.

Esto, sin embargo, depende de la naturaleza de la posición de las capas del terreno en el cual se ha preparado la cara. Si las capas son de roca, con camadas interpuestas de arcilla, de tierra ó arena, ó si están inclinadas hacia el muro, puede necesitar un espesor mayor que cualquier muro de sostenimiento ordinario, porque cuando las capas delgadas de tierra se ablandan por la filtración de la lluvia, actúan como un lubricante semejante al jabón ó al sebo, y facilita el deslizamiento de las capas de roca y de este modo producen una presión enorme contra el muro. O la roca puede entrar en movimiento por la acción de la escarcha sobre las capas de greda, ó, como suele suceder, por la trepidación producida por los trenes que pasan. Aun no existiendo roca, si las capas del suelo se inclinan hacia el muro, habrá siempre peligro de un resultado semejante, y deben tomarse precauciones adicionales, especialmente cuando las capas alcanzan á una altura mucho mayor que el muro. **En un muro vertical,** tanto *c o* como *d s* son verticales.

**La experiencia, más bien que la teoría,** debe guiarnos en la construcción de ambas clases de muros. Recomendamos que el espesor horizontal *ab*, fig. 1, en la base de un muro de sostenimiento vertical ó casi vertical *cdba*, que sostiene un relleno, sea de arena, granzón ó tierra, á nivel con su parte superior *cd*, como en la figura, no sea menor de lo que se indica en seguida en la práctica de ferrocarriles, cuando los cimientos no tengan sino una profundidad de .90 m más ó menos.

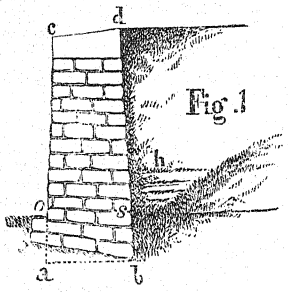

Fig. 1

**Cuando el relleno se ha depositado flojamente (es decir, cuando es de tierra echada) como de costumbre, tal** como cae de los carros, carretas, etc.

| | | |
|---|---|---|
| Muros de piedra tallada ó de piedras brutas dispuestas en hiladas grandes de primera clase, en mortero *ab* | .35 | de su altura total vert *db*. |
| Muro de buenas piedras brutas comunes desbastadas en mortero, ó de ladrillos | .4 | — — — |
| Muro de piedra en seco, bien desbastada | .5 | — — — |

Con buena mampostería, sin embargo, podemos tomar altura *ds* en lugar de *db* y entonces las fracciones de la altura arriba dadas darán un espesor suficiente en la línea de tierra *os*. Cuando el relleno está algo consolidado en capas horizontales, pueden reducirse cada uno de estos espesores, pero no se pueden dar reglas fijas para este caso. La parte saliente *oe* de la base del muro no está comprendida en estos espesores. Sin embargo, cuando el relleno es de arena limpia pura ó de granzón debemos darle las dimensiones enteras, por cuanto la trepidación producida por los pasos de los trenes perturbando la cohesión neutraliza cualquier ventaja supuesta al apisonar el material. Tales arenas pueden apisonarse con mucha ventaja con el propósito de comprimirlas en los cimientos; pero esto hace diferente el caso. Cuando se hace esto, aun en tierras de cohesión para economizar mampostería en los muros de sostenimiento, es probable que el costo resulte igual al de la mampostería economizada. La base, *ab*, fig. 1, es $^4/_{10}$ de su altura *bd*. En los espesores mencionados de la base la cara interior del muro *db* se supone vertical y la *ac* vertical ó inclinada hacia atrás, pero no más de 1 en 8, más ó menos. De este límite no debe pasarse en la práctica, debido á los malos efectos de la lluvia, etc., sobre el mortero, cuando la inclinación es mayor. La base de un muro vertical o requiere en efecto tanto espesor como uno inclinado; pero cuando la inclinación no pasa de 1 en 8, la diferencia es muy pequeña. Véase tabla, art. 7.

*Nota* 1. **Una mezcla de arena ó de tierra con una fuerte proporción** de guijarros redondos grandes, ó de piedras de las usadas para empedrar, etc., pesa considerablemente más que los materiales usados ordinariamente para rellenos y ejerce una presión mayor contra el muro, cuyo espesor debe aumentarse de un octavo á un sexto, cuando el relleno es de aquella naturaleza.

*Nota* 2. El muro será más fuerte, si todas las **hiladas de la mampostería se ejecutan con una inclinación hacia adentro,** como en, *oeb*, especialmente en la mampostería de piedra en seco, ó cuando no se le puedadar al mortero el tiempo suficiente para que tragüe bien, antes de colocar el rellen detrás de él. El objeto de esta inclinación de las hiladas de mampostería es colocar las juntas lo más próximamente en ángulo recto á la dirección de la presión *fP*, figs. 6, 7, 8,

contra el paramento interior del muro, para de este modo disminuir la tendencia de las piedras á deslizarse una sobre otra, y causar el desplomo del muro.

Cuando las hiladas son horizontales, no hay otra cosa que impida este deslizamiento, que el frotamiento de una piedra contra otra, si la mampostería es de piedra en seco; ó el frotamiento con el mortero, cuando se usa este último. Pero cuando, como ocurre á menudo (especialmente en muros gruesos construídos con mucho apuro), el mortero no tiene tiempo de fraguar, no opondrá sino muy poca resistencia al deslizamiento. Cuando las hiladas están inclinadas, no pueden *deslizarse*, sin que al mismo tiempo tengan que subir por el plano inclinado formado por ellas mismas. En los muros de sostenimiento, como en los estribos de arcos importantes, el ingeniero debe (en cuanto á la estabilidad) confiar lo menos posible en el mortero, y más bien en la posición de las juntas. Hay que hacer una objeción á esta inclinación de las juntas en los muros de piedra en seco, y es que el agua de lluvia, al caer sobre la cara inclinada de un muro, corre por las juntas hacia el interior del muro, en el relleno, el cual se ablanda y se asienta ó baja más. Pero esto puede obviarse en gran parte haciendo horizontales las hiladas exteriores ó de la cara, ó aplicando mortero en esta parte hasta una profundidad de .30 m, más ó menos. La parte superior del muro debe defenderse con un caballete *cd*, fig. 1, que sobresalga algunos centímetros del frente. Después de construída la mampostería hasta la superficie del suelo, deben rellenarse las excavaciones hechas para los cimientos, y es bueno consolidar este relleno apisonándolo, especialmente enfrente del muro.

**El paramento interior del muro debe dejarse áspero.** En los muros de mampostería de ladrillos sería bueno que cada tercera ó cuarta hilada sobresaliese de 3 á 5 cm. Esto aumenta el frotamiento de la tierra contra el paramento interior del muro, y de este modo la resultante de las fuerzas que actúan detrás del muro se acerca más á la vertical y cae más hacia dentro en la base, aumentando la estabilidad. También conduce á aumentar la resistencia el no hacer cada hilada de mampostería de una altura uniforme en todo el espesor del muro, sino colocar algunas piedras (especialmente cerca del paramento interior) de la altura de dos ó tres hiladas. De este modo toda la mampostería está más entrelazada, más unida, y por consiguiente más sólida. Se pueden hacer muros muy gruesos con el paramento exterior de mampostería y el interior de concreto.

*Nota* 3. La presión de la tierra misma contra la cara interior es la que produce el frotamiento, el cual á su turno modifica la acción de la presión; porque el peso ó la presión de un cuerpo sobre un plano inclinado produce frotamiento entre el cuerpo y el plano, suficiente á veces para impedir que el cuerpo resbale. Un muro de sostenimiento se *vuelca* al hacerle girar alrededor de su arista exterior *e*, fig. 1, como apoyo, pero para esto su paramento interior debe, evidentemente, elevarse primero; y al hacer esto tiene que rozar contra el relleno, y de consiguiente vencer este frotamiento. El frotamiento es el mismo esté el muro firme ó no; como en el caso de un cuerpo sobre un plano inclinado; la única diferencia es que en un caso *impide* el movimiento y en el otro sólo lo *retarda*.

**En el lugar donde pueda ocurrir una congelación fuerte,** al paramento interior del muro debe dársele una escarpa hacia adelante de 60 á 90 cm

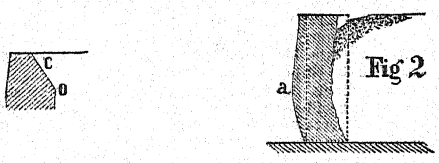

Fig 2

en su parte superior, *co*, la que debe ser enteramente lisa para disminuir la adhesión de la escarcha.

***Nota* 4.** Cuando el muro es muy delgado forma una *comba* ó *abombamiento* hacia fuera, próximamente á un tercio de su altura, sobre la superficie, y generalmente se cae, fig. 2.

Un ligero abombamiento en un muro nuevo no prueba *necesariamente* que esté inseguro. Esto se debe generalmente á lo nuevo del mortero, y á la presión mayor que ejerce el relleno nuevo; muchas veces deja de aumentar en algunos meses

No debe uno preocuparse si el abombamiento no excede de $^1/_{48}$ del espesor en *a*. Véase nota 3, art. 7.

**Art. 2.** El ingeniero joven no tiene necesidad de ocuparse mucho en la práctica **del peso específico exacto del relleno**, ni del ángulo de inclinación bajo el cual se sostiene éste, porque el material que se deposita detrás del muro hoy, puede estar seco é incoherente, como para que resbale por un talud de 1½ á 1; y mañana la lluvia puede convertirlo en un fango líquido, que busca su nivel como el agua; al día siguiente puede estar helado y capaz de sostener una carga considerable, como por ej. : un pilar vertical.

Además, no puede saberse de antemano, cual pueda ser la naturaleza del relleno; porque como regla general, éste debe ser de cualquier material que la excavación más cercana produzca de tiempo en tiempo; hoy arena, roca mañana, etc. Los muros de sostenimiento por lo regular se construyen antes de que el ingeniero conozca la condición del relleno; de modo que, en la práctica, estas consideraciones teóricas tienen comparativamente poca importancia. La teoría, sin estar sancionada por la observación y el sentido común, nos conducirá á cometer graves errores en todos los ramos de la ingeniería; pero, por otra parte, ningún grado de experiencia, por sí solo, compensa la ignorancia de la teoría. Las dos deben andar juntas.

Por otra parte, **el asiento del relleno por su propio peso**, ayudado por la trepidación que produce el pasaje rápido de trenes pesados, su expansión cuando se hiela, ó la filtración de la lluvia, la presión hidrostática producida por la penetración de ésta en las grietas que se forman en el relleno durante un prolongado tiempo seco, lo mismo que la acción lubricante que ejerce sobre él (que disminuye su frotamiento y le comunica una tendencia á deslizarse), etc., ejercen algunas veces una tendencia al volcamiento, tan fuerte que alcanza á lo indicado por la presión teórica. La acción de estos agentes es gradual. La observación atenta de los muros de sostenimiento ha demostrado, año tras año, que sus paramentos inclinados se vuelven verticales. Luego principian á inclinarse hacia afuera, y, por último, algunos se caen. La teoría hace omisión de las cargas que puedan sobrevenir y aumentar la presión del relleno.

Suponiendo correctas las ideas avanzadas por el profesor Moseley como teorías, los espesores que hemos recomendado en el art. 1 para muros de mampostería hechos con morteros, corresponden á presiones calculadas por él de 7 hasta 14 veces mayores, y en los muros de piedra en seco, más ó menos de 10 á 20 veces la presión señalada por él; y no obstante, no consideramos que nuestros espesores sean mayores de lo que la experiencia exige. Véase la tabla 3. Muros de sostenimiento calculados por buenos ingenieros, pero muy ajustados á la teoría (la cual supone suficiente una resistencia igual al doble de la presión teórica), han fallado; y es natural deducir que muchos de los existentes tienen un coeficiente de seguridad demasiado pequeño.

El hecho es (ó por lo menos así nos parece) que deben existir defectos en las suposiciones teóricas de algunos de los autores más prominentes que suministran reglas prácticas sobre esta materia. Así, Poncelet, que ciertamente está á la cabeza de ellos, dice que sus tablas de uso práctico dan espesores en la base para soportar 1.8 veces la presión teórica, y la considera suficientemente segura. Sin embargo, él trae para un muro vertical de granito tallado, construído para sostener arena seca hasta el nivel de su parte superior, como en la fig. 1, una base de .35 de su altura vertical, y para ladrillos .45; pero el autor halló que no habiendo trepidación, un modelo de madera de muro vertical, que pesaba sólo 441 kg por metro cúbico, con una base de .35 de altura, hizo equilibrio perfectamente á arena seca con talud de 1½ por 1, pesando 1402 kg por metro cúbico.

Ahora bien; la resistencia de muros semejantes de las mismas dimensiones, varía como sus pesos específicos; y como el granito pesa más ó menos 2,600 kg por m cúbico ó como 6 veces más que nuestro modelo, se sigue que un muro de dicho material con una base de .35 de su altura debe tener una resistencia 6 veces mayor, en lugar de 1.8 solamente, y un muro de ladrillos más ó menos 5 veces la resistencia teórica. Nuestros experimentos se hicieron en la habitación alta de un edificio sólidamente construído, y hallamos que la trepidación producida por los vehículos que pasaban por la calle, cerradas las puertas, ó simplemente por caminar en el cuarto, bastó para producir, gradualmente, desplomos en los muros, y creemos que los efectos perjudiciales de un tren pesado serían no menos grandes comparativamente sobre un muro de sostenimiento que soporte un material tan incoherente como la arena. Desde que el muro de Poncelet es en este ejemplo suficientemente estable en la práctica, nos parece que su teoría, que no considera los esfuerzos de la trepidación, debe ser defectuosa. Él también da $^1/_5$ de la altura como espesor de sufi-

ciente seguridad para un muro vertical de granito que sostenga una tierra dura; pero sospechamos que á pocos ingenieros les gustaría fiarse de esta proporción especialmente durante las lluvias y cuando, como generalmente se hace, la tierra está simplemente echada. Si la tierra se deposita, y se consolida en capas, la teoría nos dará poquísimo espesor para el muro, porque el relleno se vuelve, por decirlo así, una masa de ladrillos crudos, que no ejerce ninguna presión horizontal, y que sólo requiere la protección contra la influencia atmosférica, para obtener su estabilidad sin muro de sostenimiento. Es con mucha timidez y desconfianza en nuestras opiniones, que nos atrevemos á expresar nuestras dudas con respecto á las ideas de un investigador y escritor tan profundo como Poncelet; lo hacemos solamente con la esperanza de que personas más competentes que nosotros emitan sus opiniones. Las nuestras no tienen otra base que los experimentos hechos por nosotros mismos con modelos de madera y de ladrillos, en combinación con las observaciones realizadas sobre muros existentes.

**Art. 3.** Después de trazar un muro *abco*, fig. 3, de paramento interior vertical según las proporciones de nuestra regla del art. 1, **se puede convertir en uno de paramento interior en escalones como** *aino*. Este presentará mayor resistencia al volcamiento, y sin embargo no contiene más material. Por el centro *t* del paramento interior trácese una línea cualquiera, *in*, por *n* trácese *ns* vertical; divídase *is* en un número *par* de partes iguales (en la fig. hay 4), y divídase *sn* en el mismo número de partes iguales más una (en la fig. hay 5). Por los puntos de división trácense líneas horizontales y verticales para formar los escalones como en la figura.

En el muro de escalones, el centro de gravedad se encuentra más al interior de la arista *o* que en el otro muro, dando así un brazo de palanca y resistencia mayores; pero dentro de los límites ordinarios de la práctica, la diferencia es muy pequeña, y como el prisma triangular de las tierras sostenidas es más grande que cuando el paramento interior es vertical, la presión es mayor también; de modo que probablemente por este respecto no hay ventaja apreciable. **El aumento de espesor cerca de la base disminuye sin embargo, el brazo de palanca** *va*, **fig. 3, del empuje** *P*, **de la tierra** contra el paramento interior del muro. El *centro de presión* de este empuje está en ambos casos á la tercera parte de su altura vertical, medida desde su parte inferior, y por consiguiente, es claro que mientras más distante del paramento exterior se aplique, más corto será *va*. Además, en el paramento interior en escalones, la *dirección* de la presión se hace más aproximadamente vertical que cuando dicho paramento interior es vertical. Es debido á estas causas, más bien que á la transposición hacia atrás del centro de gravedad, á lo que el muro escalonado debe su aumento de estabilidad sobre los de paramento interior vertical.

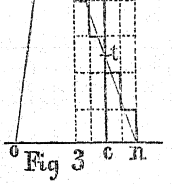

Fig 3

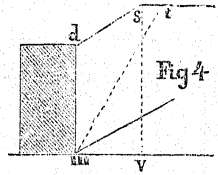

Fig 4

**Art. 4. Cuando, como en la fig. 4, el relleno tiene mayor altura que el muro y presenta una rampa hacia el interior de la arista** *d* **con una pendiente igual al talud natural,** *ds*, de 1½ á 1, creemos que los espesores de la base que siguen serán á lo menos *suficientes* para muros verticales con relleno de arena. Se han deducido de los experimentos aludidos arriba, y son solamente ligeras aproximaciones, sin ninguna base científica. No las daríamos á no ser por el hecho de que no conocemos ningunas otras que convengan á este caso.

La primera columna contiene la altura vertical *sv* de las tierras, comparada con la altura vertical del muro, el cual suponemos ser=1; de modo que la tabla prin-

cipia con el relleno de altura igual á la del muro mismo, como en la fig. 1. Estos muros verticales pueden cambiarse en otros, con caras inclinadas ú oblicuas, según el art. 8; ó sin este método, sus caras pueden hacerse oblicuas en cualquier grado que no pase de 1 en 8, sin afectar sensiblemente la estabilidad y sin aumentar su base.

**TABLA 1.** (Original.)

| Altura total de la tierra comparada con la altura del muro sobre la superficie del suelo. | Muro de piedra tallada con mortero. | Muro de piedra ó ladrillo con buen mortero. | Muro bueno de piedra en seco. | Altura total de la tierra comparada con la altura del muro sobre la superficie del suelo. | Muro de piedra tallada con mortero. | Muro de piedra ó ladrillo con buen mortero. | Muro bueno de piedra en seco. |

Cuando la tierra pasa más arriba de la parte superior del muro, como en las figs. 4 y 5, el muro está **sobrecargado**, y á la tierra que esté encima de la parte

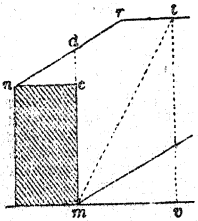

**Fig. 5**

superior se la llama **sobrecarga**; cuando se deposita con cuidado dicha sobrecarga, de modo que las tierras formen una escarpa de un ángulo mayor que 1½ á 1, como por ejemplo de 1 á 1, la teoría no exige que el muro sea tan grueso. Sin embargo de la gran reputación de Poncelet, el autor no puede imaginarse que la base de un muro de ladrillos debe ser de 1⅓ veces su altura para cualquiera altura de arena que pueda haber.

**Art. 6. Teoría de los muros de sostenimiento.** Sea *beam*, fig. 6, un muro tal, que sostenga un relleno *csmg*, cuya superficie superior *cs* sea horizontal, y á nivel con la parte superior *bc* del muro; y que *ms* represente el talud natural de las tierras de que se compone el relleno, siendo *mg* horizontal.

Muchas experiencias hechas en las obras públicas demuestran que este talud, sea arena, ó tierra, estando estas secas, puede prácticamente tomarse como de 1½ á 1; es decir, 1½ horizontal para 1 vertical; que corresponde á un ángulo *smg* de 33°41′ con el horizonte; que es también más ó menos el ángulo bajo el cual el ladrillo ó la piedra toscamente labrada, principian á resbalar una sobre otra.

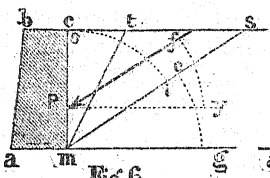

Fig. 6

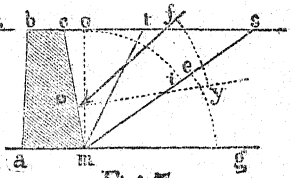

Fig. 7

Este ángulo, sin embargo, varía considerablemente, influyendo en gran manera el grado de sequedad ó humedad del material, de modo que tierra ó arena medianamente húmeda, se sostiene en un talud de 1 á 1, es decir, bajo un ángulo de 45°. Sea como fuere, se llama **ángulo del talud natural** del material. En los cálculos teóricos de los muros, lo más acertado es suponer (como lo hemos hecho continuamente) que el relleno está perfectamente seco, ya que entonces es que produce mayor presión, á menos que se le suponga tan mojado que adquiera algún grado de fluidez. El prisma triangular *oms* de las tierras que reposan sobre el talud natural *ms*, tiende á resbalar por dicho talud, pero el muro se lo impide.

Debe suponerse siempre que el muro no puede *resbalar* sobre su base, art. 9, que tiene un espesor suficiente para no combarse, y que solamente puede destruirse por el volcamiento girando alrededor de su arista exterior *a* como arista de apoyo. El espesor de seguridad requerido para que no suceda esto último, será también suficiente para impedir el desplome. Refiriéndonos ahora solamente á la fig. 6, de paramento interior vertical, si el ángulo *oms*, entre el talud natural *ms* y la línea vertical *mo*, tirada por la arista inferior del muro, se divide por una línea *mt*, en dos ángulos iguales, *omt*, *tms*, entonces el ángulo *omt* y la línea *mt* se llaman respectivamente **el ángulo** y **el talud de la presión máxima**. El prisma triangular de las tierras, del cual *omt* es una sección, se llama **el prisma de presión máxima**, porque considerándolo como una cuña que actúa contra el paramento interior del muro, produciría sobre éste una presión mayor que el triangulo entero de tierra *oms*, considerándolo como una cuña sola. Porque aunque este último es más pesado, está más sostenido por la tierra que está debajo. Los cálculos demuestran que si consideramos la tierra *oms* dividida en cuñas por *cualquiera* línea *mt*, la cuña que ejerce más presión contra el muro es la que se forma cuando *mt* divide el ángulo *oms*, ó el arco *oi* en dos partes iguales. Pero véase art. 11.

Como *mg* es horizontal, y *mo* vertical, las dos forman un ángulo de 90°; por consiguiente el ángulo de la presión máxima se encuentra restando de 90° el ángulo, *smg*, del talud natural y dividiendo el residuo por dos. De este modo un talud de 1½ en 1, ó de 33°41′ restado de 90°, da un residuo de 56°18′ y 56°18′ ÷ 2 = 28°9′ **ángulo, o m t, correspondiente á la presión máxima**. Para facilitar el cálculo se considera generalmente una unidad de longitud de muro y de relleno. El número de unidades cúbicas de muro ó de relleno es entonces igual al de las unidades cuadradas de sus respectivos perfiles ó secciones transversales. Ahora bien; según Moseley, si suponemos que las partículas de tierra que componen el relleno están perfectamente secas y sin cohesión (ó tendencia á pegarse unas con otras, lo

que casi sucede con la arena pura), y si suponemos que se quita el muro repentinamente, entonces el prisma triangular de las tierras, *cmt*, comprendido entre el talud de presión máxima, *mt*, y el paramento vertical, *cm*, del muro, fig. 6, se deslizaría hacia abajo, bajo la influencia de una fuerza (que puede representarse por *yP*) que actúa en una dirección perpendicular á la cara, *cm*, de dicho prisma (ó, en otras palabras, en ángulo recto al paramento interior del muro vertical), estando su centro de presión en P á una distancia de ⅓ entre *m* y *c* medida desde el suelo, y su intensidad igual á cualquiera de las siguientes:

**N.º 1.** Presión perpendicular $yP = \dfrac{\text{Peso del prisma triangular de las tierras } cmt \times ot}{\text{Altura vertical } om.}$

**N.º 2.** Presión perpendicular $yP = \dfrac{\text{Peso de un solo m cúbico de relleno} \times ot^2}{2}$

} Véase art. 11.

En vista de la gran incertidumbre que envuelve en la práctica el asunto relativo á la presión real de las tierras contra los muros de sostenimiento (véase art. 2), y para dar una regla sencilla, la cual, aunque no apoyada en la teoría, es, sin embargo (en opinión del autor), suficientemente aproximada para las operaciones comunes de la práctica, supondremos que el n.º 1 de las dos fórmulas arriba mencionadas, se adapta también con suficiente aproximación á los muros de **paramento interior inclinado** *cm*, figs. 7 y 8 (exactamente con las mismas letras), á lo menos **para inclinaciones del paramento interior hacia adelante como de 1 horizontal para 2 vertical**, ó de un ángulo *cmo* de 26°34'. **Lo que sigue sobre muros de sostenimiento está basado en esta suposición incorrecta y debe considerarse que sólo dan una seguridad aproximada.**

Parece que algunos suponen que esta presión perpendicular sea la única que obra contra el paramento interior del muro, y por consiguiente, llegan á conclusiones erróneas en la práctica. Cuando para impedir que esta fuerza cause el resbalamiento del prisma de las tierras, colocamos el muro de sostenimiento frente á él, entonces, en lugar de *movimiento*, la fuerza producirá presión de la tierra contra el muro, desarrollando frotamiento entre las superficies comprimidas de la tierra y el muro.

Es decir, si un muro estuviese á punto de principiarse á volcar alrededor de su arista *a* como apoyo, su paramento *cm* tendría, por supuesto, que levantarse, y al hacer esto debe rozar contra el relleno de tierra en contacto con él, y este rozamiento obraría evidentemente en el sentido de *impedir* que se volcase. Mientras el muro no se mueva el mismo frotamiento contribuye á *evitar* que se vuelque.

Para hallar la intensidad y efecto del frotamiento, representemos por *yP*, fig. 8, *en escala*, la fuerza perpendicular al paramento interior *cm*; y supondremos haberla calculado previamente por la fórmula n.º 1 que antecede. Hágase el ángulo *yPf* igual al ángulo de frotamiento del muro*; trácese *yf* en ángulo recto con *yP*, ó bien paralela á *mc*; hágase *Px* igual á *yf*, y complétese el paralelogramo *Pyfx*. Luego *xP* representará en la misma escala la **intensidad del frotamiento contra el paramento interior del muro.**

Tenemos por consiguiente dos fuerzas obrando en P, es decir, la fuerza perpendicular *yP*, y el frotamiento *xP*; por consiguiente, por la composición y descomposición de las fuerzas, la diagonal *fP* del paralelogramo *Pyfx*, medida en la misma escala, nos dará la intensidad de su resultante; **la cual es aproximadamente la única fuerza teórica, tanto en intensidad como en dirección, que el muro tiene que resistir**, incluyendo el frotamiento del muro.

Pero esta fuerza, *fP*, es también igual á la fuerza perpendicular *yP*, multiplicada por la secante del ángulo *yPf* de frotamiento del muro (ó dividida por su coseno), y puede por supuesto encontrarse de este modo:

$$\text{Presión teórica aproximada } fP = \frac{\text{Peso del prisma triangular } cmt}{\text{Altura vertical } om.} \times ot \times \frac{\text{Secante del ángulo } yPf \text{ de frotamiento del muro}}{} = \frac{\text{Peso de } cmt}{\text{Coseno } yPf} \times \frac{ot}{om}$$

O finalmente, si suponemos, como lo hemos hecho, que la tierra está perfectamente seca (su presión es entonces la mayor) y que los ángulos del talud natural

* Este ángulo de frotamiento es el ángulo de inclinación con la horizontal, que debe dársele á un plano de mampostería para que la arena ó tierra seca se deslicen sobre él. Es, más ó menos, lo mismo que el talud natural 33°41', ó 1.5 á 1. Su secante es 1.202, y su coseno = .832.

son entonces cada uno iguales á 33°41′ ó de 1.5 á 1, entonces en las figs. 6, 7 y 8, si el ángulo *cmo* que forma el paramento interior *cm* y la vertical *om* no excede de 26°34′, más ó menos, podemos suponer que la

**Presión aproximada** *fP* = **Peso del prisma triangular** *cmt* × .643

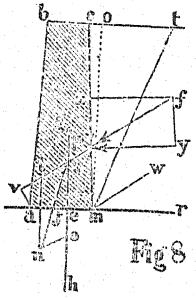

Fig 8

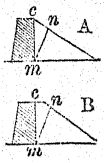
la cual comprende la acción del frotamiento de la tierra contra el paramento interior del muro.

*Nota* 1. **Cuando el paramento interior del muro está construído de escalones**, como en la fig. 3, en lugar de ser simplemente oblicuo, ó inclinado como en las figs 7 y 8, la dirección de la presión de la tierra será la misma que si el paramento interior tuviese la inclinación, *i n*.

*Nota* 2. **Para encontrar tanto la tendencia de las tierras á volcar el muro** como la resistencia de éste á ser volcado alrededor de *a* como apoyo, búsquese primero el centro de gravedad *g* del muro, y por él trácese una línea vertical *gh*. Prolónguese *fP* hacia *v*, y tírese *av* perpendicular á ella. Hágase en cualquiera escala *so* = peso del muro, y *si* = presión calculada *fP*. Complétese el paralelogramo *s i n o* y tírese su diagonal *sn*, que será la resultante de la presión *fP* y del peso del muro; y para que ofrezca seguridad, debe resultar tal que *aj* no sea *menos* de la quinta parte de *am*, *aun con la mejor mampostería y con el terreno más firme*. De lo contrario, la gran presión, tan próxima á la arista *a*, puede, ó fracturar el muro, ó comprimir el suelo cerca de aquel punto, de modo que el muro se incline hacia adelante. En los muros construídos según nuestra regla, art. 1, ó según la tabla, pág. 657, *aj*, es mayor que la quinta parte de *am*. Multiplicando la presión *fP* por su brazo de palanca, *av*, tenemos el momento de la presión en *a;* y el peso del muro multiplicado por su brazo de palanca, *ea*, nos da el del muro. *El muro ofrece seguridad contra el volcamiento* en la misma proporción en que está su momento con el del empuje. Se supone incapaz de resbalamiento, fractura ó hundimiento.

*Nota* 4. **Si la tierra se inclina** de C hacia abajo, como en la fig. A ó B, en lugar de estar horizontal como en las figs. 6, 7 y 8, úsese el peso de la tierra *cmn* en



lugar de, *cmt*, siendo, *mn*, el talud de la mayor presión. En A el punto de aplicación estará todavía en P (á una tercera parte de *mc*) como en las figs 6, 7, 8; pero en B estará un poco más alto como se indica abajo en la fig. 9.

**Muros sobrecargados** son aquellos en los cuales el relleno se prolonga por sobre la parte superior de los muros. Según la teoría, cuando, como en la fig. 9, hay una sobrecarga, *vck*, del relleno que se prolonga desde *c*, según el talud natural

*ev*; se produce la presión máxima contra el muro cuando la tierra llega al nivel *d*, donde la dirección inclinada de la presión máxima, *md*, intersecta la cara del talud natural, *ev*; de modo que si después llega la tierra hasta *v*, ó más arriba, no se ejerce por eso más presión contra el paramento interior del muro. Lo mismo deci-

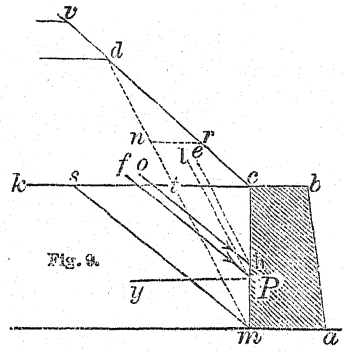


Fig. 9.

mos si el talud de las tierras parte de, *b*; ó de un punto entre *c* y *b*, con la diferencia de que entonces la dirección inclinada *md* de la presión máxima debe prolongarse hacia arriba para encontrar á este otro talud.

**La intensidad aproximada** de la presión oblicua, cuando el muro está sobrecargado (como en las figs. 4, 5 y 9), puede hallarse por el mismo principio que cuando la tierra está al nivel de su parte superior; es decir, en lugar del prisma *triangular cmt* de las tierras, figs. 6, 7, 8 y 9, búsquese el peso de todas las tierras, *dsmt*, en la fig. 4; *dmtr*, en la fig. 5; ó *cdm*, en la fig. 9 (si la sobrecarga llega á *d* ó *v* ó más arriba) entre la dirección inclinada *md*, fig. 9, *mt*, figs. 4 y 5 de la presión máxima, el paramento interior del muro y el talud, omitiendo á *den*, fig. 5, que descansa sobre la parte superior del muro (y de este modo ayuda á su estabilidad), cuando el talud principia enfrente de *c*. Después de haber hallado este peso, tenemos entonces para relleno seco que la

**Presión aproximadamente = Peso de la tierra × .643**

incluyendo la acción del frotamiento de las tierras contra el paramento interior del muro. Esto con suficiente aproximación (según la opinión del autor) para todas las operaciones prácticas en una materia tan incierta, pero esencialmente empírica.

**La dirección de la presión** hallada así es la misma que cuando la tierra está al nivel de la parte superior *bc;* es decir, como en las figs. 6 y 7, trácese primero una línea *y*P perpendicular al paramento interior *cm*, sea vertical ó inclinado. Luego tírese otra línea P*f* formando el ángulo de frotamiento del muro, el cual suponemos siempre de 33°41′, ó 1.5 á 1. Entonces P*f* dará la dirección de la presión. Pero su punto de aplicación no estará siempre en P (al tercio de la altura del muro sobre *m*) como hasta ahora, porque en todos los casos estará en un punto P, ó en alguno más arriba, *h*, tal que una línea *h*P ó *eh*, fig. 9, tirada por el centro de gravedad de las tierras sostenidas, corte el paramento interior (omitiendo las tierras que descansan inmediatamente sobre la parte superior *bc*) y paralela á la dirección *md* de la presión máxima. Una línea tal encuentra al muro á una tercera parte de su altura cuando la tierra sostenida *tcm* ó *dcm* **forme un triángulo completo**, uno de cuyos ángulos esté en el extremo superior *c* de la arista interior del muro. En todos los otros casos dicha línea, cuando haya sobrecarga, tocará más arriba de P.

**Art. 7.** En la pág. 648, fig. 1, recomendamos que la base *os* en la línea de tierra de muros **verticales** bien construídos no fuese menos de .35, .4 ó .5 de la altura *ds* sobre dicha línea de tierra, según la clase de mampostería. Pero un muro con paramento inclinado como el trazado en el art. 8 (por el cual se construyó la tabla siguiente), será tan resistente, conteniendo al mismo tiempo menos mampostería que un muro vertical, aunque el muro inclinado tenga la base *os* más ancha.

**Tabla 3, de los espesores *so* en la base, fig. 1, y en la parte superior *cd* de los muros de paramentos exteriores inclinados, y tan resistentes como los muros verticales que contienen más mampostería.**

| Todos los muros á continuación tienen la misma resistencia que un muro vertical cuya base *os*, fig. 1, sea igual á .35 de su altura *ds*. | | Todos los muros á continuación tienen la misma resistencia que un muro vertical cuya base *os*, fig. 1, sea igual á .4 de su altura *ds*. | | Todos los muros á continuación tienen la misma resistencia que un muro vertical cuya base *os*, fig. 1, sea igual á .5 de su altura *ds*. | |

Moseley y otros autores suponen un *talud de arena seca de* 21° Sería mejor no continuar la propagación de errores tan evidentes como éste. La arena seca no se mantiene sin resbalar á un ángulo menor para un sabio que para cualquiera otra persona. En las aplicaciones prácticas podemos decir que la arena, el granzón y las tierras secas toman un talud de 3:2041 ó 1½ á 1; como lo prueban las numerosas experiencias hechas en los rellenos de ferrocarriles. Poncelet da tablas para muros que sostienen tierra seca con un talud de 1 á 1, ó 45°; pero nosotros no creemos en la existencia de tal tierra, y omitimos estas tablas. La arena, el granzón y la tierra pueden humedecerse á grados diferentes, como para tomar un talud cualquiera entre la horizontal y la vertical; y humedeciéndolas y apisonándolas, pueden convertirse las tierras en masas compactas, que ejercen poca ó ninguna presión; y pueden hasta continuar así después de secas; siendo entonces, de hecho, una especie de ladrillo crudo. Algunas veces es difícil saber si la tierra ó la arena están perfectamente secas ó no, y un grado excesivamente pequeño de humedad les hace tomar un talud de 1 á 1, en pilas pequeñas, como las que probablemente han observado las autoridades en esta materia. El autor observó que la arena fina de playa bajo techo tomaba un talud de 1½ á 1 en tiempo seco y de 1 á 1 en tiempo húmedo; sin embargo, era imposible por el tacto descubrir diferencia alguna en el grado de humedad. Su sensibilidad á la humedad era debida de seguro á la sal. Algunos puñados de tierra seca pueden obligarse quizás á tomar un talud de 1 en 1 sobre una mesa; pero lo que podemos asegurar, como consecuencia de nuestras observaciones, es que cuando se la deja caer de carretas, ó carros de mano, su talud es más ó menos 1½ á 1, y creemos que éste debe ser el talud que debe usarse en la práctica, donde la seguridad es la condición de suprema importancia.

**Mientras menor sea el talud natural, mayor será la presión,** y como dicho talud menor tiene efecto cuando el relleno está perfectamente seco comitiendo por supuesto el caso en que esté tan mojado que se encuentre parcialmente líquido), hemos limitado para mayor seguridad nuestras tablas al relleno seco. Como dijimos en el art. 1, no podemos recomendar dimensiones menores de las que hemos dado allí, cuando consideramos el trato tan recio á que están expuestas las mamposterías en obras públicas.

**Al hacer un camino á lo largo de precipicios peligrosos** estuvimos tentados algunas veces á hacer muros de más espesor todavía. Creemos, por ejemplo, que la fuerza centrífuga de un tren pesado, que corre rápidamente por una curva de poco radio, convexa del lado peligroso, no debe descuidarse como elemento del cálculo para muros así situados. Esta fuerza es horizontal y se aplica cerca de la parte superior del muro; y, por consiguiente, su brazo de palanca puede considerarse igual á su altura; en tanto que la presión teórica de la tierra es oblicua, y

está aplicada á una tercera parte de altura sobre el suelo; de modo que su brazo de palanca respecto de su pie es muy corto. Además, el solo *peso* del tren produce presión contra el muro; lo mismo que el peso del relleno. Los teóricos omiten todas estas consideraciones. La presión perjudicial causada por la trepidación, etc., no se puede suponer aplicada, á la tercera parte de la altura, ni puede calcularse de manera alguna.

*Nota* 2. **Los muros de muelles** son ejemplo de muros donde el espesor debe aumentarse, á pesar de que la presión del agua frente á ellos ayuda á sostenerlos. La tierra detrás de estos muros, no solamente está expuesta á una carga pesada durante la descarga de barcos, sino que también es capaz de saturarse de agua, especialmente bajo el nivel de la marea baja; y esto la hará ejercer una presión muy grande contra los muros. Además, el agua penetra debajo del muro; y por su presión hacia arriba, reduce realmente su peso, y por consiguiente su estabilidad. La misma causa disminuye también de seguro el frotamiento del muro sobre su base. Estos muros son por lo tanto muy propensos á resbalar, si los cimientos son horizontales y lisos, y se han resbalado aun teniendo los cimientos una inclinación considerable hacia atrás, como en la fig. 1. Véase art. 5.

*Nota* 3. Un muro de sostenimiento está generalmente en mayor peligro durante pocos meses después de su construcción, que cuando el mortero ha tenido tiempo de fraguar perfectamente, y de asentarse el relleno. Si hay sospechas de que pueda peligrar la seguridad de un muro nuevo, es bueno reforzarlo colocando fuertes puntales contra el muro, á ¼ ó á la mitad, más ó menos, de su altura sobre el terreno. En algunos casos pueden construirse contrafuertes ó estribos permanentes con este objeto; éstos deben estar bien trabados penetrando en el muro.

*Nota* 4. La presión del relleno de tierra puede reducirse mucho, si se hacen las primeras capas delgadas, y que se vayan consolidando al usarlas como andamio de los albañiles, como se ve en *h*, fig. 1. A menudo puede hacerse esto sin inconveniente y á un costo muy pequeño.

**Art. 8. Cambiar un muro de sostenimiento vertical en uno de paramento exterior inclinado, que oponga igual resistencia al volcamiento y con menos mampostería.** Esto se llama **transformación del perfil.** (Original.)

Sea *aboi*, fig. 10, un muro vertical. Multiplíquese su base *oi* por 1.225 (1.22475 es más aproximado); y su producto será la base *oe*, de un muro triangular *boe*, que posee la misma estabilidad, y que sin embargo no requiere mucho más de la mitad de la mampostería del muro vertical. Véase nota 1. Hecho esto, supongamos que

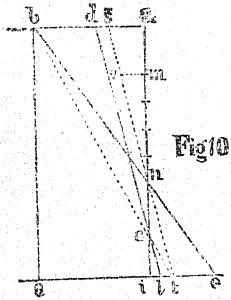

Fig 10

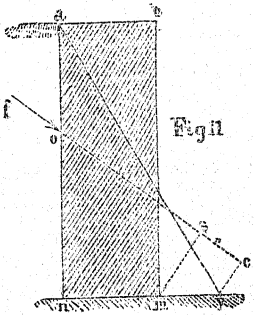

Fig 11

se desea un paramento inclinado, por ejemplo de 1 en 4. Del punto *n*, donde el paramento del muro triangular, intercepta el del vertical, márquense verticalmente hacia arriba 4 espacios pequeños iguales, y del superior de ellos *m* llévese á *v* un espacio horizontal; por *v* y *n* trácese la línea de puntos *st*, la cual evidentemente dará una inclinación de 1 en 4. Entonces, *bsto*, es aproximadamente el muro que se requiere, pero con un poco más de espesor del necesario. Para reducir éste, de *t* tírese la línea de puntos *tb*. Márquese el punto *c*, donde encuentra el paramento *ai*, del muro vertical, y por *c* trácese *ld*, paralela á *st*; entonces *bdlo* es el muro que se desea. Nuestra figura está trazada de un modo exagerado, para evitar confusión.

en las líneas. La base *oe* del muro triangular no sería en realidad tan grande como está representada.

Se observará que, á medida que la base aumenta, la cantidad de mampostería disminuye.

*Nota* 1. **El muro de paramento inclinado ofrece de hecho más seguridad que el vertical.** El muro de paramento inclinado tiene el mismo momento de estabilidad que el vertical; y la presión de la tierra contra él tampoco cambia, pero el *momento ó tendencia* de la presión á volcar el muro se hace menor. Sea *abmn*, fig. 11, un muro vertical, y *fo* la intensidad y dirección de la presión que obra detrás de él. (Para ilustrar con más facilidad el asunto hemos colocado á *o* **más arriba** del verdadero centro de presión del relleno, el cual debería estar más ó menos al tercio de *an* á contar de *n*.) Ahora bien, el brazo de palanca con el cual esta presión tiende á volcar el muro alrededor de su pie *m*, es la distancia *ms*, medida del pie ó punto de apoyo *m*, en ángulo recto á la dirección, *fose*, de la presión; y este brazo de palanca, multiplicado por la fuerza *fo*, da la tendencia al volcamiento ó el momento de dicha fuerza. Por otra parte, sea *a n y* un muro triangular de la misma estabilidad que el otro, como se halló por nuestra regla. Tendremos todavía la misma intensidad *fo*, la dirección, *fose*, de la presión contra el muro; pero obrando ahora para volcar el muro *any* alrededor de la arista *y*, y por tanto, con un brazo de palanca reducido, *ye*. Por consiguiente, su tendencia al volcamiento es menor que antes. Por eso, en lenguaje vulgar, podemos decir que el muro es más fuerte que antes, aunque su momento de estabilidad, ó tendencia á permanecer firme, no ha sufrido cambio. Si la presión *fo* contra el paramento vertical fuera horizontal, como sucede cuando es agua, entonces su brazo de palanca sería evidentemente el mismo en ambos muros; y la proporción entre el momento de volcamiento de la presión y los momentos de estabilidad de los dos muros serían constantes.

*Nota* 2. Al pretender reducir la mampostería adoptando un muro, *obe*, fig. 10, de sección triangular, ó de una forma casi aproximada á un triángulo, debe tenerse especial atención con la calidad de la mampostería que se coloque cerca de la arista delgada *e*, pues de lo contrario puede fallar bajo la presión.

*Nota* 3. **Por otra parte, cuando se usa mortero ordinario sin mezcla de cemento**, lo que jamás debería hacerse en muros de sostenimiento, donde la durabilidad es uno de los objetos, no se puede aconsejar una gran inclinación

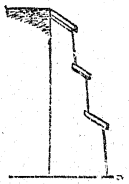

Fig 12

por cuanto la lluvia combinada con la escarcha, etc., destruye prontamente el mortero. En estos casos la inclinación debe, por consiguiente, no exceder de 1 en 12 ó 1 en 8, y aun entonces deben cogerse las juntas con cemento, como también deben hacerse con cemento ó con mortero de cemento las capas inferiores de la mampostería hasta la altura de algunos decímetros. Hemos observado una diferencia muy marcada en la corrosión del mortero cuando en muros iguales situados del mismo modo se construye una parte de paramento vertical y la otra con una inclinación de solamente 1 en 8. El mortero común expuesto á la humedad de la tierra no fragua jamás bien ni se conserva firme. Esto se puede observar muy bien cerca de las cabezas y pies de los estribos, muros de sostenimiento, etc., en cuyos puntos se verá que el mortero de cal se ha desvirtuado generalmente. Un perfil algo semejante á la fig. 12, puede algunas veces ser útil en lugar del perfil triangular. Este es el diseño de los estribos ó contrafuertes góticos que probablemente tuvieron su origen en la causa de que acabamos de hablar.

**Art. 9. Un muro de sostenimiento puede resbalarse sin perder su verticalidad**, y ciertamente sin peligro alguno de volcarse. Esto es fácil que

ocurra si está construído sobre una plataforma de madera ó sobre una superficie á nivel, de roca ó greda, sin otra resistencia que el frotamiento, para impedir el resbalamiento. Éste puede evitarse dándole á la base una inclinación como en la fig. 1; haciendo los cimientos del muro de una profundidad tal que le dé una resistencia adecuada al terreno situado enfrente del muro; ó en caso de una plataforma, fijar una ó más hileras de vigas fuertes á su parte superior transversalmente á la dirección en que el resbalamiento pueda tener efecto. Sobre la **greda mojada** el frotamiento puede ser tan pequeño como de .2 á $^1/_3$ del peso del muro; sobre tierra seca es, más ó menos, de $^1/_2$ á $^2/_3$; y sobre arena ó granzón, de $^2/_3$ á $^3/_4$, más ó menos. El frotamiento de la mampostería sobre una plataforma de madera es, más ó menos, de $^9/_{10}$ del peso si está seca, y $^7/_8$ mojada.

**Contrafuertes.** Como se muestran en el plano en *ccc*, fig. 13, se componen de un aumento de espesor en el paramento interior del muro, á intervalos regulares de su longitud. Nosotros no los consideramos sino como un desperdicio verdadero

Fig 13

de mampostería. Cuando un muro de esta clase se cae, casi siempre se separa de sus contrafuertes, á los cuales está unido solamente por la adhesión del mortero, y muy poco, por la traba de la mampostería. La tabla del art. 7 demuestra que una muy pequeña adicion que se haga á la base de un muro causa un aumento considerable de su resistencia; y por consiguiente creemos que la mampostería de los contrafuertes podía emplearse mejor y más barato dando al muro un espesor adicional en toda su longitud, y hasta la tercera parte de su altura á partir del suelo. Los contrafuertes son usados generalmente en los muros de sostenimiento por los ingenieros europeos, pero raras veces por los americanos.

**Los estribos** (*buttresses*) son lo mismo que los contrafuertes, con la excepción de que se colocan *enfrente* del muro en lugar de colocarlos detrás, y que su perfil es generalmente triangular, ó casi triangular. Aumentan la resistencia de los muros considerablemente, pero son de mal efecto á la vista; se usan raras veces, exceptuando el caso en que haya que impedir la caída de un muro.

**Amarras de tierra** (*land-ties*), ó vientos, ó largas barras de hierro se han empleado algunas veces como medio provisional de sostener muros débiles. Atraviesan el muro y se fijan sus extremidades en tierra anclándolas en mampostería ó á postes de hierro ó de madera enterrados á alguna distancia bajo tierra.

**Los muros de sostenimiento de perfiles curvos** se mencionan aquí solamente para advertir á los jóvenes ingenieros que no los construyan. Aunque su uso está sancionado por la práctica de algunas altas autoridades, ellos realmente no poseen mérito suficiente para recompensar el costo adicional y las dificultades de su construcción.

(*Obs. del T.* — Aunque en español (por lo menos en Venezuela) no existen las diferencias que el autor señala en el próximo art. 10, hemos querido dejarlas.)

**Art. 10.** Entre los militares, un muro de sostenimiento es llamado de **revestimiento escarpado.** Cuando la tierra está al nivel de su parte superior, se llama **revestimiento escarpado;** cuando la tierra está sobre el muro, **revestimiento contraescarpado** ó **semirevestimiento.** Cuando el paramento exterior del muro está inclinado, se llama *rampa* (sloping), y cuando el fondo está inclinado, se llama *contra rampa*. La pendiente se llama **talud.**

**Art. 11.** La presión de la arena, etc., contra un muro, fig. 6, á nivel de su parte superior, no disminuye reduciendo la cantidad de arena, en tanto que su anchura superior *cs* no sea menor que la (*ct*) correspondiente al ángulo *cmt* de mayor presión. La presión principia entonces á disminuir; pero en la práctica la disminución no es apreciable en tanto que el ancho no se reduzca á una sexta parte, más ó menos, de la distancia (*cs*) correspondiente al ángulo *cms* del talud natural, ó más ó menos á la mitad de *ct*. Entonces la presión principia á disminuir rápidamente á medida que la anchura se reduce.

# PUENTES DE PIEDRA

**Art. 1.** En un arco *sis*, fig. 1, la distancia *eo* se llama **luz**; *ia*, **flecha**; la línea del límite inferior *eao*, **intradós**; la línea superior *rtr*, **trasdós**. Los términos **intradós** y **trasdós** se aplican también ó la *superficie* interna inferior y superior de la bóveda entera. Las extremidades del arco, ó las áreas visibles comprendidas entre el intradós y el trasdós, son sus **caras**; de modo que el área *stsa* es una cara. Las superficies inclinadas, ó juntas *re* y *ro*, sobre las cuales descansan las extremidades del arco, y de las cuales *arranca* el arco, se llaman **arranques**. Los bloques de que se compone el arco, son las **dovelas**; la dovela del centro *ta* es la **clave del arco**, y las inferiores *ss*, **las impostas**. Las partes *tr*, *tr*, son los **riñones del arco** **, y los espacios *trl*, *trb*, encima de ellos, **las enjutas**. El material depositado en estos espacios se llama **relleno de las enjutas** y se compone algunas veces de tierra ó de mampostería, ó de ambas como en la fig. 1.

En los arcos grandes, el relleno lo forman á menudo varios muros **paralelos** *ll*, fig. 2½, sobre la enjuta, que se prolongan á lo largo de la calzada, ó á través del arco. Se cubren en su parte superior ó por arcos pequeños de muro á muro, ó por piedras chatas, para sostener el material de la calzada. Algunas veces están conectados por

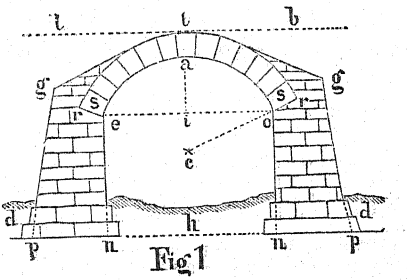

Fig 1

muros transversales verticales de distancia á distancia, para afianzarlos lateralmente, como en *tt*, fig. 2½. Las partes *gpen*, *gpon*, fig. 1, son los **estribos ó pies derechos del arco**; *en*, *on*, los **paramentos exteriores**; *gp*, *gp*, los **paramentos interiores**, y *pn*, *pn*, *las bases de los estribos*. Estas bases se ensanchan generalmente por *escalones dd*, para distribuir el peso del puente sobre una área mayor, disminuyendo así el peligro que hay al asentarse. La distancia *at* de cualquiera dovela es su espesor.

Los únicos arcos de uso común en los puentes son los circulares (á menudo escarzanos) y los elípticos.

**Art. 2. Para encontrar el espesor en la clave para arcos de piedra tallada de primera clase, sean circulares ó elípticos** *. Búsquese el radio *co*, fig. 1, que toca el arco en *a*, *o*, y *e*. Súmese este radio y la *mitad* de *la luz*, *oe*. Tómese la raíz cuadrada de esta suma. Divídase esta raíz por 4, al cociente agréguese $^2/_{10}$ de pie, ó empleando una fórmula,

$$\text{Espesor en pies} = \frac{\sqrt{\text{Radio} + \text{mitad de la luz}}}{4} + .2 \text{ pies.}$$

* Por cuanto las reglas que damos para arcos y estribos son enteramente originales y nuevas, no estará demas hacer constar que no son enteramente empíricas, si no que están basadas sobre diseños y cálculos exactos hechos por el autor, de líneas de presión, etc., en arcos desde 0.30 cm hasta 90 m. de luz y de todas flechas, desde = radio hasta 1/15 de la luz. De estos diseños él trató de encontrar proporciones, las cuales, aunque quizás no soporten la prueba de una crítica estricta, pueden sin embargo aplicarse en todos los casos con una exactitud suficiente para las operaciones ordinarias de la práctica.

** Haunches. — *Diccionarios de Ponce de León y de Cuyás.*

(*N. del T.* — La misma fórmula para el sistema métrico:

$$\text{Espesor de la clave en metros} = \frac{\sqrt{\text{Radio} + \text{mitad de la luz}}}{7.244} + .061 \text{ metros.})$$

**Para obras de segunda clase**, este espesor puede aumentarse $^1/_8$ parte más ó menos, y para obras de ladrillos ó piedras brutas $^1/_5$ más ó menos.

En los arcos grandes es prudente aumentar el espesor hacia los arranques; pero si la luz no es mayor de 18 ó 24 ó 30 m, no es necesario si la piedra es buena; aunque el arco será más fuerte dándole dicho espesor. En la práctica este aumento, aun en las aberturas más grandes, no excede de ¼ á ½ el espesor en la clave; aunque la teoría indique mucho más en arcos de una gran flecha.

*Nota.* **Para hallar el radio** *co*, sea el arco circular ó elíptico; tómese el cuadrado de la *mitad* de la luz *eo*. Tómese el cuadrado de la flecha entera *ia*. súmense estos dos cuadrados, y divídase la suma por el doble de la flecha *ia*. O puede hallarse con suficiente aproximación para el objeto por medio del compás, trazando un arco pequeño en escala.

**Intensidad de la presión soportada por las dovelas.** En puentes del mismo ancho que la calzada, si todas las otras partes soportan en la misma proporción que la luz, la presión total aumentaría como el cuadrado de ésta, mientras que la presión *por m²* aumentaría como la abertura. Pero en la práctica el espesor del arco aumenta con *mucho menos rapidez* que la luz; mientras que el espesor del material de la calzada, y la carga extraña por metro cuadrado, permanecen lo mismo para todas las aberturas. Por tanto la presión total, en la clave y los arranques, aumenta con *menos* rapidez que los *cuadrados* de *las luces;* pero más rápidamente que las luces simples, como sucede también con las presiones *por metro cuadrado*.

Con la misma luz, la presión en la clave se hace menor, mientras que la de los arranques aumenta á medida que aumenta la flecha. También cuando las dovelas tienen espesor uniforme, la presión en cada arranque de un arco semicircular es más ó menos 4 veces mayor que cuando la flecha es solamente de una sexta parte de la luz, la presión en los arranques es por término medio solamente una tercera parte mayor que la de la clave. Estas proporciones varían algo en diferentes luces.

La mayor presión por metro cuadrado en los arranques, puede reducirse aumentando el espesor de las dovelas hacia los arranques. Esto, sin embargo, no es *necesario* en luces medianas, por cuanto la piedra buena ofrecerá seguridad aun bajo estas presiones mayores.

**Por el uso de muros de enjuta paralelos**, fig. 2½, ó rellenando en parte con tierra en lugar de mampostería, la presión sobre las dovelas puede disminuirse, por término medio aproximado, en $^1/_5$ parte más ó menos.

**Tabla 1. De algunos arcos existentes**, con espesores en la clave, efectivos y calculados (según nuestra regla). Cuando se dan dos espesores en la columna de claves, el menor es para piedra tallada de primera clase, y el mayor para buena piedra bruta, ó para ladrillos. Los que no están especificados, son de piedra tallada de primera clase. C quiere decir circular; E, elíptico. Para obras de segunda clase, agréguese más ó menos ⅛ parte; y para ladrillos ó piedras brutas buenos, ¼ parte más ó menos.

* Véase arco de experiencia en Souppes, Francia.
** Puente de Staines. Algunos autores dan .71 metros para el espesor en la clave.

**Arco de prueba en Souppes, Francia.** Véase la tabla. Abertura, más ó menos, 18 × flecha.

| | Abertura. | Flecha. | Radio del intradós. | Espesor del arco. En los arranques. | Espesor del arco. En la clave. En las caras. | Espesor del arco. En la clave. Entre las caras. | Anchura. |
|---|---|---|---|---|---|---|---|
| Metros..... | 37.886 | 2.125 | 85.5 | 1.10 | 1.10 | .80 | 3.5 |
| Pies..... | 124.30 | 6.97 | 280.52 | 3.61 | 3.61 | 2.264 | 11.5 |

El arco es de granito; se dejaron las cimbras durante cuatro meses sobre arena en 16 cilindros de .30 m de diámetro, .30 m de alto, hechos de planchas de hierro de $^3/_4$ mm de espesor. El arco descargado descendió 15 milímetros al quitar las cimbras. El descenso adicional bajo cargas extrañas fué como sigue.

| Carga extraña. | Kilogramos. | Libras. | Aumento en el descenso. Milímetros. | Pulgadas. |
|---|---|---|---|---|
| Distribuída..... | 367,000 | 809,000 | 21 | .8 |
| En el centro..... | 4,975 | 11,000 | .3 | .012 |
| Distribuída..... | 132,600 | 292,000 | 1.2 | .047 |

Con la carga distribuída de 367,000 kg, una carga de 4,975 kg cayendo sobre la clave de una altura de .3 mets causó vibraciones de 2.88 mm. *Annales des Ponts et Chaussées*, 1866, *Part* 2. 1868, *Part* 2.

El arco del ferrocarril Bourbonnais, es probablemente el arco de piedra más atrevido*, y el de Cabin John, por el capitán, ahora general, M. C. Meigs, del ejército de los E. U., el arco de piedra más grande existente. Pont y Prydd, en Gales, es un puente en un camino ordinario, de una construcción muy ruda, con una calzada de una pendiente peligrosa. Fué construído enteramente de piedras brutas, con mortero, por un albañil ordinario del campo, en 1750, y está todavía en perfecta condición. Sólo las dovelas exteriores ó las que *están á la vista* son de .75 m de espesor, y este espesor se compone de dos piedras. Las dovelas interiores no tienen sino .45 m de espesor y de 15 á 23 cm de grueso. Las piedras son de cantera con caras medianamente buenas, y se labraron muy poco ó nada. Este puente es un buen ejemplo de esa ignorancia, que muchas veces pasa por audacia. El puente Napoleón soporta un ferrocarril que atraviesa el Sena en París. Los arcos son de un espesor uniforme, de 1.20 m de la clave á los arranques. Los arcos se componen principalmente **de pedazos de piedra pequeños, sobrantes de canteras**, bien lavados para librarlos del sucio y del polvo; y luego colocados en buen lecho de cemento, con las juntas del mismo material. Este arco es por tanto como un arco de concreto. El puente de l'**Alma** cerca de él, y **construído del mismo modo**, tiene arcos elípticos de 38.40 á 43 m de luz, con flechas de $^1/_9$ de la abertura y clave de 1.49 m. Estos dos puentes, considerada la escasez de precedentes en estas construcciones en grande escala, deben considerarse como muy atrevidos y dan una gran reputación de prácticos á sus ingenieros señores Darcel y Cauche. La contracción desigual de los diferentes espesores de cemento originó algunos trastornos. Estos puentes demuestran lo que fácilmente puede hacerse en arcos de luz mediana con piedras pequeñas y *cemento hidráulico bueno*, á falta de piedras grandes propias para arcos. En el **puente Napoleón** el espesor del arco es menor de lo que nuestra regla da para piedras talladas de segunda clase.

**Art. 3. Los espesores de las claves calculadas para arcos grandes elípticos** por los mejores ingenieros, tienen generalmente una tercera parte más del que da nuestra regla, ó del que se da á los arcos circulares de la misma

* Construído como el de Souppes.

luz y flecha, para conservar así la línea de presión dentro de las juntas; aunque el arco elíptico, con las enjutas rellenas, tiene un peso algo menor; este peso tiene un brazo de palanca ligeramente menor que en un arco circular, y por consiguiente ejerce menos presión, tanto sobre la clave como sobre los arranques. Véanse los puentes Londres, Gloucester y Waterloo en el cuadro precedente.

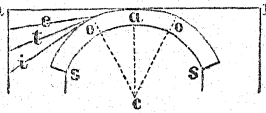

Fig. 1/2

*Nota.* Los ingenieros jóvenes son afectos á los arcos delgados, pero sería mucho mejor adoptar un sistema opuesto; porque no solamente los arcos gruesos hacen que la obra sea más estable, sino que un arco delgado es de un efecto tan desagradable á la vista, como una columna demasiado delgada. El arco es preferible hacerlo con 1/3 más de espesor del que da nuestra regla para las piedras talladas de primera clase, atendiendo á la apariencia. Especialmente cuando un arco es de piedra bruta, cuya mampostería cuesta más ó menos lo mismo en el arco que en el relleno de la enjuta, es una necedad construir los arcos de poco espesor. La estabilidad y la duración debe ser el objeto deseado, y cuando podemos lograrlo, aun con exceso, sin aumentar el costo, siempre es mejor hacerlo.

**Tabla 2. Espesor en las claves para arcos** de piedra tallada de primera clase, según el art. 2. Para los de segunda clase auméntese 1/8 parte; y para obras superiores de ladrillo, de 1/4 á 1/3, si el arco excede de 4.5 á 6 m más ó menos. (Original.)

**Art. 4. Encontrar las dimensiones de los estribos de un arco de piedra ó ladrillo, circular ó elíptico.** (Original.)

El autor se toma la libertad de ofrecer la regla siguiente en la creencia de que servirá para combinar las exigencias de la teoría con las de la economía y fácil eje-

cución, tanto como es posible, para reducir materia tan complicada **á una regla sencilla y segura que sirva para los trabajos de constructores prácticos de puentes.** Esto es todo lo que reclama. Sin embargo de su sencillez, es el resultado de mucha labor personal. Esta regla se aplica igualmente á la alcantarilla más pequeña como al puente más grande, cualesquiera que sean las proporciones de luz y flecha, y para cualquier altura de estribos. También se aplica á todos los rellenos sobre los arcos, generalmente en uso, háganse con mampostería sólida hasta el nivel *v f*, fig. 2, de la parte superior del arco, ó con tierra; ó con ambas; ó bien, con muros paralelos en las enjutas, prolongados hasta el paramento interior de los estribos, fig. 2½. Aunque la estabilidad de un estribo no puede permanecer exactamente la misma bajo todas estas condiciones, sin embargo la diferencia de espesor que resultaría de una investigación estricta en cada caso particular, no es suficiente fundamento para que compliquemos una regla destinada al uso práctico con una multitud de excepciones y modificaciones que destruirían el verdadero objeto para que fué creada.

**Damos espesores de estribos que sin relleno alguno detrás, ofrecen por sí solos seguridad; y también resisten las presiones en todos los casos, cuando el puente está sin carga.** Además, en los arcos muy grandes, en los cuales la carga máxima que probablemente tienen que soportar en la práctica es pequeña, comparadas con el peso del arco mismo y del relleno que hay encima, nuestros estribos ofrecen también seguridad para el puente *cargado*, independientemente de la tierra que está detrás de ellos; pero, cuando los arcos son más pequeños, y por consiguiente el peso de la carga es mayor, en proporción al peso del arco y del relleno, debemos contar más y más con la resistencia de la tierra colocada detrás de los estribos, para evitar la necesidad de dar á éstos un espesor extravagante. *Por lo tanto debe entenderse (excepto en el caso en que haya muros paralelos en las enjutas)* que nuestras reglas suponen que, como de costumbre, se depositen tierras detrás de los estribos, á la altura de la calzada, después de construído el puente.

En puentes pequeños ó alcantarillas grandes de ferrocarriles de primera clase, sujetos á la trepidación de los trenes pesados de gran velocidad, el poco costo, relativamente, con el cual se puede obtener un exceso de resistencia para construcciones importantes, ha inducido en muchos casos al uso de estribos de un espesor desde una cuarta parte, hasta la mitad mayores de los que da la regla siguiente.

**Si es de piedra bruta** agréguense 15 cm para obtener un espesor completamente seguro en todas partes.

$$\left.\begin{array}{l}\text{Espesor } on\text{, en pies, de los estribos en los arranques, cuando la elevación no excede de } 1\tfrac{1}{2} \text{ veces la base } sp.\end{array}\right\} = \frac{\text{Radio en pies}}{5} + \frac{\text{flecha en pies}}{10} + 2 \text{ pies.}$$

(*N. del T.* — La misma fórmula para el sistema métrico:

$$\left.\begin{array}{l}\text{Espesor } on\text{, en metros, de los estribos en los arranques, cuando la elevación no excede de } 1\tfrac{1}{2} \text{ veces la base } sp.\end{array}\right\} = \frac{\text{Radio en metros}}{5} + \frac{\text{flecha en m}}{10} + .61 \text{ m.)}$$

Marquénse los puntos *n*, *y*, así obtenidos. Después desde el centro *i*, de la luz ó cuerda *eo*, trácese *ih* igual á $^1/_{24}$ parte de dicha luz. Trácese *ha;* y por *n*, paralela á *ah*, trácese la línea indefinida *gnp* del estribo. Hágase lo mismo con el otro estribo. Hágase *ym* y *ng* ambas iguales á la mitad de la altura total *it* del arco; y desde *g* trácese una línea recta *gx*, tocando el trasdós del arco tan arriba como sea posible, ó, mejor todavía, como está representado en *tm*, con un radio *dt* ó *dm* (hallado por tanteo) descríbase un arco *tm; gx* ó *tm* será la parte superior del relleno de mampostería sobre el arco *, el cual debe terminarse antes de quitar las cimbras; antes de lo cual debe concluirse también el terraplén, por lo menos hasta *yn*.

---

***Excepto cuando la flecha es sólo 1/5 parte de la luz,** ó menos, en cuyo caso se lleva la mampostería sólida hasta el nivel *vtf*, de la parte superior del arco. O si el arco es grande, si excede, por ejemplo, de 18 m de abertura, más ó menos, y especialmente si su flecha es más ó menos mayor que $^1/_5$, entonces es mejor economizar la mampostería usando muros de enjuta interiores *ll*, fig. $2^1/_2$, los cuales se levantan hasta *vtf*. fig. 2. También se pueden introducir ventajosamente muros interiores como éstos en arcos mucho menores. Cuando son elevados pueden reforzarse con muros transversales *tt*. fig. $2^1/_2$. Sus bases debían terminar en escalones como se representa en *ooo*, de modo que descansen sobre toda la superficie del trasdós, igualando así la presión sobre

Búsquese luego por tanteos el punto *s*, fig. 2, donde el espesor *sp* es igual á dos tercios de la elevación vertical correspondiente *os*, y trácese *sp*. Entonces el *espesor on* ó *ey* será el de la línea de arranques del arco circular ó elíptico dado, de cualquier flecha ó luz; y la línea *gp* será el paramento interior del estribo, con tal que su elevación no exceda de 1½ veces *sp*; ó, en otras palabras, con tal que *sp* no sea menor de $^2/_3$ *os*. En la práctica *os* raras veces excede este límite; solamente en arcos de

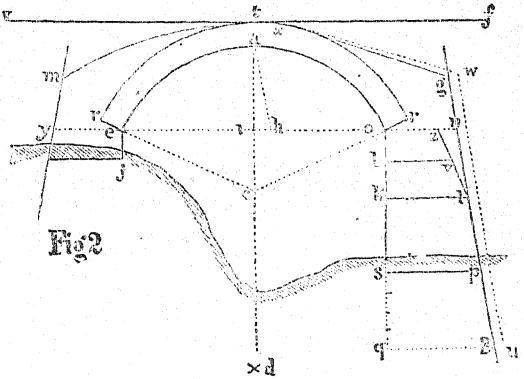

Fig 2

flecha considerable. Pero si sucede así, como por ejemplo en *oq*, entonces hágase la base *qu* igual á *sp*, más una cuarta parte de la altura *adicional sq*; y trácese el paramento interior *uw*, paralelo á *gp*, prolongado hasta la misma altura, etc., fig. 2. En el caso, sin embargo, de que esta adición de ¼ parte de *sq* dé en cualquier caso una base *qu*, menor de la *mitad* de la altura total *oq* (lo que en la práctica sucede raras veces), entonces hágase *qu* igual á la mitad de dicha altura total, trazando el paramento interior paralelo á *gp*, prolongado hasta la misma altura como se hizo antes. Los espesores adicionales hallados así debajo de *sp*, se refieren más bien á la presión de la tierra que está detrás de los estribos, que al empuje del arco. En un estribo muy elevado, la línea interior *gp* daría un espesor insuficiente para sostener la tierra con seguridad.

Cuando la altura *ob*, fig. 2, del estribo es menor que el espesor *on* en el arranque

---

éste. En la parte superior de los muros pueden colocarse lajas, ó construirse pequeños arcos de un muro á otro, para sostener el balasto, etc., de la calzada. Los espacios que quedan debajo entre muro y muro se dejan vacíos. En la fig. $2^1/_2$ la parte más obscura,

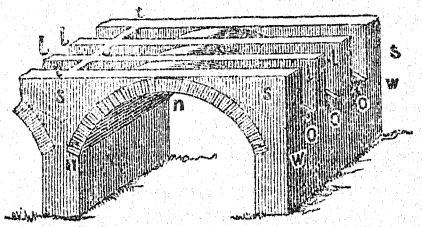

**Fig. 2 1/2.**

*ww*, se supone ser una sección transversal de un estribo, en la cual se ha omitido el segundo muro transversal semejante á *tt*. En puentes de ferrocarriles, colóquese un muro de enjuta *ll* debajo de cada riel.

puede economizarse un poco de mampostería (lo que no vale la pena, excepto en arcos muy grandes y rebajados ó en platabandas) reduciendo el espesor de todo el estribo de este modo: Hágase *ok* igual á *on* y trácese *kl*. Hágase *oz* igual á $^{4}/_{5}$ partes de *on* y trácese *lz*. Entonces, para cualquiera altura *ob* menor que *on*, trácese *bv*, terminando en *lz*. Esta *bv* será suficiente base si los cimientos son firmes. El paramento interior del estribo se trazará de *v* hacia arriba, paralelo á *gp*, y terminando á la misma altura que *g* ó *w*.

*Nota* 1. — Todos los estribos hallados así ofrecerán seguridad (con las precauciones del art. 6) independientemente de los muros en alas; no importando la altura á que llegue el terraplén sobre la parte superior del arco. Si el puente es angosto, y los paramentos de los muros en alas están, por consiguiente, tan próximos unos á otros que presten importante refuerzo á los estribos, estos últimos pueden tener menor espesor hasta un límite que fijará el ingeniero á su juicio.

Nosotros, sin embargo, advertimos á los jóvenes ingenieros que tengan cuidado al adoptar dimensiones más pequeñas que las dadas por nuestras reglas. Existen ciertas consideraciones prácticas, tales como descuidos en la ejecución de la obra; mortero nuevo ó reciente, el peligro de fuerzas indebidas al quitar las cimbras; la probabilidad de producir perturbación, descomposición, durante el proceso del relleno detrás de los estribos y sobre el arco, etc., á esto debe atenderse, aunque es imposible reducirlo al cálculo.

Siempre que sea posible, se deben dejar las cimbras colocadas hasta que esté concluído el relleno; y durante algún tiempo después para dar tiempo al mortero á que fragüe bien.

*Nota* 2. Algunos reducen con mucha libertad la cantidad de mampostería sobre la línea de los arranques de los arcos de flecha considerable y de luz mediana, teniendo cuidado de dejar las cimbras hasta que se concluye el relleno detrás de los estribos y sobre el arco, á fin de que no puedan producirse trastornos por algún accidente durante esta operación; esto se hace sobre todo cuando se usa buen cemento en lugar de mortero ordinario. Estos experimentos se pueden hacer con seguridad relativa, especialmente en arcos de alcantarillas, en los cuales el espesor es grande en proporción de la luz. Todo esto, sin embargo, debe dejarse al juicio del ingeniero, porque no se pueden dar reglas especiales para estos casos. Apenas pueden considerarse como fruto de la práctica y no podemos recomendarlo. Hemos visto puentes con arcos casi semicirculares, de 9 á 12 m de abertura, construídos así, y con éxito, teniendo apenas un poquito de mampostería sobre los arranques para reforzarlos. Estos arcos, sin embargo, están expuestos á caerse, al quitarles más tarde el relleno, si no se tiene la precaución de sostenerlos por medio de cimbras ó de otro modo. Aun cuando el terraplén pueda concluirse antes de quitar las cimbras, no podemos recomendar (y esto solamente en aberturas pequeñas) sino que se haga *ng*, fig. 2, *a lo menos* igual á $^{1}/_{5}$ parte de la elevación total *it* del arco; y desde *g* así encontrado, trazar una línea recta que toque el trasdós del arco tan arriba como se pueda.

*Nota* 3. Nada hemos dicho sobre la inclinación de los frentes de los estribos, porque, atravesando ríos, la inclinación ó disminuye el curso del agua, ó exige un arco mayor. Sin embargo una inclinación como de $^{1}/_{24}$ á $^{1}/_{8}$ es útil, como son los escalones, para distribuir el peso de la construcción y del terraplén sobre un área mayor de cimientos, especialmente cuando estos últimos no son muy firmes, ó cuando el terraplén llega á una altura considerable sobre el arco. En nuestra tabla n.º 3, de cantidades aproximadas de mampostería en puentes semicirculares de .61 á 15.25 m de luz, los paramentos exteriores de los estribos se suponen verticales.

**Art. 5. Pilas-estribo.** Cuando un puente consta de varios arcos sostenidos por pilas de un espesor ordinario solamente, si uno de los arcos fuere destruído por una creciente, ó de otro modo, los arcos adyacentes volcarían las pilas, y se caería un arco tras otro. Para impedir esto, se acostumbra, en puentes importantes, hacer algunas de las pilas de espesor suficiente parar resistir la presión de los arcos adyacentes, en el caso de un accidente semejante; y de este modo preservar una parte del puente de la ruina. Estas pilas se llaman pilas-estribo.

La fórmula (transformada por el traductor al sistema métrico) : $\frac{\text{Radio en m}}{5} + \frac{\text{flecha en m}}{10} + .61$ m para el espesor en los arranques; con la inclinación detrás como dijimos arriba, á razón de $^{1}/_{24}$ de la luz á la flecha, (*ih* para *ia*, (fig. 2) para paramentos exteriores verticales, (*sin modificación alguna para ele-*

*raciones grandes*) una pila-estribo perfectamente segura, para cualquier puente no cargado, y hasta cualquiera altura; teniéndose, sin embargo, debida consideración á las observaciones del artículo próximo. Así, para una pila-estribo tan elevada como *oq*, fig 2, ó de una elevación mayor aún, es solamente necesario hallar primero el espesor *on* en los arranques, como antes, y luego trazar el paramento interior inclinado *gnp*, extendiéndole hasta la base en B, sin agregar $\frac{1}{4}$ parte de la altura adicional *sq*. Esta adición se hace en el caso de estribos que deban ofrecer seguridad contra la presión de la tierra detrás de ellos, y contra la presión del arco; consideración que no se aplica á estas pilas, las que no deben resistir sino la presión de los arcos.

Pero aunque las pilas-estribos así calculadas por nuestra fórmula son suficientemente seguras, sin embargo su forma *abco*, fig. 3, es inadmisible. En la práctica se cambiaría por una forma más ó menos como la que indican las líneas de puntos, con una inclinación igual en ambas caras. Esto, por supuesto, requiere más mampostería, con poco aumento de estabilidad, pero no se puede evitar.

**Cuando se construye una pila-estribo en agua profunda** ó en corriente poco honda expuesta á crecientes, es necesario tener cuidado de que el agua no penetre por *debajo* de las pilas, y produzca una presión hacia arriba, la cual ó disminuye, ó enteramente destruye su eficacia como estribo. Véase nota 2, art. 4, de Hidrostática.

Fig 3

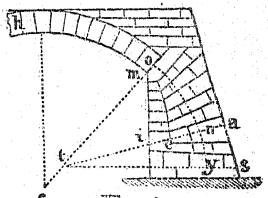

Fig. 4

**Art. 6. Inclinación de las hiladas de mampostería situadas debajo de los arranques de un arco.** Aunque nuestra regla precedente da el espesor que debe tener un estribo para no ser **volcado** por la presión del arco, sin embargo, si el arco es de una abertura grande y de pequeña flecha, su gran empuje horizontal puede producir un resbalamiento hacia afuera de la mampostería, cerca del nivel de los arranques, si la piedra se dispone en hiladas horizontales, especialmente si el mortero no ha fraguado bien.

Es cierto que este peligro podía evitarse ligando las hiladas de mampostería entre sí por medio de pernos ó lañas de hierro, ó aumentando considerablemente el espesor de los estribos; pero el costo necesario para esto nos induce á adoptar el método más económico de inclinar la mampostería como se indica entre *o* y *n*, fig. 4, dándoles á las hiladas cercanas á *o* más inclinación, y disminuyendo gradualmente la de las próximas á *n*. De este modo el arco se prolonga virtualmente dentro del cuerpo del estribo á tal distancia que, cuando la inclinación de las hiladas de mampostería inferiores cesa, como en *n*, la dirección de la línea de presiones, ó la presión del arco (representada por la línea curva de puntos *on*) esté casi en ángulo recto con las juntas de las hiladas horizontales situadas debajo de *n*; y, por consiguiente, dicha presión es incapaz de producir resbalamiento en este punto. Entre *o* y *n* la línea de presión está en todos sus puntos tan próximamente en ángulo recto con las diferentes hiladas inclinadas que llega á impedir también la posibilidad de un resbalamiento en dicho intervalo. Estando el estribo de este modo seguro contra el volcamiento y el resbalamiento, puede solamente fallar por causa de cimientos defectuosos ó por la inferioridad de las piedras con que esté construído, las cuales, si son blandas, pueden desmoronarse.

Esta inclinación de la mampostería es tan necesaria en un arco elíptico, fig. 4½, como en un arco circular. La forma elíptica, claramente, se presta poco para unir las dovelas con la mampostería inclinada cerca de los arranques, á fin de que resista

el empuje conveniente, ó más ó menos en ángulo recto á sus resultantes. En los casos ordinarios estas dificultades pueden vencerse haciendo solamente las juntas de las dovelas exteriores, ó de las que están á la vista, de conformidad con la curva elíptica, como entre *e* y *a*, mientras que las juntas interiores de atrás pueden tener la dirección indicada entre *g* y *u*, casi en ángulo recto á la línea de presiones. Rara vez

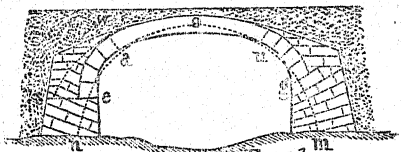

Fig. 4 1/2

sucederá, sin embargo, que un ingeniero joven tenga que construir arcos elípticos de suficiente magnitud para tener que emplear estos procedimientos. Para aberturas de menos de 15 m con flechas no menores de 1/4, más ó menos, de la luz no se requiere nada de esto, si el mortero es bueno y tiene tiempo de endurecerse *.

Para inclinar la mampostería de cualquier estribo con suficiente exactitud sería necesario trazar primero la curva de presión de dicho arco, para de este modo disponer las juntas de las hiladas de mampostería más ó menos en ángulo recto á dicha línea en cada punto; pero nosotros ofrecemos el método siguiente, que lo creemos suficiente para todos los casos prácticos, mientras que su sencillez lo coloca al alcance de un albañil ordinario. En puentes efectivos la dirección real del empuje varía con el paso de la carga; por consiguiente, en la práctica, ningún grado de inclinación dado de la mampostería de los estribos puede adaptarse exactamente á dicha dirección durante el paso de la carga. Por lo tanto, todo exceso de cálculo en este particular, es simplemente ridículo, especialmente en pequeñas luces.

**Reglas para fijar la inclinación de las hiladas de mampostería en los estribos.** Súmese el radio *cm*, fig. 4, con la luz del arco; divídase esta suma por 5 y al cociente agréguense 3 pies. (*N. del T.* — O, empleando el sistema métrico, súmese el radio *cm* y la luz del arco en metros, divídase la suma por 5 y al cociente agréguense .915 metros.) Hágase *ot* sobre el radio igual á esta última suma, y entonces *t* será el centro hacia el cual deben converger las direcciones de las juntas, como se indica en la figura. Trácese *ts* horizontal y desde *t* como centro descríbase el arco *oy;* siendo *o* el centro del arranque. Desde *y* tómese en el arco la dist *yn*, igual á una sexta parte de *ty*, trácese *tna*. Nunca *será necesario* inclinar la mampostería situada debajo de *tna*. Tampoco *es preciso* que la inclinación se prolongue enteramente hasta el paramento *mi* del estribo, sino que puede terminar en *e*, próximamente en medio de *i y n*. De, *e*, hacia arriba, la inclinación puede prolongarse hacia adelante hasta la línea *em*.

**El cemento** debe usarse sin restricción, no solamente en los arcos mismos, y en la mampostería de encima, para preservarlos de la filtración de la lluvia, sino también en los estribos, muros en alas y de sostenimiento, y en toda mampostería expuesta á la humedad. Todo el trasdós de los arcos importantes de ladrillos debía cubrirse con una capa de buen cemento, de 3 cm de espesor, más ó menos. La falta de esta precaución puede notarse en casi todas nuestras obras públicas. El mortero ordinario se pudre (descompone) y se cae del intradós de los arcos, y de las juntas de mampostería en general, próximamente á 1 ó 2 m de la superficie del suelo. La humedad sube por la acción capilar, hasta aquella distancia sobre la superficie del suelo; ó desciende á ella desde la superficie artificial del terraplén, etc.; por lo tanto, debería emplearse el mortero de cemento por lo menos en aquellas partes.

---

*Los pies de los arcos, tanto elípticos como semicirculares, se hacen siempre horizontales; pero se ve claramente en la fig. 4 1/2, que esta práctica está en desacuerdo con los principios de estabilidad en el caso de la elipse. Lo mismo sucede en el semicírculo. En los puentes ordinarios de esta última forma, la presión vertical, ó peso que descansa sobre cada arranque (hablando en general), es comúnmente de 3½ á 4 veces la presión horizontal sobre la misma, y la presión total es, más ó menos, 4 veces la presión sobre la clave. Por consiguiente, teóricamente, el arranque debía tener un espesor 4 veces mayor que el de la clave, y su lecho, en lugar de ser horizontal, debía tener una inclinación á razón, más ó menos, de 1 vertical por 4 horizontal.

La lluvia y la intemperie perjudican más al mortero que se aplica en los paramentos exteriores de los muros inclinados (aun cuando la inclinación no sea sino de $^1/_8$ á $^1/_{12}$) que en los muros verticales, y por consiguiente aquél debe ser de mejor calidad. Véase Mortero, etc.

Hemos visto, no obstante, una regular filtración de aguas superficiales á través de arcos de ladrillos de casi 1 m de espesor, aun usando el cemento sin restricción. En puentes de acueductos, creemos que el cemento no basta á impedir las filtraciones, ya sean los arcos de ladrillo, ó de piedra tallada. ¿No sería esto efecto de grietas producidas por el asiento del arco, ó por la contracción y dilatación bajo las influencias atmosféricas? El cemento á lo menos impide que las juntas se desmoronen.

Cuando el arco es muy rebajado, esta inclinación puede llegar á ser tan fuerte, especialmente en sus partes superiores, que hay que emplear puntales de cualquier clase para impedir que la mampostería resbale, hasta que, completo el arco, lo impida. Las hiladas horizontales comprendidas entre el paramento *mi*, y la línea *oe*, ayudarán algo en este respecto.

Este método debía aplicarse *á todos los arcos muy grandes*, cuya flecha sea una tercera parte, ó menos de la luz. Como se observó anteriormente, no es muy necesario en los arcos que no exceden de 15 m de luz y no rebajados más de $^1/_3$ de dicha luz. Ciertamente, si se puede depositar el relleno de tierra antes de quitar las cimbras, estos límites pueden extenderse considerablemente sin peligro. Sin embargo, como cierto grado de inclinación puede hacerse con muy poco trabajo y costo, recomendamos, aun para tales arcos, un método algo semejante al que sigue: De la *mitad* de la abertura réstese la flecha; divídase el residuo por 3. (*N. del T.* — Lo mismo en pies que en metros.) Hágase *ot*, fig. 5, igual al cociente; trácese *tn*, y *om*, horizontales; divídase el ángulo *som* en dos partes iguales, por la línea *ao;* désele á la mampostería una inclinación tal que sea paralela á *ao*, y que llegue hasta *tn*. Las hiladas inclinadas pueden ó no prolongarse hasta el paramento *ot*, según se quiera.

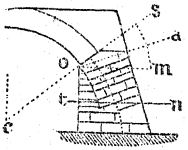

Fig 5

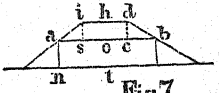

Fig 7

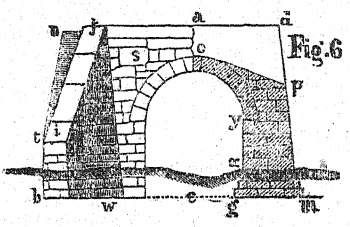
*Nota* 1. **Hallar la longitud** (*ab*, fig. 7) de boca á boca, **de una alcantarilla** que atraviesa un terraplén. De la altura *ht* del terraplén, tómese la altura, *na*, de la alcantarilla; el residuo será la altura, *ho*, del terraplén sobre la alcantarilla. Luego la longitud requerida *ab* es igual al ancho de la parte superior *id* del terraplén, más las dos distancias *as*, *cb*, que corresponden á los taludes laterales. Por tanto, si el talud lateral es, como de costumbre, de 1½ á 1, entonces *as* y *cb* serán cada una iguales á 1½ veces *oh;* ó las dos serán 3 veces *oh*. De modo que si el ancho *id* es = 6 m, y *ho* 1.80 m, la longitud *ab* será $6+(1.8\times3)=6+5.4=11.40$ m.

**Art. 7. Las tablas siguientes n.os 3 y 4**, servirán para facilitar los cálculos de presupuestos preliminares aproximados; por tanto, no se han hecho escrupulosamente exactas, sino más bien un poco exageradas. La primera columna de la tabla 3 contiene la altura vertical total *oc*, fig. 6, desde la clave *o* de un arco semicircular, hasta los cimientos ó base *gm* de sus estribos. Las otras columnas dan aproximadamente el número de *metros cúbicos* contenidos en cada metro corrido, ó metro de longitud de la alcantarilla ó puente, medido entre las caras del arco justamente, é incluyendo solamente el arco y sus estribos, como se indica en la fig. 1, ó en la semisección *opmgy*, fig. 6; incluyendo la base de los estribos, pero omitiendo los muros en alas (*wn*) y los muros en las enjutas (*s*), figs. 6 y 2½. Al pie de cada columna está el volumen aproximado en metros cúbicos de los dos muros de las enjutas por sí solos; calculando uno sobre cada frente de arco.

Estos últimos se calcularon en la suposición de que su espesor en la base, en su unión con los muros en alas, donde su altura es máxima, sea igual á $^1/_{10}$ de su altura

en dicho punto; exceptuando el caso en que esta proporción dé un espesor en la parte superior menor que .75 m y que tengan una altura de .60 m (*oa*) sobre la parte superior *o* del arco. En esta parte se suponen de .75 m de espesor, arriba, espesor que se juzga para estos casos, más ó menos, el mínimo admisible en muros de piedra bruta. Tanto el paramento interior como el exterior se suponen verticales. Los volúmenes ó cubos de estos muros de enjutas varían aún algo para la



misma luz, con la altura de los estribos y disposición de las alas. Sin embargo forman una parte tan pequeña del cubo total, que puede prescindirse de esta consideración en los presupuestos preliminares. Están unidos tan firmemente á la mampostería de los muros en alas en sus puntos más altos, y tan fuertemente conectados por mortero con el relleno del arco en su base, que no requieren un espesor mayor, cualquiera que sea la altura del terraplén.

**El volumen de los cuatro muros en alas**, de los cuales *njwb*, fig. 6, es uno, se encontrarán en una tabla (n.º 4) que sigue inmediatamente á las alcantarillas.

*Nota* 1. Aunque el espesor de los muros en alas aumenta en todas sus partes con su altura, no aparecen con un espesor mayor en *nj* que en *ti*, fig. 6; pero (como se ve en la figura) se construye un escalón en su paramento interior *tn*, un poco más abajo de la superficie superior inclinada *ij*, para dar de este modo una anchura uniforme á las lajas (ó piedras labradas, según el caso) con que están cubiertos. Para impedir que las baldosas resbalen en el plano inclinado *ji*, la piedra ó baldosa inferior *i* debe ser grande y gruesa, y colocada en un lecho horizontal. Algunas veces se fijan las lajas ó baldosas al muro con lañas de hierro y por medio de pernos. Haciendo escalones (lo que es preferible) no se requiere nada de esto, como se ve en *s*, fig. 11.

*Nota* 2. **Las tablas demuestran la inconveniencia de estrechar demasiado el cauce de las aguas**, por vía de economía, adoptando arcos de pequeña luz cuando pueda hacerse una alcantarilla de la misma altura *total* y de mayor luz.

Como las alas deben ser lo mismo, sea la abertura grande ó pequeña, con tal de que la altura total sea la misma en ambos casos, y como ellas constituyen una gran parte de la cantidad total de mampostería, en las alcantarillas de longitud ordinaria, la luz por sí, dentro de límites medianos, ejerce relativamente poca influencia sobre el volumen de aquélla. De este modo, la cantidad total de mampostería de una alcantarilla semicircular de .91 m de luz, de una altura total de 2.44 m, y de 18.30 m de longitud entre los frentes de los arcos, tiene la misma mampostería (dif uno ó dos m³) que una de 1.52 m de luz, de la misma altura y longitud.

*Nota* 3. En parte por esta razón, y en parte debido á que las **alcantarillas destinadas á una vía doble no tienen el doble de la longitud de las de una sola vía**, la cantidad de mampostería de alcantarillas de las primeras no es, por término medio, sino de $^{1}/_{4}$ á $^{1}/_{3}$ parte, más ó menos, mayor que la de las últimas; de manera que muchas veces es conveniente hacer las alcantarillas de una vez, con la longitud requerida para una vía doble, aunque los terraplenes se hagan al principio sólo para una vía sencilla, con la idea de hacerlos más tarde para vía doble.

**Tabla 3, del número aproximado de metros cúbicos de mampostería por metro corrido, contenidos en los arcos y estribos solamente,** como se muestra en la fig. 1 (omitiendo las alas y los muros de las enjutas colocados sobre los frentes de los arcos) de alcantarillas y puentes semicirculares, de .61 hasta 15.25 m de luz y de diferentes alturas totales *ht*, fig. 1, ó bien *oc*, fig. 6. Se verá que en muchos casos, un puente de una luz mayor contiene menos mampostería que otro, de luz más pequeña, *cuando sus alturas totales son las mismas* En dicha tabla se tienen en cuenta sin restricción alguna los zócalos ó escalones de las bases de los estribos.

**Art. 8. La tabla que sigue** da el volumen de mampostería de los muros en alas; es, como la anterior, de utilidad para la ejecución de presupuestos preliminares. Las alas *no*, *no*, representadas en proyección en la fig. 8, se suponen que forman un ángulo *aoc*, de 120° con la cara *oo* de la alcantarilla. Sus caras exteriores

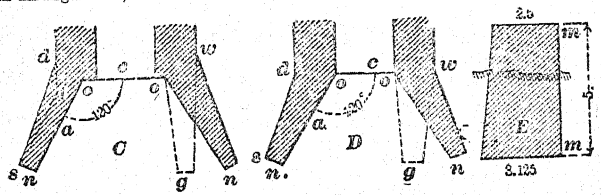

**Fig. 8**

extremas, *m*, se ven en una escala mayor en E. Espesor uniforme en toda la base igual á $^{4}/_{10}$ parte de la altura del muro en dicha parte; excepto el caso en que dicha cantidad resulte demasiado pequeña é impida darle á la parte superior un espesor de .75 m; en cuyo caso se ensancha aquélla lo suficiente. Véase nota 2. Esto sucede solamente cuando la altura *mm* del muro, fig. E, es menor de 2.70 m. Inclinación del frente 1 en 8. Paramento interior vertical, pero escalonado (si fuese necesario), á una pequeña distancia debajo de la parte superior, como para darle

á la parte superior visible un espesor uniforme de .75 m. La mampostería se supone de piedra bruta (bien picada) con mortero. Las alturas dadas de la primera columna son las mayores; es decir (*w y*, en la fig. 6), donde el ala se une con el frente de la alcantarilla. En la tabla no se tiene en cuenta el zócalo ó escalones de la base de los muros en alas; porque éstos se omiten frecuentemente cuando hay buenos cimientos. Al tomar las cantidades de la tabla, téngase en cuenta que la altura de las alas es generalmente un poco mayor que la de la alcantarilla misma.

El plano indicado en C es el que generalmente se usa; pero el plano D es preferible para alcantarillas; porque los recodos *oo* en la fig. C, además de que pueden sujetar los objetos arrastrados por la corriente, como ramas de árboles, etc., ofrecen por sí mismos una resistencia mayor á la entrada del agua de la que oponen las esquinas *oo*, fig. D.

**Tabla 4, del volumen aproximado, en metros cúbicos, de los cuatro muros en alas de un puente ó alcantarilla.**

| Altura de los muros en alas. | Largo de un ala. | M. cúb en las 4 alas. | Altura de los muros en alas. | Largo de un ala. | M. cúb en las 4 alas. |
|---|---|---|---|---|---|
| m. | m. | m cúb. | m. | m. | m cúb. |
| 1.830 | .5276 | 3.07 | 9.150 | 13.206 | 621 |

| 8.540 | 12.139 | 510.72 | 21.350 | 34.465 | 7.717 |

(*N. del T.* — Convertida al sistema métrico.)

El volumen para alturas intermedias puede hallarse aproximadamente por una simple proporción.

*Nota* 1. No se recomienda prolongar todas las alas hasta hacer sus dimensiones tan pequeñas como las representadas en E, fig. 8. En los muros grandes en alas es generalmente más económico aumentar algo la altura de su extremidad *mm*. El cubo de la mampostería puede también hallarse fácilmente en este caso por la tabla. Así, suponiendo la altura de las alas de 9.15 m en una extremidad, y 2.44 m en la otra, tenemos solamente que restar el cubo dado por la tabla para 2.44 m de altura, del que da para 9.15 m. De modo que 621—11.10 = 609.90 es el volumen buscado.

*Nota* 2. Podría suponerse, que como los muros en alas tienen á menudo que sostener la presión de terraplenes que llegan hasta más arriba de su parte superior, debían hacerse en este caso de mucho más espesor, como muros de sostenimiento ordinarios. Pero el hecho de que dichos muros tengan mayor estabilidad, por estar unidos por sus extremidades elevadas con el cuerpo del puente ó alcantarilla, hace innecesario este aumento, cuando las alas tengan las dimensiones prescritas en nuestra tabla, y no importa hasta dónde se extienda la tierra sobre ellos; así está demostrado por numerosas experiencias.

Confiados en este refuerzo, podemos ciertamente, cuando la tierra no se prolongue sobre la parte superior, reducir la base en *o á'* un tercio de la altura, como se indica en *ot*, y por la línea de puntos *ts*. La experiencia demuestra que podemos hacer lo mismo, aun cuando la tierra llegue á una gran altura sobre la parte superior, con tal que las alas, en lugar de estar más separadas ó abiertas en sus extremidades como en *on, on*, sólo formen prolongaciones rectas de los estribos del arco, como se indica por las líneas de puntos *ogw*. En esto caso, la presión de la tierra contra las alas es menor que cuando están abiertas. Hemos sabido que el espesor en *o* se redujo en tales casos á menos de una tercera parte de su altura, cuando las alas tenían

4.5 m de alto, y la altura del terraplén *sobre sus partes superiores* era de 4.8 m en un caso, y de 11 m en otro. En otro puente, alas semejantes de 7.78 m de altura, y con un terraplén de 8.84 m sobre su parte superior, tenían en sus bases, *o*, más bien menos de $\frac{1}{4}$ parte de su altura. Siempre, el espesor uniforme en la parte superior era de .75 m, con los paramentos interiores verticales. Mencionamos estos casos, porque parece que en especial esta materia, no puede reducirse á una regla práctica. El último muro nos parece demasiado delgado, especialmente si la tierra no se deposita con cuidado y en capas, y después que el mortero esté endurecido. Sin embargo, el trabajo de depositar la tierra cuidadosamente en capas, puede costar más de lo que se economiza en la mampostería. El joven practicante debe tener esto en miente cuando desea economizar mampostería por estos medios; y también debe acordarse que un muro delgado puede desplomarse, ó caerse enteramente, si el relleno de tierra se deposita mientras el mortero no se ha endurecido perfectamente.

**Art. 9.** Debe tenerse cuidado especial en hacerles **cimientos firmes á las alcantarillas y desagües construídos debajo de terraplenes elevados**; porque de otro modo el peso, especialmente bajo la mitad del terraplén, puede hundirlos, si el suelo es blando ó cenagoso; y de este modo disminuir la sección de salida del agua, ó por lo menos causar una depresión de mal efecto en el centro de la alcantarilla. También, en un terreno blando, el relleno puede comprimir los muros laterales, y acercarlos, haciendo más angosto el canal. Esto puede impedirse por medio de un arco invertido ó por medio de un lecho de mampostería entre los muros. Una capa de granzón, arena, ó piedras trituradas de 1 á 2 m de espesor, será generalmente suficiente cimiento para alcantarillas en terrenos cenagosos y sospechosos; también puede usarse la arena suelta, pero en rellenos de altura mediana. Estos cimientos artificiales deben sobresalir algunos metros fuera de la mampostería, en todas direcciones, y apisonar si es posible cuando el granzón ó la arena están completamente mojados, para contribuir á la consolidación. Algunas veces será necesario clavar estacas. Si la mampostería se construye sobre una plataforma de madera, ó sobre superficie lisa de roca, debe tenerse cuidado de impedir que resbale por la presión de la tierra que está detrás. Esta misma puede volcar las estacas si no están bien sujetas.

**Art. 10. Desagües.** Los desagües de las dimensiones indicadas en la fig. 11 (cuyos números indican pies, 1 pie = .305 m. *N. del T.*) tienen 2.32 metros cúbicos de mampostería por metro lineal. Se construyen á menudo de piedra en seco

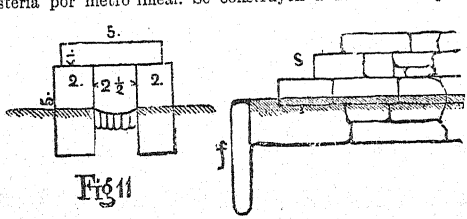

Fig. 11

desbastada haciéndoles el fondo ó piso con fragmentos de piedras. Cuando pasa una gran cantidad de agua por ellos y tienen una pendiente considerable, es mejor hacer el cimiento continuo á través de todo el desagüe. Muchas veces se hace esto aun sin los motivos indicados, porque la mampostería que se agrega es una cantidad insignificante, y la excavación de una sola fosa ancha para los cimientos, se hace más fácilmente que dos angostas. Puede enterrarse á la entrada y á cortas distancias en longitud lajas gruesas, *f*, fig. 11, tanto en las alcantarillas, como en los desagües para impedir que se socaven.

Estos desagues se prolongan debajo de todo el ancho del terraplén y pueden terminarse en escalones, como lo indica la vista lateral S. Por supuesto que es mucho mejor construirlos de mortero de cemento, para impedir cuando está lleno de agua que se filtre y ablande el terraplén.

Algunas veces se pueden colocar dos ó tres de estos desagües unos al lado de otros y paralelos, en lugar de una alcantarilla. Cuando se colocan dos de este modo, sólo contienen 1½ veces la mampostería de uno; sin embargo su uso no ofrece más economía que las alcantarillas. Un hombre puede penetrar en el interior para limpiarlos, fig. 11.

**Art. 11. Los desagües de las calzadas** en los puentes de mampostería, de varios arcos, se hacen generalmente por medio de canales abiertos en la clave de los arcos y en cada lado, hasta que llegan cerca de las extremidades de las luces respectivas. Aquí, descargan sobre tubos verticales de hierro introducidos en la mampostería. La extremidad superior de estos tubos debe cubrirse con un enrejado. Cuando el agua que sale de estos tubos causa un inconveniente, cayendo sobre la gente que pasa por debajo de los arcos, estos tubos deben prolongarse hasta el pie de dichos arcos; pero si no fuese así, pueden llevarse solamente hasta el intradós, dejando que el agua caiga libremente de esta altura.

**Art. 12. Arcos de ladrillo.** Como hasta los ladrillos buenos, propios para arcos grandes, tienen mucha menos resistencia á la ruptura por compresión que el buen granito ó piedra caliza buena, y es inferior aún á la buena piedra arenisca, mientras que su peso no difiere mucho del peso de la piedra, es claro que no pueden usarse en arcos de tan gran abertura como se usa la piedra. Algunos de ellos ya construídos, y que han durado muchos años, solamente tienen un coeficiente teórico 3 de seguridad, más ó menos; mientras que las autoridades nos enseñan á no confiar, aun á la piedra, en más de una vigésima parte de su carga de ruptura por compresión. Esto último, sin embargo, nos parece una de esas suposiciones ligeras, que, una vez admitidas en los libros profesionales, es difícil destruirlas. En nuestra opinión con buen cemento, y el cuidado necesario al quitar las cimbras, es suficiente la décima parte de la máxima resistencia aun contra los esfuerzos anormales producidos por el asiento de la clave y elevación de los riñones de la bóveda, cuando se quita la cimbra. Es inútil tratar de fijar los límites de seguridad de los materiales malos y peor dispuestos.

*Nota* 1. La práctica ordinaria de construir arcos de ladrillo en una serie **de anillos concéntricos** como en *acee*, fig. 12, sin otra trabazón entre ellos que la del mortero, la censuran las autoridades, porque la curva de presión al pasar del trasdós al intradós tiende á separar los anillos, y de este modo debilita el arco, rajándolo, por decir así, longitudinalmente. La razón de usar estos anillos, en lugar de hacer las juntas radiales continuas en todo el espesor del arco *mn*, como en *b*, es para evitar las juntas gruesas de mortero en el trasdós del arco, como lo indica la figura. Si en un arco, construído como se indica en *b*, se quita la cimbra demasiado pronto, el mortero blando de estas juntas gruesas, se comprimirá tanto, que causará un gran descenso de la corona, quitándole de este modo la forma al arco, y causando tal desigualdad de presión, que puede ocasionar hasta su caída, especialmente si el arco es rebajado. Como sistema intermedio entre el arco de anillos y el de juntas continuas, se emplean algunas veces los dos combinados, á fin de eliminar **algunas** de las juntas largas radiales, y al mismo tiempo alternar á **intervalos** la continuidad de los anillos. De modo que, en la fig. 12, que puede suponerse de un y medio ladrillo de espesor, principiando en el estribo *a*, podemos colocar anillos de medio ladrillo hasta *eoe;* y luego, cortando el ladrillo *o* hasta la línea *ee*, podemos colocar desde *ee* hasta *mn* una hilera de ladrillos con juntas radiales continuas, lo mismo que en *b*, y allí principiar nuevamente con los tres anillos; y así alternativamente. Otro método mejor todavía, pero más costoso, sería introducir en el espacio *eemn* una dovela de piedra tallada. Los intervalos propios para efectuar el cambio de los anillos por los bloques dependerán del número de los anillos y el espesor *ca* del arco; evitándose también lo más posible cortar los ladrillos.

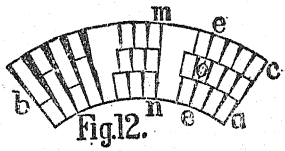

Fig.12.

Esto puede decidirse mejor en un plano de una parte del arco, en una escala de ¼ á ⅛. Generalmente los anillos se hacen de medio ladrillo solamente, ó de 10 á 12 c m de espesor, como en *ac*. En el viaducto de Maidenhead, los dos arcos elípticos de ladrillos de 39 m de luz y de 7.40 m de altura, son los más atrevidos construídos hasta ahora. Se les ha calculado que tienen un coeficiente 3 de seguridad solamente contra la ruptura por compresión en la corona.

Se han construído con éxito tantos otros arcos (de 21 á 30 m de abertura) entera

mente de anillos de ladrillos enteros ó de medio ladrillo, como para comprobarnos que no debemos prestarle poca atención á la objeción teórica arriba mencionada, con tal de que se use cemento de primera clase y se le dé el tiempo necesario para que se endurezca tanto ó casi como los ladrillos mismos, antes de quitar las cimbras. Bajo tales circunstancias no tendríamos objeción alguna que hacerle á una serie de anillos aun de 1.5 ladrillo de espesor, dispuestos alternativamente en hiladas como en *b*.

**Si los ladrillos tuviesen la forma de dovelas**, es decir, un poco más grueso en una punta que en la otra, podrían hacerse anillos del espesor de un ladrillo entero sin aumentar el espesor de las juntas del mortero en el trasdós de cada anillo. Sin embargo, con más de un anillo, las juntas radiales no serían continuas como en *b*, sino alternadas como en *ac*. Pero tales ladrillos serían de construcción más costosa, y además, para que convengan perfectamente al fin destinado, tendrían que hacerse muchos modelos diferentes para adaptarlos á los distintos radios del arco y aun para que se adapten á los radios de los diferentes anillos, cuando el espesor del arco requiere varios de ellos.

*Nota* 2. **Mójense los ladrillos** antes de asentarlos.

*Nota* 3. Cuando las caras ó frentes de un arco de ladrillo han de terminarse con dovelas de piedra tallada, es mejor no colocar estas últimas hasta algún tiempo después de la conclusión de la obra de ladrillos y del fraguado del mortero, y aun después de haber aflojado parcialmente las cimbras, para que no se rajen ó se agrieten al asentarse desigualmente con los ladrillos.

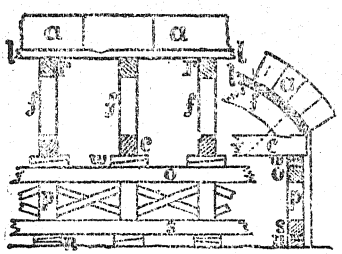
*Nota*. **Los arcos de ladrillo** á consecuencia del gran número de juntas, están expuestos á bajar más que los arcos de piedra tallada, y en consecuencia á cambiar de forma, y algunas veces, si no se tiene el cuidado debido, peligra su seguridad, especialmente cuando son grandes y rebajados. Cuando la abertura excede de 9 á 11 m más ó menos, y especialmente si es un arco rebajado, empléense solamente ladrillos de superior calidad con buen mortero de **cemento**. Aun con los mejores materiales y ejecución, aconsejamos á los jóvenes ingenieros que no construyan arcos de ladrillo para puentes de ferrocarriles con luces mayores que las siguientes. Se han construído algunos considerablemente más grandes, y han aguantado; pero su coeficiente de seguridad no es satisfactorio en todos los casos. En esta Tabla se da la flecha en partes de la luz.

| F. | L. | F. | L. | F. | L. | F. | L. | F. | L. |
|---|---|---|---|---|---|---|---|---|---|
| .5 | 30.5 | ⅜ | 26.8 | .225 | 20.7 | 1/10 | 15.2 | .134 | 10.7 |
| .4 | 29.6 | .29 | 25.0 | 1/5 | 18.3 | .155 | 13.7 | 1/8 | 9.1 |
| .36 | 28.4 | ¼ | 22.9 | .183 | 16.8 | 1/7 | 12.2 | | |

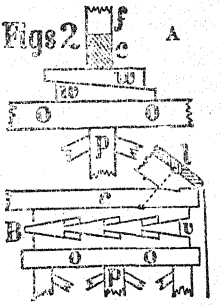
**En el ferrocarril de Pensilvania, en la calle Filbert, en Filadelfia**, hay 4 arcos de ladrillo de 15.27 m de abertura, con la muy pequeña flecha de 2.13 m. Tienen .76 m de espesor excepto en sus frentes visibles, donde sólo tienen 2.61m. Las juntas son de mortero ordinario, y de 6 mm de grueso, más ó menos. Estos 4 arcos, situados á una distancia de 182 m más ó menos unos de otros, y con un gran número de otros arcos de 7.93 m de abertura, forman un viaducto. Las pilas situadas entre los arcos cortos tienen 1.30 m de espesor, y las de las extremidades de los arcosgrandes, 5.64 m. Las líneas de arranques de todos estos arcos están más ó menos sè 1.80 á 2.4 m sobre el suelo. Uno de los arcos de 15.25 m de abertura bajó 7½ cm por haberse quitado la cimbra antes de tiempo; pero no se observó ningún descendo después, aunque el viaducto ha tenido desde su construcción (1880) un tráfico pesado de pasajeros y carga, á razón de 16 á 32 kilómetros por hora. Las calzadas son como de 30.5 m de ancho, con espacio para 9 ó 10 vías de ferrocarril.

# CIMBRAS PARA ARCOS

**Art. 1. Una cimbra** es una construcción de madera provisional (se la traza sobre una plataforma de tamaño natural, bajo techo ó no) para sostener un arco durante la construcción. La cimbra se compone de un número de cerchas ó **armaduras** *ff*, fig. 1, colocadas de .30 á 1.80 m de distancia de centro á centro y cubiertas con un piso *ll* de tablones ó tablas brutas, generalmente unidas, sobre el cual se colocan inmediatamente las dovelas. En la fig. 3 esta cubierta no está unida. No hay gran economía en colocar las cerchas á gran distancia unas de otras, porque así su espesor aumenta rápidamente. Para este espesor, véase nota 9, art. 8. Las cimbras descansan en las extremidades de sus cuerdas, *c*, sobre cuñas, *w*, fig. 1, que se apoyan en postes, *p*, con sus partes superiores unidas por **dinteles**, *o*, y cuyos pies descansan sobre durmientes, *s*, estando el conjunto ligado por piezas diagonales como lo indica la figura.



Figs 1.



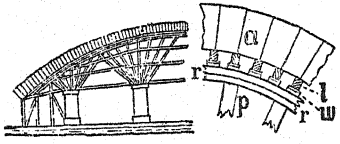
Figs 2

Cuando el terreno es muy firme y el arco liviano, los pedestales pueden descansar sobre él, con la interposición de bloques de ajuste, *n*, colocados debajo de los durmientes para adaptarlos á las irregularidades del terreno como en la figura. Estos bloques deben tener la forma de cuñas dobles, de modo que apretándolos á golpes de martillo, los pedestales pueden alzarse en caso de que desciendan ó penetren en el terreno. Pero para arcos pesados los pedestales deben descansar sobre cimientos mucho más firmes, como pilares de ladrillos enterrados un poco en el suelo, ó puede adoptarse cualquier otro medio. Frecuentemente se dejan en la mampostería de los estribos escalones ó huecos expresamente con este objeto, y en vista de esto es bueno hacer el proyecto de la cimbra al mismo tiempo que el del arco. Hasta aberturas de 15 á 18 m, una sola hilera de postes (uno debajo del extremo de cada armadura) es suficiente; pero para otras mucho más grandes pueden necesitarse 2 ó 3 hileras de .60 m ó más de separación unas de otras, como en la fig. 2. Las cuñas citadas arriba sirven para bajar ó quitar la cimbra después de concluído el arco. Se componen de piezas de madera dura en forma de cuñas *w w*, como en A, fig. 2, de .30 á .60 m de largo, 15 cm de ancho y 7 cm de grueso ó más (suficiente para bajar las cimbras de 5 á 15 cm, según la abertura ó luz y otras circunstancias) que descansan sobre el dintel, *o*, del pedestal mientras que la cuerda, *c*, de la armadura se apoya sobre ellos. Cuando la extremidad de una cercha está sostenida por dos ó más postes, *p*, como en B, fig. 2, en lugar de estarlo por uno solo, se hacen á veces las cuñas como se indica en dicha figura, y B*w* es una cuña larga en ángulo recto con el estribo y que obra como cuatro cuñas que pueden bajarse todas juntas golpeando en la extremidad B. En los arcos de 18 á 24 m de luz todas las cerchas pueden descansar sobre 2 cuñas semejantes á B*w* solamente; cada una de un largo tal que alcance **transversalmente** á todo el arco. Entonces todas las cerchas pueden bajarse en una sola operación, como se ha descrito al fin del art. 9.

Si tuviésemos que considerar solamente el frotamiento de la madera seca contra madera seca, el declive de las cuñas podría ser de 1 vertical para 3 horizontal, sin peligro alguno de resbalar una sobre otra; y entonces no necesitarían sino golpes suaves para moverlas; ó separarlas enteramente, cuando hay que quitar la cimbra. Pero es de la mayor importancia, especialmente en los arcos grandes, **bajar las cimbras muy lentamente**, porque de otro modo la fuerza adquirida por un cuerpo, tan pesado como el arco, al descender repentinamente aunque sean 5 ó 7 cm, es muy factible que dañe su forma y aun su estabilidad.

Por consiguiente, las cuñas no deben tener una inclinación mayor de 1 en 6 ú 8, más ó menos, en arcos de menos de 15 m de luz más ó menos; ó de 1 en 8 ó 10 para luces mayores. En los grandes lados de las cuñas deben trazarse líneas verticales equidistantes como guía para hacerlas descender la misma cantidad á un tiempo, y este descenso no debe exceder por todo de 12 mm por día más ó menos y á intervalos de 3 mm más ó menos á la vez, para arcos de 15 m; y de 3 á 6 mm por día por todo, en arcos mayores de 30 m. Se recomienda especialmente la lentitud del descenso en los **arcos de ladrillo**, no solamente porque el mayor número de juntas los expone á una deformación, sino también porque aun los ladrillos buenos tienen por término medio una resistencia á la ruptura por compresión mucho menor que el granito, la piedra caliza y la piedra arenisca buena, y por consiguiente están mucho más expuestos á rajarse, y aun á desmoronarse (como lo ha visto el autor) cuando las fuerzas todas, como se ha descrito en el art. 3, están obrando sobre sus aristas.

**En el puente de Gloucester**, Inglaterra, de piedra tallada de primera clase, con una luz de 45.7 m, una flecha de 10.67 m, las cimbras se quitaron del todo en el muy corto espacio de 3 horas; y la corona del arco descendió 25 cm! **En el puente de Grosvenor**, Inglaterra, de piedra tallada de primera clase, de 61 m de luz, y 12.81 m de flecha, se tuvo tanto cuidado al aflojar las cimbras, que la corona del arco no bajó sino 6.2 cm. Este caso sin embargo se distinguió por circunstancias que contribuyeron á tan favorable resultado. Es decir, las cimbras en lugar de ser una serie de cerchas ó armaduras sostenidas por sus extremidades como de costumbre, y de consiguiente permitiendo cierto grado, aunque pequeño, de descenso, se componía esencialmente de postes verticales é inclinados (véase fig. 3) que descan-



Figs 3,

saban sobre cuatro pilares provisionales de mampostería de 2.1 á 2.4 m de espesor, construídos dentro del río, paralelamente á los estribos, y tan largos como éstos. Estos pilares sostenían seis cerchas (ó más bien seis series) colocadas á 2.10 m más ó menos de distancia de centro á centro y descansando sobre zapatas de hierro fundido. La fig. 3 representa la mitad de una de estas series. Cada armadura ó serie consistía en cuatro juegos de postes en forma de abanico, todos colocados en el mismo plano vertical. Las piezas largas horizontales que se ven extend das de un lado al otro del arco se fijan á los postes por medio de pernos para aumentar la rigidez; y otras piezas, con el mismo fin, unían las seis series transversalmente. Cada poste ó puntal soportaba su correspondiente parte del peso de las dovelas transmitiéndolo á la cimentación inflexible del pilar, mientras que en las cimbras usuales de cerchas la carga entera descansa sobre las cerchas, y es transportada á los soportes relativamente instables de los puntales en sus extremidades.

Las partes superiores *p* de los puntales de una serie variaban de 1.5 á 2.4 m de dist de centro á centro y estaban unidas por una pieza curva *rr*, del espesor de dos tablones de 10 cm, adaptada aproximadamente al arco. Sobre esta pieza se colocaban pares de cuñas *w*, semejantes á las de la fig. 2, más ó menos de 40 cm de largo, 25 á 30 de ancho y con una disminución de 4 cm y próximas (de .75 á 1.07 m de centro á centro), de manera que había un par debajo de cada junta de las dovelas *aa*. Sobre estas cuñas, y prolongadas sobre todas las seis cerchas, se colocaron piezas de forro *l*, de 12 cm de grueso.

**Esta disposición especial de las cuñas** y de los forros, en luces grandes, tiene muchas ventajas sobre el sistema generalmente adoptado de colocar aquéllas solamente en las extremidades de las cerchas. En estas últimas, la cimbra y el arco enteros descienden juntos sin dar oportunidad para rectificar cualquiera irregularidad de forma ó desigualdad en los puntos de apoyo que puede haber ocurrido en el arco durante su construcción.

Esta cimbra, ideada por el Sr. Trubshaw, se presta para bajarla toda igualmente, ó para bajar una parte cualquiera de ella, un poco más ó un poco menos que las otras. Este señor tenía mucha experiencia respecto de los arcos grandes, y afirmaba que, durante el descimbramiento, había encontrado que se comportaba mejor el arco *o*, se asentaba mejor, bajándole un poco en los riñones, y suspendiendo la corona otro poco, hasta cerca del fin de la operación.

*Nota* 1. **En lugar de pilares de mampostería** para soportar los pies de los puntales, pueden emplearse á menudo cajones de madera, ó estacas, si el arco está sobre agua.

**El sistema de sostener las armaduras** por medio de puntales, situados en puntos de la cuerda, tan retirados de los estribos como las circunstancias lo permitan (á más de los situados en sus mismas extremidades), debía siempre aplicarse, cuando fuera posible, para reducir á un mínimo la tendencia á bajar. Pueden hacerse escalones en la mampostería de los estribos y pilas para apoyar los pies de los puntales, cuando éstos sean inclinados.

*Nota* 2. También *pueden usarse* **tornillos** en lugar de cuñas para bajar las cimbras. En el puente de *l'Alma*, en París, de arcos elípticos de 43 m de luz y de 8.6 m de flecha, las cerchas estaban sostenidas por columnas macizas de madera, cuyos pies descansan sobre **arena confinada en cilindros de palastro** de 30 cm de diámetro y de altura, que tenían cerca del fondo un tapón que podía sacarse ó ponerse á voluntad, y que regulaba de este modo la salida de la arena y el descenso de la cimbra. Este expediente tuvo éxito perfecto, y bien vale la pena de adoptarlo para arcos que excedan de 18 m de luz. Cuando son mucho más grandes, la encajada de las cuñas, golpeándolas, requiere golpes muy fuertes, y resulta una operación ruda, donde á veces no basta el simple martillo aun cuando las cuñas estén lubriadas. En las cortadas de ferrocarriles atravesadas por puentes, **la tierra situada debajo del arco** se ha aplicado como cimbra, dando á su superficie la curvatura adecuada, y colocando luego en ella piezas de madera curvas á conveniente distancia unas de otras, y de un estribo al otro, para sostener la cubierta de tablas.

*Nota* 3. **Toda cimbra debe ceder** ó asentarse más ó menos bajo el peso del arco, especialmente cuando está sostenido solamente cerca de sus extremidades; y como el arco mismo también se asienta algo, no solamente cuando se quitan las cimbras, sino durante algún tiempo después, es prudente hacerlos un poco más altos de como van á quedar. Este exceso de altura, cuando la cimbra está sostenida en sus extremidades, puede ser de 5 á 10 cm por 30 m de luz en los arcos de piedra tallada (según el tiempo en que se bajan, condición de la mampostería, ejecución), y del doble para los arcos de ladrillo.

*Nota* 4. **El tiempo adecuado para quitar las cimbras** es un punto discutido entre los ingenieros; algunos afirman que debe hacerse tan luego como esté concluído el arco y tenga el suficiente relleno, y otros dicen que debe dársele tiempo al mortero para que endurezca. Es opinión del autor, por cuanto en los arcos de piedra tallada las juntas de mortero son muy delgadas, y como en estos arcos el mortero sirve de poco, es de poca importancia quitar las cimbras, con tal que el relleno de mampostería y el terraplén estén concluídos hasta *yn*, fig. 2, pág. 667; pero en los arcos de ladrillo ó de piedra bruta, cuyas numerosas juntas requieren mucho mortero (el cual para que se endurezca debe contener bastante cemento), debe concedérseles 3 ó 4 meses, ó más todavía, si fuere posible, para que aquél se endurezca suficientemente, á fin de impedir una presión indebida, y el descenso consiguiente después de descimbrado. La permanencia de las cimbras no impide el tráfico sobre el puente.

**Art. 2.** La presión que ejercen las dovelas contra una cimbra es muy pequeña, mientras el arco no se ha construído á ambos lados hasta el punto en que las juntas formen ángulos de 25° ó 30° con la horizontal. Las discusiones teóricas sobre esta cuestión no acuerdan nada por los golpes accidentales durante la colocación de las dovelas, ó por la acumulación del material, tráfico de los albañiles que trabajan sobre él, etc. Sin ocuparnos de detalle alguno, aconsejamos solamente, para mayor seguridad, no apreciar esto en menos de lo que fijamos en las siguientes fracciones del peso del arco completo; á saber : en un arco semicircular, .47; para flecha de .35 de la luz, .61; para flecha de .25 ,.79; para flecha de .2 de la luz .86; para

flecha de .167 de la luz ó menos, 1, ó sea un peso igual al del arco. Esto da para la presión de un arco semicircular sobre sus cimbras, más bien menos de la mitad de su peso. **El peso de las cimbras mismas**, cuando están sostenidas solamente cerca de sus extremidades, debe considerarse como parte de la carga soportada por ellas.

**Art. 3.** Hemos visto que cuando se está construyendo un arco *aaa* gradualmente hacia arriba por ambos lados, después de pasar los puntos *ee*, fig. 4, donde sus juntas forman ángulos *ase* de 30° más ó menos con la horizontal *aa*, el arco principia á comprimir las cimbras más y más; tendiendo por esta razón á hundirlas en los riñones, como se indica en *h* con la línea de puntos, y por consiguiente, á alzarse en la corona como se ve en *c*. Pero como la conclusión continúa hacia arriba, las piedras ó dovelas que se agregan comprimen mucho más á la cimbra que las de más abajo, y por tanto tienden á deformarla exactamente á la inversa de como lo hacían las dovelas inferiores, es decir, á deprimirlas desde la corona *a* hasta *o;* y por consiguiente, á suspender los riñones como en *n;* y á éstos aún más, porque las piedras superiores realmente tienden á levantar ó á aflojar las piedras inferiores de la cubierta de la cimbra. En algunos casos cuando esta tendencia se aumenta *a*

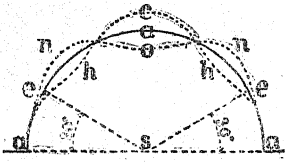


Fig. 4.

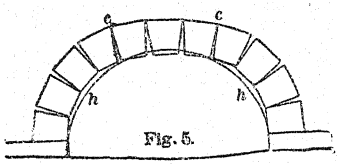

Fig. 5.

*forzar* la clave con golpes fuertes para que llegue á su lugar, podrían sacarse las piezas del forro que están bajo los riñones, sin trabajo alguno, antes de aflojar las cimbras. Al quitar éstas, dicha tendencia de los arcos á descender en la corona y á elevarse en los riñones, es capaz de ofrecer más ó menos peligro á las dovelas mismas, como se ve en la fig. 5, obligando á las situadas cerca de la corona á comprimirse muy fuertemente en el trasdós y á desunirse en el intradós, mientras que en los riñones resulta lo contrario. De aquí que los ángulos de las dovelas se astillan á menudo cerca de *c* y *h* por esta desigual presión.

Estas deformaciones son, por supuesto, mucho más importantes en arcos levantados que en los rebajados, especialmente si sus enjutas no están bastante adelantadas antes de quitar las cimbras.

En el puente Grosvenor arriba mencionado, de 61 m de luz, este exceso peligroso de presión cerca de *c* y *h* se evitó cubriendo las juntas, en la hilada de los arranques, en cada estribo con una cuña de plomo de 35 mm de grueso en el intradós, y reduciéndola hasta cero en el trasdós. Además de esto se colocó una tira de plomo de 22 cm de ancho en la arista del intradós de cada junta, hasta el punto donde se juzgó que la línea de presión pasaría del intradós al trasdós; en seguida se colocaron tiras iguales á lo largo de las aristas de las juntas del trasdós, hasta llegar á la corona. Por consiguiente, al quitar las cimbras, este exceso de presión no comprimió sino el plomo, y de este modo se distribuyó más igualmente sobre toda la extensión de las juntas. Véase « Trans. of the Ins. of Civ. Eng. », London, vol. 1.

**En el puente de Neuilly**, en Francia (de 5 arcos de 36.6 m de luz y 9 de flecha), se trazaron las cimbras de tal modo imperfectas desde su origen, que los arcos bajaron 33 cm en la corona, durante el tiempo de la construcción, y 26 cm inmediatamente después de quitar las cimbras, ó sea en todo 59 cm. Su construcción hizo el descimbramiento muy peligroso y fastidioso, poniendo en gran peligro la vida de los trabajadores y la existencia de los mismos arcos. Algunas de las juntas del trasdós en los riñones se abrieron 25 mm cada una, y las del intradós de la corona, 6 mm. Se redujeron estas aberturas debido al mucho cuidado, y por seguir el método más adecuado y propio, cuando se quitaron las cimbras.

*Nota* 1. **Biselando las aristas de las dovelas** disminuye mucho el peligro de que se astillen por la presión desigual; y también debe **rasparse el mortero de las juntas** hasta la profundidad de 2 á 4 cm antes de quitar las cimbras.

*Nota* 2. Es evidente que para evitar ó, á lo menos, disminuir la deformación alternada de la cimbra, las piezas que primeramente obraban como *puntales*, cerca de los riñones, fig. 4, para impedir que baje, como en *h*, deben después obrar como

cuerdas para impedir que se levante, como en *n;* mientras que, las que primeramente obraban como cuerdas, cerca de la corona, *a*, para evitar que se levante, como en *c*, deben después obrar como puntales para impedir que la corona descienda, como

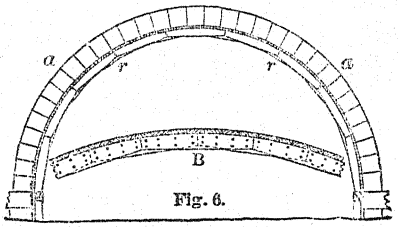

Fig. 6.

en *o*. En otras palabras, deben también usarse los contrapuntales tanto en la armadura de una cimbra como en la de un puente.

**Art. 4.** De lo que antecede resulta que **un simple arco de madera** es, á causa de su gran flexibilidad, poco adecuado para una cimbra, excepto para muy pequeñas luces; para éstas puede fácilmente obtenerse de un espesor adecuado. Sin embargo el autor las ha visto empleadas en un arco de 10.67 m de luz, con dovelas de piedra tallada de .61 m de espesor. La fig. 6 representa una de estas cimbras *rr* y el arco *aa*, trazados en escala. Cada elemento curvo de la cercha se componía de dos espesores de tablones de 5 cm de espesor y de 1.95 m de longitud más ó menos, fijos con clavijas ó tarugos de madera de modo de alternar las juntas, como en B. Cada pieza del tablón tenía 30 cm de ancho en el centro y 20 en las extremidades, con sus aristas superiores labradas para adoptarlas á la curva del arco. Las clavijas de madera eran de 3 cm de diámetro y había 12 de ellas en cada pieza. Estas cerchas se colocaron á una distancia de 43 cm de centro á centro y se afianzaron por medio de piezas de tablas de 2½ cm y de 32 cm de largo colocadas en cada junta de los tablones, es decir, á una distancia de un metro más ó menos. Como había necesidad de establecer una vía para el tráfico debajo del arco, no había cuerdas para unir los pies opuestos de los camones. Éstos estaban cubiertos por un forro unido, que también contribuía á afianzarlos transversalmente. Cuando el arco estaba construído más ó menos hasta las dos terceras partes de su altura en cada lado, las cerchas principiaron á descender en los riñones, como en *h*, fig. 4, y á elevarse en la corona, como en *c*. Esto se remedió cargando la clave con las piedras que debían usarse para terminar el arco, el que después se concluyó sin más dificultad.

**Un ejemplo más sorprendente todavía** del uso de una cercha simple sin trabazones, es el que ofrece el puente del antiguo camino nacional construído

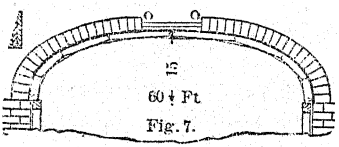

Fig. 7.

sobre *Wills Creek*, en Cumberland, Md. Este puente, del cual la fig. 7 representa en escala un arco con su cimbra, se componía de dos arcos elípticos de piedra tallada con una calzada de 8.08 m de ancho, 18 m de luz y 4.5 de flecha. Tenía .91 m de espesor en la corona y 1.20 en los arranques.

**Cada cimbra** se componía de cerchas simples de 15 cm de grueso, formadas de 3 espesores de tablones de roble de 5 cm en piezas de tamaños diferentes (2.10 á 4.50 m) para adaptarlos á la curva nueva, y al mismo tiempo para conservar un ancho de 40 cm más ó menos en el centro de cada pieza y de 30 cm en cada una de sus extremidades. Estos tablones estaban bien trabados por clavijas de madera, alternando las juntas, y había de 10 á 16 clavijas en la longitud de cada pieza.

Aquí, como en la fig. 6, no había cuerdas, debido á la violencia de las crecientes. Estas cerchas se colocaron á distancia de 45 cm de centro á centro, y ligadas unas con otras por medio de pedazos de tabla de 30 cm de largo colocados cada 1.5 m. A darles más firmeza contribuía, por supuesto, el revestimiento de tablas.

Cuando las dovelas se aproximaron como 3.66 m hacia el medio de la luz, el descenso de la corona, y la elevación de los riñones, se hizo tan alarmante, que se insertaron apuradamente, á ciertas distancias, piezas de madera de roble de 30×30 cm, *oo*, bien acuñadas contra las dovelas. Luego se concluyó el arco en secciones comprendidas entre estas piezas de madera que se removían una por una, según avanzaba la obra.

*Nota* 1. **Tales ejemplos de empujes parciales de un arco** son muy instructivos. Es cierto que más bien es debido á esto que á deducciones teóricas, que se ha llegado á conocer las dimensiones adecuadas en un gran número de casos pertenecientes á la ingeniería, maquinaria, etc. * De este modo podríamos emplear, con entera confianza cuando no hay serios peligros, cerchas de simples camones de las dimensiones expresadas en luces de la mitad de las arriba mencionadas.

*Nota* 2. Presumiendo que las planchas de los camones sean de 30 cm de ancho, sería mejor, como asunto de detalles, hacerlas de 25 cm más ó menos en sus extremidades en lugar de 20 cm, fig. 8, haciendo la curva superior de 5 cm.

Para conseguir esto, sus longitudes, que dependen del **radio** de las cerchas, no deben exceder de las **de la tabla siguiente** :

| Radio del arco. | Longitud mayor. | Radio del arco. | Longitud mayor. |
|---|---|---|---|
| Metros. | Metros. | Metros. | Metros. |
| 1.525 | .735 | 9.150 | 1.930 |
| 3.050 | 1.015 | 10.675 | 2.135 |
| 4.575 | 1.270 | 12.200 | 2.285 |
| 6.100 | 1.525 | 13.725 | 2.390 |
| 7.625 | 1.750 | 15.250 | 2.490 |

Si se cortan de 1½ veces, el tamaño dado por la tabla, tendrán muy aproximadamente 20 cm de ancho en sus extremidades, ó cada una tendrá en su parte superior una curva de 10 cm.

**Art. 5. En los casos donde sea necesario dejar cualquiera vía para el tráfico por debajo del arco**, durante la construcción de éste, como en los dos casos que anteceden, el autor indicaría un medio conveniente, ilustrado ligeramente en la fig. 8, que consiste en **colocar las cimbras encima del arco**, en lugar de **colocarlas debajo**, y después que el arco esté concluído en secciones ó por partes *aa*, desarmar las cimbras en lugar de bajarlas.

La fig. 8 es una sección transversal hecha por una parte de la cimbra y del arco *aa*. Aquí, *rc*, *rc*, *rc*, son cerchas de la cimbra colocadas como de 1.5 á 1.8 m de distancia entre sí, de un espesor cualquiera y de cualquier construcción que se necesite, para una absoluta seguridad; y *ll* es el forro ó revestimiento. Habiéndose construído el

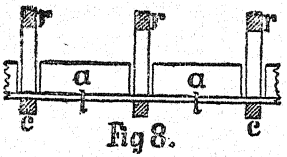

Fig 8.

arco de estribo á estribo en una serie de secciones *a*, *a*, *a*, necesariamente separadas como 30 cm ó más por el espesor de armaduras ó cerchas, podemos quitar las cimbras y llenar las secciones angostas intermedias sobre un forro suspendido por barras de hierro de las secciones ya concluídas. Podía emplearse un buen concreto en estas secciones angostas. En algunos casos puede ser conveniente emplear cambas **altas de hierro** en forma de I haciendo descansar el forro sobre el borde inferior.

* Los jóvenes ingenieros debían hacer y conservar notas ampliamente detalladas de todos los casos como éstos, que pueden llegar á su conocimiento.

Una parte de estas piezas podía quedar embutida en la mampostería, quitándose la parte superior después, cuando esté terminado el arco.

**Art. 6. Las cimbras con cuerdas horizontales** *cc*, fig. 9, son objetables (á pesar de su resistencia) en aberturas grandes de mucha flecha, como en el lado derecho de la figura, por la excesiva longitud requerida para las piezas; y en estos casos es conveniente adoptar algo análogo á lo que está representado en el lado izquierdo. Se ha sustituído aquí una armadura, *f*, más corta y menos elevada que la del lado derecho. En sus extremidades debe proveerse de apoyos no sólo para ella misma, sino también para las dovelas que están debajo de ella. Como la presión de estas dovelas inferiores es comparativamente pequeña, esto puede efectuarse generalmente dejando descansar la extremidad de la armadura *f* sobre otra armadura más baja *oa*. A ésta se puede reforzar en arcos grandes por medio de puntales verticales ó inclinados, solos ó ligados entre sí. Algunas veces una cercha baja como *f* está sostenida por otra en toda su longitud. Las cuñas pueden colocarse en las partes superiores ó en las inferiores, según sea más conveniente.

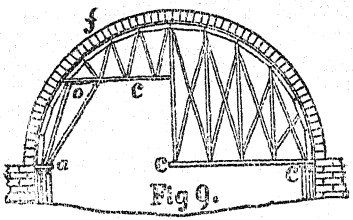

Fig 9.

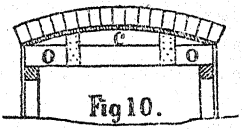

Fig 10.

**Art. 7. Para arcos rebajados de una luz de 3 m** bastará una simple tabla, *oo*, fig. 10, de 30 cm de ancho por 4 de grueso, con otra pieza *c* del mismo espesor, colocada sobre la primera, recortada según la curva, y sujeta en *oo* por dos listones de madera, á intervalos de 45 cm de centro á centro. Si la pieza superior también es de 30 cm de ancho en el centro, la luz puede extenderse hasta 4.5 m. Para luces de 4.5 á 6 m y de cualquiera flecha, servirán dos tablones de 3 á 5 cm de grueso, según la luz; de 20 á 30 cm de ancho en el centro de cada pieza, con longitudes dadas por la tabla, nota 2, art. 4, **bien clavadas** ó ensambladas, según el tamaño del arco, y alternando sus juntas como en la fig. 6, colocadas á distancias de .60 á .90 m de centro á centro. Para distancias mayores auméntese el espesor de los tablones.

**Cuando hayan que mudarse las cimbras de un lugar á otro** para utilizarlas, deben unirse sus pies para impedir que sufran, clavando en uno ó ambos lados de cada cercha una tabla de 2 ó 3 cm, á manera de cuerda, y una ó más piezas verticales del mismo tamaño, colocadas del centro de la cuerda á la parte superior de la cercha.

Aun cuando no hayan de moverse, dichas piezas aplicadas como cuerdas son convenientes hasta en arcos pequeños, porque facilitan el descimbramiento; estas cuerdas impiden que los pies se abran hacia afuera y ejerzan presión contra los estribos.

**Para luces de 4.5 á 9 m**, de flechas no menores de una sexta parte de la luz, pueden adoptarse las dimensiones siguientes que varían con la luz, para cerchas

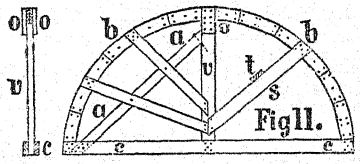

Fig 11.

distantes .90 m de centro á centro. Véase fig. 11. **Para el arco** *b*, dos tablones de 3 á 5 cm de grueso, de 20 á 30 cm de ancho en el centro, y de 17 á 25 cm en las extremidades, bien clavados como en B, fig. 6. **Para la cuerda** *c*,

dos espesores de tablas del mismo tamaño, fig. 11, que las del arco del centro, colocadas á los lados exteriores del arco, y bien clavadas en sus extremidades. **Un pendolón vertical, v,** en una sola pieza tan ancha como las del arco y de doble grueso. Su extremo superior está debajo del arco y fijado á él por dos piezas, *oo*, de una longitud doble del ancho del arco y clavadas al arco y al pendolón *v*. El pie de *v* pasa por entre la cuerda *c* y está clavado á ella. Dos puntales oblícuos, *s*, clavados en cada lado del arco y del pendolón *v*. Éstos, con *v*, dividen el arco en 4 partes.

*Nota* 1. Las dimensiones arriba establecidas son para flechas de $^1/_6$. Si la flecha es de $^1/_4$, los **espesores solos**, de las piezas, deben ser reducidos en una tercera parte, y para flechas de $^1/_3$ ó más, á la mitad.

*Nota* 2. Si los puntales, *s*, tienden á doblarse, clávense piezas, *t*, de cercha á cercha. En las más grandes, con flechas de más de $^1/_4$, pónganse 4 puntales dobles *s*, en lugar de dos, dividiendo así el arco en 6 partes. Para luces de 7 á 10 m, agréguense dos piezas como *aa*, de las mismas dimensiones de *v*.

**Art. 8. Para luces mayores de 9 m** más ó menos, el autor cree que, como regla general (sujeta á modificaciones según el juicio del ingeniero encargado), las ideas siguientes dan una seguridad práctica.

A saber: adoptar una armadura de arco y cuerda de piezas simples del sistema Warren ó de triángulos, como al lado izquierdo de la fig. 9. El arco ha de descansar sobre la cuerda, y cada uno debe ser de un solo espesor. Los miembros (especialmente en aberturas grandes) deben ser también de un solo espesor, colocados debajo del arco que descansa sobre la cuerda, y bien fijos á ambos por medio de abrazaderas, para que obren como puntales y como cuerdas. En aberturas más pequeñas, dichos miembros pueden ser cada uno de 2 espesores, uno de ellos fijado con clavijas á cada lado del arco y de la cuerda. Hay otros métodos; pero no tenemos espacio para estos pequeños detalles.

Pueden usarse también piezas del sistema Howe, ó Pratt, como en el lado derecho de la fig. 9. Pero con respecto á estas dos, debemos observar **que el uso de largas barras de hierro en las cimbras** de una abertura grande está sujeto á objeciones debido al diferente grado de dilatación entre el hierro y la madera. Por consiguiente, al usar estos sistemas, todos los miembros deben ser de madera. Puede adoptarse el sistema de **celosía**.

Aun cuando la flecha del arco exceda de .25 de la luz, es mejor no permitir que **las cimbras pasen** de este límite, sino adoptar el método demostrado al lado izquierdo de la fig. 9.

*Nota* 1. **Para fijar el número de triángulos de la** armadura Warren, para una cimbra, búsquese la raíz cuadrada de la abertura y agréguese á ella una décima parte de dicha abertura, divídase la suma por 2, y llámese el cociente *n*. Divídase la abertura por *n*. Si este cociente es en parte decimal, tómese el número entero más aproximado, como distancia en pies para marcarlos en la longitud de la cuerda, dividiendo así ésta en un número de partes iguales. Los puntos encontrados de este modo en la cuerda son los lugares donde han de situarse **los pies** de los triángulos *. Luego desde el centro de la distancia comprendida entre cada dos puntos trácense líneas verticales hacia el arco; donde éstas cortan el arco, es en donde deben terminar los vértices superiores de los triángulos.

En los arcos grandes **no debe desperdiciarse la madera** del arco de la cimbra, recortando sus aristas superiores conforme á la curva, sino que debe dejarse recta y colocarse con clavos en su parte superior piezas diferentes, *c*, fig. 10.

**El tamaño de la cuerda** debe ser el mismo que el del arco, y como él, uniforme de una punta á otra, teniendo sin embargo cuidado de no debilitarla demasiado para alojar los extremos del arco de la cercha en sus extremidades; y evitar por medio de las ensambladuras necesarias que sea alargada ó rota por el empuje del arco. Pero cuando la cuerda puede colocarse en los arranques, ó un poco debajo de ellos, puede evitarse todo peligro de esta especie acuñando bien sus extremidades contra los paramentos de los estribos.

**Con respecto al tamaño de las piezas,** cuando una armadura de arco y cuerda **está cargada completamente** en la parte superior del arco (como es aproximadamente el caso con la cimbra y las dovelas), los esfuerzos que obran

---

* *N. del T.* — Empleando el sistema métrico y con suficiente aproximación: Multiplíquese la raíz cuadrada de la luz en metros por 1.81, agréguese la tercera parte de la luz, en metros, divídase la suma por 2; llámese el cociente *n*. Divídase la luz en metros por este cociente *n* y síganse todas las indicaciones (usando medidas métricas que el autor hace después para encontrar puntos de división de la cuerda.)

sobre sus miembros son enteramente insignificantes, y provienen principalmente del peso de la cimbra misma; **pero, durante el tiempo y á proporción que se carga**, los esfuerzos no son solamente mayores, sino que cambian constantemente de intensidad y de dirección, obrando como presiones en un período y como tensiones en otro.

Por consiguiente, sería muy fastidioso calcular los tamaños de las piezas. Afortunadamente la necesidad de hacerlo se ha evitado en muchos casos por el hecho de que una cimbra es solamente una construcción provisional, y que la madera de que se compone no se inutiliza y se puede emplear una cantidad mayor de la que se requiere estrictamente. Además, se facilita la obra de mano no teniendo que emplear maderas de muchos tamaños diferentes.

Por esto el autor se atreve á indicar como regla empírica, que se dé *á cada miembro la mitad del área de la parte curva*, teniendo cuidado de construir aquéllos de tal modo, que cada uno sirva tanto de puntal como de cuerda.

*Nota* 2. **Con respecto á los detalles de las juntas**, nos referimos á las figuras de las págs. 794-95; indicando aquí simplemente el uso de zapatas de hierro, largas y anchas, en el caso en que las maderas estén sometidas á gran presión lateral.

*Nota* 3. Para impedir que el empuje del arco, cuando su flecha es pequeña, raje las extremidades de la cuerda, los dos pueden unirse con muchos más tornillos de los que se emplean en las armaduras de techos, etc., donde generalmente no se pone sino uno cerca de cada extremidad de la cuerda. Los tornillos deben estar provistos de arandelas grandes y fuertes. Otro medio de lograr el mismo objeto en aberturas pequeñas, consiste en forrar completamente los dos lados del arco y de la cuerda por piezas cortas de tablones ó tablas, clavadas sobre ambos, á algunos decímetros de distancia de sus extremidades, con la misma inclinación más ó menos que la pieza más corta.

*Nota* 4. Constrúyase el arco por ambos lados al mismo tiempo, para forzar las cimbras lo menos posible.

*Nota* 5. Cuando un puente se compone de más de un arco, y hay que construir uno de ellos, entonces debe haber por lo menos dos cimbras; porque una cimbra no debe quitarse en tanto que los arcos contiguos á ambos lados no estén concluídos, por el peligro de que vuelquen la pila exterior que no está apoyada. Por consiguiente, si no hay más que dos arcos, deben construirse al mismo tiempo, y requieren dos cimbras.

*Nota* 6. **Colóquense siempre apoyos**, verticales ó inclinados, provistos con cuñas debajo de las armaduras y entre los apoyos extremos cuando sea posible; aun cuando no puedan sino colocarse á poca distancia de los estribos, como en el lado izquierdo de la fig. 9.

*Nota* 7. **El peso de las cimbras grandes** y de su revestimiento es mayor en los arcos rebajados que en los elevados de la misma luz.

*Nota* 8. **Espesor del revestimiento.** La siguiente tabla da espesores que no se doblan más de 3 mm (y generalmente no tanto) bajo el peso de cualquier dovela adecuada á sus respectivas luces.

## TABLA DE LISTONES. (Original.)

(*N. del T.* — Convertida en medidas metricas).

| Dist de las cerchas. | LUZ DE LA CIMBRA EN METROS | | | | | |
|---|---|---|---|---|---|---|
| | 3 | 6 | 15 | 30 | 45 | 60 |
| | Espesor de los listones para no flexarse más de 3 mm. | | | | | |
| metros. | m. | m. | m. | m. | m. | m. |
| 1.83 | .082 | .092 | .107 | .120 | .127 | .133 |
| 1.52 | .063 | .068 | .086 | .092 | .098 | .101 |
| 1.22 | .043 | .053 | .063 | .069 | .072 | .076 |
| .91 | .030 | .035 | .044 | .047 | .050 | .050 |
| .61 | .019 | .022 | .025 | .028 | .028 | .031 |

**Con espesores** iguales á las tres cuartas partes de éstos, la flexión puede llegar á 3 mm, lo que puede admitirse para separaciones de cerchas de 1 ó más metros entre sí.

*Nota* 9. **Las cimbras se arman** (lo mismo que los puentes de hierro) sobre una plataforma firme provisional, sobre la cual se ha trazado primero el diseño de un arco de tamaño natural. Cuando está lista cada cercha se lleva á su lugar y se coloca sobre las pilas ó estribos.

**Art. 9. El puente de Wissahickon**, del ferrocarril de Reading, en Filadelfia, consta de 5 arcos de 19.82 m de abertura, 7 m de flecha y 8.54 m de ancho. El espesor del arco es de .90 m (los lechos y juntas de mortero de cemento) y con cuatro pilas de piedra tallada de 2.90 m de espesor en la parte superior, y de 10.67 á 15.25 m de altura. El puente contiene 11704 metros cúbicos de mampostería*. **Cada cimbra** se compone de 7 armaduras ó cerchas de madera de abeto del Canadá; es del modelo de « arco y cuerda », el alma de celosía, y, lo más posible, de la misma abertura y flecha que los arcos. Se colocaron á una distancia de 1.35 m de centro á centro, y estaban sostenidos cerca de cada extremidad *f*, fig. 13 (una sec-

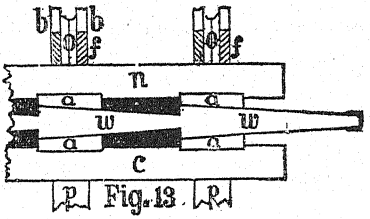

Fig. 13.

ción transversal en escala), por un poste *p* de abeto de 30 cm en cuadro. El arco de la cimbra consistía en dos tablones *bb* de abeto á una distancia de 15 cm entre sí, en trozos de 1.80 m de longitud con sus aristas superiores recortadas para adaptarlas á la curva del puente. Cada tablón era de 10 cm de espesor por 24 cm de ancho en su centro, y 30 cm en sus extremidades. Estas piezas no tenían las juntas alternadas, pero en cada junta había 4 pernos de $^3/_4$ de pulgada con tuercas y arandelas, que las unían á cuñas de madera.

El arco de la cimbra *bb* descansaba en la parte superior de las extremidades de las cuerdas *f*, y el ángulo formado por su intersección (representado aquí sólo en una vista lateral) se rellenaba (en un espacio de .75 m horiz y 1.65 vertical) con piezas de madera macizas y verticales, para formarle una base más firme en que apoyar en *n* la armadura, la cual se prolonga (en una vista lateral) 45 cm más allá.

**Las cuerdas** *f* se componían de dos tablones de abeto de 10×30 cm, colocados á una distancia de 15 cm entre sí, y la mayor parte de ellas constaban de dos ó tres piezas con juntas alternadas y fijas por medio de pernos de $^3/_4$ de pulgada de diámetro, provistos de tuercas y arandelas, y tacos de madera.

**Las almas** de cada armadura estaban formadas por un enrejado de 26 listones *o*, de madera de abeto de 7½×30 cm. que se cruzaban, más ó menos, en ángulo recto, á distancia de 1.05 m de centro á centro, más ó menos, y pasaban por entre los dos tablones, *bb*, del arco, *ff*, de las cuerdas. Algunos de estos listones que formaban la celosía se componían de dos piezas, pero sus juntas no estaban en los cruzamientos. Los listones estaban fijos en cada cruzamiento por 2 clavijas de madera dura de 23 cm de largo y de 5 de diámetro; y una de estas clavijas, de 46 cm de largo, pasaba por la intersección de cada extremidad del listón con el arco ó la cuerda. El primer listón se apoyaba como á 1.20 m del extremo de la cuerda. No sobresalían de la parte superior del arco de la cimbra. Todos los espacios comprendidos entre los dos tablones del arco de la cimbra y de las cuerdas, no ocupados por las extremidades de los listones, se rellenaron completamente con tacos, bien clavados.

**Cada armadura contenía** 10 metros cúb de madera, más ó menos, y pesaba como 5 toneladas. Eran muy flexibles, lateralmente, aun colocados en su lugar, y

* Este puente, concluído sin accidente en 1882, reflejó mucho crédito sobre el difunto Sr. William Loveng, I. C.; sobre Mr. Charles W. Buchholtz, ayudante encargado, y sobre los hábiles y enérgicos contratistas Srs. William y James Nolan, de « Reading, Pens ». Estos últimos ayudaron muy cordialmente al autor á hacer observaciones durante el progreso total de la obra.

estaban afianzadas por medio de 4 tablones horizontales transversales clavados sobre las cuerdas, y por 5 tablones más, clavados más arriba, en los listones.

Hasta la colocación de las claves, todas las juntas de las armaduras continuaron cerradas bajo la presión del arco del puente y del relleno no concluído hasta la altura de 4.20 m más ó menos sobre las líneas de los arranques; pero después de colocar las claves, todas las juntas de las cuerdas solamente, se abrieron de 6 á 18 mm; al mismo tiempo los listones de la armadura bajo los *riñones* del arco del puente se separaron ligeramente del intradós de la mampostería.

Cada cimbra bajó por todo 2½ cm hacia el medio, bajo la presión del arco de puente y de los 4.20 m de relleno.

La porción del puente sobre las pilas fué terminada como hasta las dos terceras partes antes de que las cimbras fuesen quitadas.

Debajo de cada extremidad de la cimbra **había una cuña de roble**, *ww* (de 9.90 m de largo, por .30 × .30 m). Se recortó de manera que formaran 7 cuñas más pequeñas, *ww*, cada una de 1.35 m de largo y disminuyendo hasta 17 cm; se colocó una debajo de la extremidad de cada armadura *f*. Se movían entre tarugos cónicos ó disminuídos *aa*, de roble de .61 de largo y .30 de ancho, embutidos unos 2½ cm en el dintel *c*, ó en la pieza *n*, sobre la cual descansaban las armaduras, *f*, *f*. Las superficies de resbalamiento se lubricaron bien con sebo al ponerlas en su lugar.

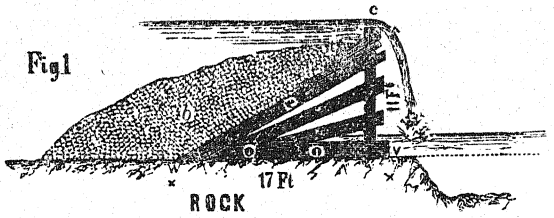
**Las cuñas se quitaron** fácilmente, en una extremidad de la cimbra á un tiempo, por medio de un mazo hecho de un trozo de roble, de 5.40 m de largo y de casi .30 m de diámetro, suspendido por cuerdas, y mecido y guiado por 4 hombres. Generalmente las cuñas cedían y se movían algunos centímetros al segundo golpe. Aunque cada una se aflojaba **enteramente** á los 2 ó 3 minutos, bajando así las cimbras muy repentinamente, sin embargo por la buena calidad de la mampostería no pudo notarse ni la más mínima rajadura en una junta de mortero ni en parte alguna de la obra. Después de tres días, el descenso medio de las claves fué sólo de 9 mm; el mínimo, de 6 mm, y el máximo, de 15 mm. Las cabezas y pies de los postes *p*, comprimieron los dinteles de abeto *c*, y los durmientes, como 9 mm cada uno, demostrando que para arcos de puentes de este tamaño los dinteles y durmientes deben ser de una madera más dura, como pino amarillo ó roble, aunque probablemente contribuyeron á la compresión las escopladuras grandes, de 7½ × 30 cm y de 15 cm de profundidad.

# REPRESAS DE MADERA

**Son requisitos importantes y elementales**, en la construcción de represas, unos cimientos suficientemente firmes para impedir que bajen y produzcan filtraciones, evitar también éstas en la cara atrás de la represa, ó bajo sus bases, é impedir la destrucción del fondo del río enfrente de la represa por la acción del agua que cae. Para lo primero, un lecho de roca dura nivelada es por supuesto lo mejor, y debe escogerse cuando sea posible. En este caso basta para evitar las filtraciones unos tablones gruesos, *tt*, fig. 6 (sencillos ó dobles, según el caso), bien unidos, y que lleguen desde el copete *c*, hasta la orilla inferior de la parte posterior *w*, donde deben estar clavados ó enterrados en la roca; y, además, un buen respaldo *b* de granzón. Granzón, ó más bien tierra con mucho granzón, es mejor que tierra sola, porque si el agua labrara por casualidad un hueco, el granzón de arriba lo llenaría otra vez. Para evitar que este montón de granzón sea movido cerca del copete de la represa, por cuerpos flotantes traídos por la corriente en tiempo de crecientes, se hace un empedrado en bruto, como lo indica la fig. 7, de más ó menos 40 á 45 cm de profundidad, en una extensión de 3 á 6 m ó hasta un punto situado de 1 á 2 metros más bajo que el copete de la represa, según las circunstancias.

En la fig. 1 (represa hecha en la navegación del Schuylkill) los maderos superiores *e*, están todos unidos en sus juntas y tocándose unos con otros, para evitar así la necesidad de cubrirlos con otros.

Fig 1

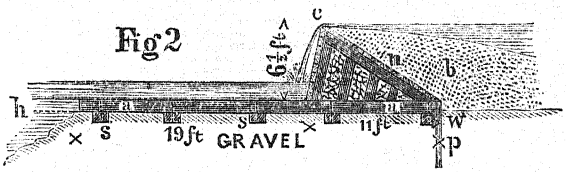


(*Obs. del T.* — Damos en seguida las medidas que trae el clisé *en pies* convertidas *en metros*, para más facilidad del lector; 11 pies = 3.35 m; 17 pies = 5.18 m.)

Pero si el lecho del río es de granzón ó de tierra, entonces deben usarse dos hileras de pilotes de palastro *p*, puestas una al lado de la otra, fig. 2, trabadas en sus juntas, y enterradas á la profundidad de algunos m, para evitar así las filtraciones por debajo de la base de la represa. Frecuentemente no se usa sino una sola hilera. Si el lecho ó fondo está blando ó poroso á la profundidad de pocos metros solamente, sería mejor quitarlo, y colocar la base de la represa más bajo sobre la capa más firme; usando sin embargo las estacas como se ha indicado arriba. Deben quitarse de la base las maderas podridas y otras basuras. En un suelo muy malo hasta una profundidad mayor, puede hacerse necesario sostener la represa enteramente con una plafatorma que descanse sobre estacas. Entonces son necesarias grandes precauciones para evitar las filtraciones; pero este caso ocurre tan rara vez, que no nos detendremos en considerarlo.

Con respecto á la destrucción del fondo producida por la corriente de agua que cae por el frente de la represa, deben tomarse precauciones en todos los casos, á menos que exista una roca muy dura, ó medianamente dura y protegida por una profundidad considerable de agua. La represa, fig. 1, se construyó sobre un lecho bastante firme de gneis micáceo en una capa casi vertical, cubierta, más ó menos, con .61 m de agua. En 39 años la roca se ha gastado enfrente de la represa, como se ve en la figura, hasta una profundidad de .91 m más ó menos, ó casi 2½ cm por año. La altura del agua sobre el copete era generalmente .15 m á .46 m, raras veces de 1.52 m á 1.83 m en las crecientes, y muy pocas veces durante todo el tiempo dicho, de 2.74 m de altura.

Fig 2

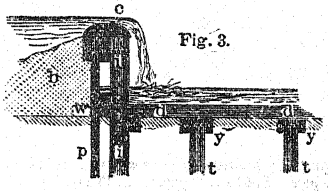


(*Obs. del T.* — Damos *en metros* las medidas que trae el clisé *en pies*, para mayor facilidad del lector; 6½ pies=1.98 m; 19 pies=5.79 m; 11 pies=3.35 m.)

**En la represa de Jones**, en el río Cape Fear, la altura era de 4.88 m y el frente vertical; la caída generalmente de 3.05 m en una profundidad de 1.83 m de agua; la roca blanda de pizarra, en capas verticales, se gastó en pocos años hasta la profundidad de 4.88 m, y la represa se minó por debajo al extremo de caer en la cavidad. En otro caso, en una represa de 10.97 m de altura, con el frente vertical, caía el agua sobre una roca de pizarra dura en capas verticales, cubierta generalmente con .61 m de agua; y en 20 años más ó menos se gastó hasta una profundidad irregular de 3.05 m á 6.10 m, extendiéndose la parte socavada de la cara 23.47 m á 26.52 m enfrente de ella.

En la fig. 2, en un río sometido á grandes y violentas crecientes, el granzón se lavó y desapareció en una profundidad y anchura considerable más allá de la plataforma en *h;* para evitar que se repitiera esto se llenó la cavidad con divisiones rectangulares hechas con maderos gruesos, y los cajones que quedaban en el centro se llenaron de piedras; toda esta construcción atravesaba el río de un lado al otro.

Un depósito de bloques de piedras sueltas, de una tonelada de peso y hasta más, no sirve de protección enfrente de una represa expuesta á grandes crecientes, pues sería arrastrada pronto por las aguas. Generalmente se toma una precaución contra



esta destrucción en las represas bajas; consiste en hacer una plataforma *aa*, fig. 2, ó *dd*, fig. 3, sea de trozas de árboles redondos, ó de madera labrada, colocadas muy juntas, extendiéndose bajo la base entera de la represa, á 5 ó 10 metros enfrente de ella. Estos maderos se aseguran algunas veces por medio de pernos á otras piezas *ss*, fig. 2, ó *yy*, fig. 3, colocadas debajo al través del río. En la fig. 3, estas piezas *yy* se suponen aseguradas por pernos á unas estacas cortas *tt*, enterradas con tal fin. Algunas veces se pone frente á la represa, para recibir la caída del agua, una especie de cajón ancho y bajo (hecho con maderos gruesos), lleno de piedra y cubierto en su parte superior con tablones. Esto es muy eficaz para proteger el fondo del cauce. También en algunos casos se ha construído una represa de menos altura, y de poco precio, á corta distancia aguas abajo de la represa principal, para formar en todo tiempo, enfrente de la última, un pozo hondo que destruya la fuerza del agua.

Otra precaución consiste en sustituir un frente inclinado como *cl*, fig. 4, ó como el que presentarían las figs. 1 y 2, invertidas, en lugar del frente casi vertical de las otras figuras, para disminuir de este modo la fuerza del agua. Este, sin embargo, es solamente un remedio parcial para fondos blandos, porque la lámina de agua que se desliza, siempre cae con una gran fuerza. La mejor forma para una represa en estos casos, es quizás la de la fig. 5, que consiste en una serie de escalones construídos en proporción de 1 de contrahuella para 3 ó 4 de huella. Éstos destruyen perfectamente la fuerza del agua; y agregándoles una plataforma *oo*, se logra un resultado satisfactorio. A esta forma y á las de las figuras 4 y 6 se ha objetado que los frentes están expuestos á ser rotos por árboles, hielo ú otros cuerpos, que des-

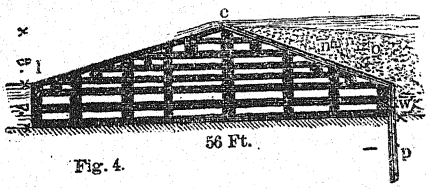


Fig. 4.

(*Obs. del T.* — Damos en seguida *en metros* las medidas que trae el clisé *en pies;* 8 pies=2.44 m; 7 pies=2.13 m; 56 pies=17.07 m.)

ciendan arrastrados por la creciente; pero la experiencia demuestra que esta objeción es de poco valor porque cuando estos cuerpos pasan por la represa, la lámina

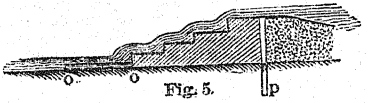

Fig. 5.

de agua es también de más espesor y protege las maderas del frente. En *Sch. Nav.* los maderos *cl*, fig. 6, apenas se gastan á razón de 25 mm cada 10 ó 15 años.

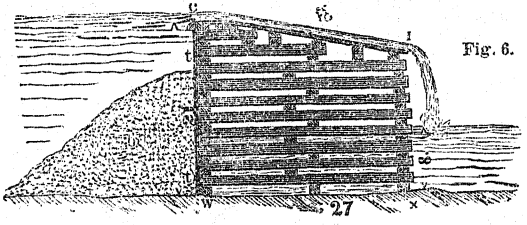

Fig. 6.

(*Obs. del T.*— Damos en seguida *en metros* las medidas que trae el clisé *en pies:* 8 pies=2.44 m; 21 pies=6.40 m; 27 pies=8.23 m.)

Las formas de represas de madera son muchas (véanse las figuras, que muestran las más usadas), variando con las circunstancias del caso y con el criterio del que proyecta. En los Estados Unidos se hacen generalmente de madera en bruto (es decir, de palos redondos) ó de madera labrada; pero en ambos casos de más ó menos de .30 m de grueso. Estos maderos están simplemente puestos uno sobre otro, formando en un plano una serie de rectángulos con lados de 2.13 m á 3.60 m. Están asegurados simplemente por pernos cuadrados (muchas veces arponados) de 60 á 75 cm más ó menos de largo, y colocados como para asegurar dos maderos en cada intersección. Estos pernos no se oxidan ni se gastan mucho, aunque están expuestos á la corriente. Los pernos cuadrados son los mejores. Lábrense chatos los maderos redondos en las partes donde descansan uno sobre otro. La experiencia ha demostrado que es innecesario ligarlos de un modo más firme y por tanto más costoso. Generalmente, pero no siempre, se llenan los cajones hechos con estos maderos con piedras brutas. En represas triangulares dispuestas como en las figs. 1, 2 y 7, estos rellenos de piedras no son tan necesarios como en otras formas, porque el peso del agua y del granzón sobrepuesto tienden á sujetar la represa en su base. Sin embargo puede hacerse necesario, aun en estos casos, cargarlos con unas piedras durante la construcción, si los maderos de la parte baja no están asegurados á la roca, para evitar que el agua se los lleve, antes de estar concluídos y antes que el granzón se haya depositado sobre ellos. Cuando el agua tiene una profundidad de algunos metros es necesario construir cajones con los maderos (ataguías) de pocos metros de alto solamente y llevarlos entonces flotando á un lugar y sumer-

girlos allí, cargándolos con piedras, para lo cual deben proveerse de una plataforma en bruto. Haciéndolo así no es necesario asegurarlos á la roca por medio de pernos. El agua pasa por las aberturas de este cajón ó especie de jaula mientras continúa la construcción de otro encima, teniendo cuidado de agregar siempre piedras suficientes para evitar que una creciente los arrastre. Estas jaulas *cc*, como se indica en proyección horizontal, fig. 8, pueden sumergirse, cargadas de piedras, dejando unos

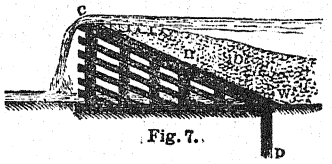

Fig. 7.

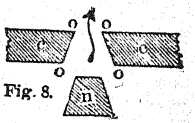

Fig. 8.

huecos *oooo*, entre ellas, para la salida libre del agua. Estas aberturas se cierran después con piezas *n*, que calcen bien.

La mano de obra en aguas profundas se ejecuta mejor construyendo ataguías (*cofferdam*) especiales para el caso, en lugar de sumergir simples jaulas de madera gruesa como hemos dicho. Las juntas pueden hacerse más cerradas, las piedras acomodarse mejor y colocar más juntos los pilotes.

Cuando la superficie del fondo es muy desigual y el agua es profunda, ó la introducción de compuertas en la represa, ó cualquiera otra circunstancia hacen prudente construir una ataguía (*cofferdam*), ambas deben construirse por *secciones* ó *partes*, para dejar de este modo una salida para el agua. Comenzando en una ó ambas orillas la primera sección del agua puede llegar á una cuarta parte del ancho del río ó más. En la sección de la represa construída dentro de esta ataguía, deben dejarse suficientes compuertas para darle salida al agua mientras se construye la última sección del dique. Cuando la represa está construída, se cierran dichas compuertas por medio de travesaños corredizos ó colgantes de madera gruesa *.

Antes de quitar una sección, la extremidad exterior de la represa misma debe concluirse de firme. Es imposible dar detalles para cada contingencia; el ingeniero debe con su propio ingenio hacer frente á las particularidades que se le presenten. En algunos casos, cuando el agua es poco profunda, bastan simples montones de tierra ó de piedras, con tierra y granzón sobrepuesto.

Después que el agua haya pasado por el copete *c*, como en las figuras, no hay necesidad de evitar que se filtre entre los maderos; al contrario, los forros de los tablones gruesos (ó de maderas cuadradas, según el caso) *cl*, figs. 4 y 6, que forman la inclinación por la cual el agua corre en algunas represas, no están generalmente colocados muy cerrados, sino con una separación de 12 milímetros, para permitir que parte del agua pase, con el fin de tener mojadas las maderas por debajo, lo que, en cierta cantidad, las hace más durables. En las figs. 1, 4, 6 y 7 el agua del pozo más bajo penetra libremente entre las maderas y entre las piedras brutas empleadas en llenar en parte ó totalmente los cajones. En las figs. 4 y 6 no se ven estas piedras. En la represa, fig. 1, no se usaron. En la fig. 2, estaban como se indican.

Una represa poco costosa es la de la forma de la fig. 7; puede construirse de piedras brutas con cemento. Deben ponerse horizontalmente algunas piezas de madera cuadrada y asegurarlas firmemente en la mampostería del plano *cnw*, á conveniente distancia entre sí, con su parte superior al nivel de la mampostería. Sobre estas maderas debe clavarse un forro de tablones *cnw*, para proteger la mampostería de la acción del agua y de otros cuerpos flotantes. El granzón *b*, que va detrás, puede omitirse; pero las estacas *p* y una plataforma enfrente de la represa son indispensables en los pisos blandos. Las figs. 1, 2, 4, 6 y 7 son secciones de represas existentes en Pensilvania, trazadas en escala, que han aguantado con éxito la fuerza de crecientes grandes por una larga serie de años**. Estas crecientes traen algunas veces moles grandes de hielo, árboles, casas, puentes, etc., y llegaron á subir

* Maderos preparados de antemano para cerrar una abertura por donde sale el agua y que se dejan caer de repente en su lugar por medio de guías. Varios de estos maderos pueden fijarse en un marco, para después dejarlos caer al mismo tiempo cerrando así la abertura ó compuerta de una sola vez; sobre todo si es pequeña.

** Las de *Schuylkill Navigation*.

hasta 3.35 m sobre los copetes. La de la fig. 1 se construyó en 1819 en la *Sch. Nav.*, y sirvió perfectamente durante 39 años, hasta que en 1858, á consecuencia de estar podridos muchos de los maderos, especialmente los de su parte superior *e*, se construyó una nueva, inmediata y enfrente de la otra. Se construyó muy sencilla y nunca se llenó de piedras. Los maderos inferiores *oo*, á 3.05 m de distancia entre sí, se sujetaron á la roca con pernos, é inmediatamente encima de cada uno de ellos había una serie de maderos inclinados, como se ve en la figura. Los superiores *e*, sin embargo, se colocaron tocándose unos con otros, para formar así el forro superior, en lugar de hacerlo con tablones más delgados. Las piezas cortas en *t* se colocaron del mismo modo. No se usaron ataguías, sino que las piezas del fondo se fijaron en la roca con pernos, y separadas 3.05 m; entonces se colocaron las piezas diagonales y verticales, y por último las piezas inclinadas. El forro *e* que tapaba se extendió desde las extremidades de la represa hasta dejar en el centro un espacio de 18 m más ó menos para la salida del agua. Estando listo el forro para cubrir este espacio que había quedado abierto, un número considerable de hombres principiaron con el trabajo de cubrir el espacio, lo que se ejecutó tan rápidamente, que el río no tuvo tiempo de subir á una altura suficiente para impedir la operación.

La fig. 2 representa una represa de alimentación de canal en el río Juniata; *ss* son maderos atravesados en la corriente (como 90 metros) que sostienen el entarimado *aa*, de fuertes maderos que se tocan. Esta represa se llenó con piedras, y para sostenerlas se agregó el forro de tablones al frente.

La fig. 6 es la del *Sch. Nav.*; fué construída en 1855. Esta estructura ha sido muy alabada para esta forma de represa; está situada sobre pura roca, con una considerable profundidad de agua por delante. La más alta represa (9.60 m) sobre el *Sch. Nav.* es muy semejante á ésta y fué construída en 1851. Todas estas represas son de maderos labrados, en su mayor parte de pino blanco y amarillo. El agua corre, á veces, hasta con 2.40 á 3.60 m de espesor sobre sus copetes, y luego se derrama y cubre muchos de los estribos. La parte vertical posterior permite al agua derramada colarse por entre *todos* los maderos inferiores de la represa contribuyendo á su conservación.

La fig. 4 representa las represas sobre el río Monongahela para la navegación en el repunte de la marea, construídas por el ingeniero W. Milnor. Son de maderos redondos con sus cortezas, aplanados en los cruzamientos. Los más largos que se ven en la figura están colocados á 3 m de separación á lo largo de la represa. La experiencia ha demostrado que estas represas tienen la necesaria resistencia para fuertes corrientes. En roca pura los maderos inferiores se aseguran con pernos.

La fig. 7 se ha empleado con éxito en alturas de 12 m *.

La fig. 3 da solamente una idea para represas bajas en fondos que ceden á la presión. Sus principales apoyos son los postes *ii*, separados de 1.2 á 2.4 m, según la altura de la represa y otras circunstancias, y *tt* son postes pequeños para sostener el entarimado *dd*. Se puede aumentar á mayores alturas con vigas, que se pueden cubrir con fuertes tablones, para formar un declive para el agua desbordante. Al ingeniero se le ocurrirán muchas combinaciones de maderos y declives para represas en terrenos blandos. Por ej., la colocación, á intervalos de algunos metros, de hileras de 3 ó más postes situados transversalmente á la represa, dejando el tope del pilote de cada hilera á la altura que se desee dar al copete, mientras que los de atrás se hincan más y más bajos sucesivamente, de manera que al ser unidos después por maderos transversales y longitudinales, y cubiertos con tablones fuertes y granzón, formarán una represa de forma triangular semejante á la fig. 7. Sería conveniente hincar los pilotes inclinando sus topes corriente arriba.

En la construcción de represas en diversas circunstancias hay mucho campo para lucir el ingenio y el dibujo; por ej. : en el cambio de curso de las aguas por medio de acequias, tubos ó sifones, etc., á diversas alturas, aprovechando á veces represas provisionales, montones de tierra ó tabiques de estacas, etc., ó por ataguías, para mantenerlas separadas de la parte en construcción. Cada localidad presenta sus peculiaridades y el ingeniero debe emplear su criterio para aprovecharlas.

---

* **Costo de las represas de cajón.** Con jornales ordinarios á $1.50 por día; maderos á $20 por 4,000 pies (2.36 m³) de medida ancha, entregado en el lugar; piedra para llenar, $1.3 por metro cúbico; granzón, $0.70 por metro cúbico; hierro para pernos, etc., $0.14 por kg. Estas represas en aguas bajas cuestan, generalmente, de $3.2 á $4.2 por metro cúbico.

**Los estribos de las represas** no deben, por regla general, reducir el ancho natural de la corriente, y si es preciso, debe ser lo menos posible, pues la contracción aumenta la altura y la violencia del desbordamiento en tiempo de crecientes, cuando precisamente se desea gran amplitud para facilitarlo. Los estribos deben estar muy bien unidos á los extremos de las represas, y si el terreno lo permite, deben ser tan altos y penetrar tanto en el terreno, que las aguas de las crecientes no pasen por sobre ellos ó alrededor de sus extremos, amenazando socavarlos y destruirlos. En valles anchos y muy llanos, no se pueden extender sin mucho costo y la única alternativa es cimentarlos tan profunda y firmemente que puedan soportar aquella acción, dándoles suficiente altura para que los desbordamientos sean lo menos frecuente posible. Sus extremos adyacentes á las represas deben redondearse para facilitar el paso del agua por los copetes.

La mejor construcción es la de grandes piedras en cemento, pues aunque los maderos le darían bastante resistencia, éstos, así expuestos, se pudren rápidamente. Si se construyen de tierra solamente pueden ser arrastrados por una fuerte creciente que les pase por encima.

**Toda represa importante debe** *tener compuertas*, á fin de que se pueda extraer toda el agua si fuese necesario, en caso de reparaciones, ó para extraer el fango, ó para buscar artículos de valor perdidos, etc. Las compuertas pueden ser tan sólo fuertes cajas, con fondo, paredes y tapa de maderos cuadrados y colocados en el espesor de la represa sobre el fondo. Para impedir que árboles, etc., penetren y se claven en ellas, sería conveniente emplear fuertes traviesas. En casos ordinarios las compuertas no deben *exceder* de $1 \times 1\frac{1}{2}$ m en sus secciones transversales; de otra manera son difíciles de manejar. Cuando el agua que se va á sacar es mucha, se usan dos ó más de estas salidas. Deben estar situadas cerca de los estribos. Las puertas, ó válvulas, para abrirlas ó cerrarlas deben estar aguas arriba, pues situadas abajo, el fango acumulado, etc., llenaría las compuertas impidiéndoles trabajar. Se hacen generalmente de maderos; corren verticalmente en cajuelas y suben y bajan por medio de un engranaje de cremallera y piñón pero, en las represas de gran importancia se pueden hacer de hierro colado. Es conveniente establecer dos juegos de compuertas de manera que una esté siempre lista para usarse si la otra está en reparación.

La parte del entarimado frente á la compuerta debe ser especialmente firme, de manera que no sufra con la presión del agua cayendo de mucha altura.

En represas de mampostería ordinaria y de concreto, si las márgenes son de roca, se le da frecuentemente la forma de un arco rebajado convexo corriente arriba. Utilizando así las márgenes como estribos para el arco (horizontal), se puede lograr una importante reducción en el volumen del material de la represa; pero, á menos que las márgenes sean de roca, ellas constituyen muy imperfectos estribos para el arco, y están expuestas á ser destruídas por la corriente.

**Una represa construída oblicuamente á la corriente**, tendrá menos espesor de agua sobre su copete que otra normal y, por consiguiente, producirá menor derrame sobre el terreno adyacente. En igualdad de circunstancias, mientras menor sea el desnivel de la corriente, mayor será la altura de la creciente.

Las figs. 9 y 10 son adecuadas para pequeñas represas de aforo, en aguas de poca profundidad y de no más 30 m de anchura. La 9 para fondos de tierra ó granzón, y la 10 para roca.

En el primer caso, se ponen primero, atravesando el fondo del río, durmientes de cicuta $S_1$ y $S_2$ de $20 \times 25$ cm, haciendo en dicho fondo las zanjas necesarias y teniendo cuidado de colocar $S_1$ en línea recta. Los durmientes deben extenderse de 2 á 3 metros fuera del río y estar encajados en los bordes. Se entierran detrás é inmediatos al durmiente superior $S_1$, y con .60 á 1.20 m de profundidad, pilotes de palastro P de sección rectangular machihembrados y con una escuadría de $8 \times 25$ centímetros, y se clavan con clavos grandes en $S_1$. Un tercer durmiente, $S_3$, se pone entonces detrás de pilotes, y los dos durmientes $S_1$ y $S_2$ se unen por medio de pernos de 2 ó 3 cm de diámetro, colocados á cada 50 ó 60 cm de distancia más ó menos. Las partes superiores de la estacada P sobresalen más ó menos 30 cm á los durmientes y para hacerlos más consistentes se ligan con maderos *w* de 10 cm de escuadría, asegurados también con pernos. Este piso, lo mismo que los durmientes, sobresale pocos metros á las extremidades de la represa y están enterrados en los bordes del río y cargados de piedras pesadas. Cualquier hueco que resulte debajo de ellos por desigualdad del fondo, debe nivelarse también con piedras ó granzón.

Un poste M de pino amarillo de 25 cm de escuadría y un metro de largo se coloca por medio de una espiga entre los durmientes $S_1$ y $S_2$ en cada extremidad de la

vertiente y se asegura por un puntal N de pino amarillo de 20 × 25 cm, embutido en M y también en el durmiente $S_2$. Más allá de los postes M, la estacada de pilotes de palastro continúa á la altura de M hasta el borde del río. Las partes superiores

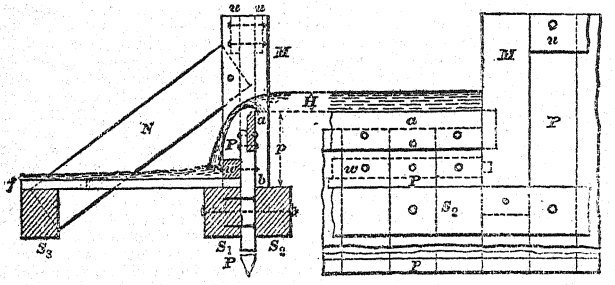

**Fig. 9.**

*N. del T.* — Esta figura está construída en la escala $\frac{1}{40}$

de las estacas se mantienen en una misma línea por unos listones *uu*, de 5 × 20 cent asegurados con pernos.

En la fig. 10, los durmientes $S_1$ de 25 × 25 cm y los durmientes $S_2$ de 15 × 20 cm, descansan sobre un muro de concreto, hecho con cemento Portland con alturas diferentes, para acomodarse á las desigualdades del fondo de roca, y asegurado por pernos de 25 mm de diámetro á 1.20 m de distancia uno del otro. Estos pernos pasan por la mampostería, como está indicado, y penetran á 30 cm ó más de profundidad en la roca de abajo. Entre los dos durmientes se colocan tablones, P, de 8 × 20 cm machihembrados y se aseguran con pernos. En cada extremidad de la represa, se coloca, entre los durmientes de espiga, un poste de pino amarillo de 25 × 25 cm, lo mismo que en la fig. 9, y asegurados en los extremos de la mampostería de la represa, que también debe penetrar en los bordes del río.

En ambas figuras la pieza del copete *a* es de roble de 5 × 20 cm, cortado al sesgo para dejar una cara superior horizontal de 12 mm. La pieza del copete está embutida en todo su grueso en los tablones verticales P, asegurándola con pernos, y también está embutida de 5 á 8 cm en los postes de las extremidades M. En tiempo de poca agua, la corriente puede hacerse pasar por sólo una parte del copete por medio de tablones ó tabiques colocados á lo largo de la represa.

Un copete hecho de una lámina de hierro de 20 cm por ½ cm es preferible á los de madera. Hay menos trabajo para embutirlo, y la cara superior no se destruye tan pronto. El filo superior y las puntas de tope de las diferentes piezas deben estar acepillados, lisos y cuadrados, para tener un borde interior afilado, *a*, por donde pase el agua, y para evitar la filtración.

Como otra precaución contra la filtración, puede embutirse *entre las estacas y el copete, enfrente* de cada junta de la pieza del copete, otra tira de hierro de 20 × ⅓ cm, de 30 cm de largo más ó menos, y cuyas puntas cubran las puntas de la pieza del copete. Si esta lámina de tope en la parte alta del copete se colocara del lado aguas arriba, destruiría la continuidad de la lámina de agua que pasa por la represa, y se opondría algo á la exactitud de los aforos. Estos hierros pueden obtenerse en cualquier centro comercial, en planchas de 5 metros más ó menos.

Todas las juntas deben calafatearse con estopa. Para aplicar la fórmula ordinaria de las represas (véase el art. 14 *f* de Hidráulica) el dorso de éstas debe ser vertical en una profundidad *p* debajo del copete igual lo menos al doble de la carga H sobre la represa. Es mejor proteger la cara, corriente arriba de la represa (excepto la porción cerca del fondo) con alquitrán, en lugar de greda pisada.

En una represa larga de poca caída de agua, es difícil asegurarle un acceso suficientemente libre al aire por detrás de la lámina de agua que cae, especialmente cuando la corriente tiene poca profundidad y la lámina tiende á acercarse mucho

á la represa. En estos casos se forma un vacío* parcial entre la lámina de agua y la cara de la represa, y aumenta la salida, impidiendo la exactitud de los resultados. Por consiguiente es muy importante, al hacer los planos para represas de aforos, disponerlos (hasta donde sea posible) de modo que la lámina de agua pueda caer

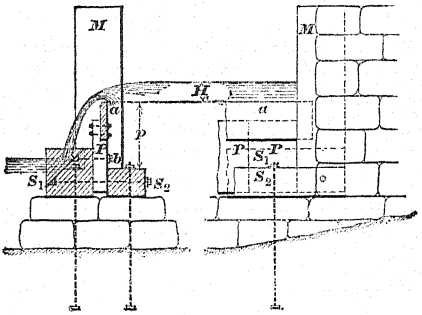

**Fig. 10.**

*N. del T.* — Esta figura está construída en la escala $\frac{1}{40}$

libremente sin adherirse en parte alguna á la represa misma, porque así disminuiría el espacio detrás de la lámina y hace más difícil evitar la formación del vacío.

**Vibraciones en las represas.** Las represas en que el agua cae formando una lámina larga lisa y sin interrupción y de una altura considerable, están más ó menos sometidas á vibraciones ú oscilaciones causadas por la rarefacción y compresión alternativa del aire por la lámina de agua que cae perpendicularmente en el espacio (W, fig. 20, art. 14 (*a*) de Hidráulica) detrás de la lámina, donde muchas veces se forma un vacío parcial, porque el aire se mezcla con el agua que cae y es lanzado aguas abajo en forma de espuma y burbujas.

Estas vibraciones producen algunas veces un ruido en las ventanas de las casas, situadas hasta mil metros ó más de distancia. Hemos sabido que se han suprimido estas vibraciones construyendo una vez (sin intención) un tabique ancho de troncos de madera de altura conveniente y colocado como antepecho frente á la represa para evitar que se le gaste el fondo. En otros casos ha sido suficiente para suprimir las vibraciones una hilera de maderos puestos oblicuamente contra el frente de la represa, y hasta una parte de su altura inclinados más ó menos de 1½ á 1 cubiertos con tablones. En fin, cualquier sistema que permita al aire entrar más libremente detrás de la lámina que cae, ó que destruya la continuidad de ésta, ó interrumpa su altura y su extensión, debe disminuir y hasta evitar este inconveniente.

**La buena época para la construcción de represas** es, naturalmente, el período más largo de las aguas bajas.

---

* Este vacío hace que el agua río abajo cerca de *w* suba por detrás de la lámina, fig. 9. Cuando la rarefacción del aire ha llegado á cierto grado, el aire exterior la rompe, entra y llena el vacío. Entonces se vuelve á formar otro, que á su vez desaparece al penetrar el aire, siguiendo así, alternativamente. Durante estos movimientos se ha notado que los cuerpos livianos, como un pedacito de madera, etc., que flotan en el agua río abajo cerca de las extremidades de la represa, son atraídos hacia el espacio detrás de la lámina y llevados hasta la mitad del ancho de la represa, y de aquí otra vez al punto donde entraron para ser botados hacia afuera, después de vaivenes hacia adelante y hacia atrás en el espacio formado detrás de la lámina de agua.

**Tabla de los espesores de tablones de pino blanco, que no se doblan sino 1/480 de su extensión horizontal libre, bajo diferentes cargas de agua.** (Original.)

# ABASTO DE AGUAS

**Consumo de agua.** Debido en gran parte á la adecuada extensión del uso del agua en las habitaciones, la cantidad requerida en las ciudades aumenta más rápidamente que la población. Dicho de otro modo, el consumo por cabeza aumenta.

**Uso.** Una larga experiencia demuestra que una provisión de 50 galones (189 litros) por cabeza y por día es abundante para todas las necesidades y gustos de familias acomodadas en las ciudades americanas. El consumo de los manufactureros, por supuesto, no lleva relación fija con la población. En las ciudades, es generalmente mucho menor que el consumo doméstico.

**Desperdicio.** En las ciudades americanas, el desperdicio sube á dos ó tres veces la cantidad realmente usada. De los 438 lit por cabeza y por día, suministrados en Nueva York en 1899, estima el Sr. Freeman* que de 117 á 208 lit se usaban : 38 inevitablemente desperdiciados; y de 189 á 283 desperdiciados, pero, pudiendo evitarse.

En Filadelfia, las investigaciones hechas por medio del indicador del desperdicio de agua de Deacon, en 142 habitaciones modernas, de siete piezas, de dos pisos, con baño, etc., en dos calles intermedias, resultó que de 839 lit por cabeza y por día, suministrados por 782 instalaciones, 726 lit, ó el 86.5 por ciento, se desperdiciaban, y sólo 13.5 por ciento eran usados. La ciudad ha construído vastas obras con el fin de bombear, filtrar, conducir, rebombear, acopiar y distribuir el agua desperdiciada, como también la cantidad más pequeña usada. Del costo total **, menos de la mitad habría bastado para el agua usada é inevitablemente desperdiciada.

**Fuentes de desperdicio.** El desperdicio es causado por descuido : por dejar correr el agua para que se bote á fin de impedir que se congele en el invierno y para obtener agua más fresca en verano; por instalaciones defectuosas, por filtraciones fijas no sospechadas en los canales y tubos de servicio, etc.

Como una « conjetura » clasifica el Sr. Freeman los 189 á 283 lit por cabeza y por día, desperdiciados en Nueva York, como sigue :

| | | | |
|---|---|---|---|
| Filtraciones en canales..... | 38 á 57 lits | por cab, | por día. |
| — en tubos de servicio..... | 38 á 57 — | — | — |
| — en tuberías defectuosas..... | 57 á 94 — | — | — |
| Desperdicio por descuido voluntario..... | 53 á 64 — | — | — |

El desperdicio evitable lo hace de ordinario una pequeña fracción (digamos de un quinto á un tercio) de la población, pues el resto usa el agua razonablemente. En el

* Informe sobre el Abasto de Agua de Nueva York, hecho á Bird S. Coler, por John R. Freeman, ingeniero civil, 1900.

** El costo total se aproxima á $30,000,000.

caso de Filadelfia, arriba citado, de las 782 instalaciones se halló que 22 dejaban perder el agua poco á poco y 32 lo hacían continuamente.

**Restricción del desperdicio. Medidores de agua.** El mejor modo de restringir el desperdicio consiste en interesar pecuniariamente al consumidor para que lo evite, y esto como mejor se realiza es usando el medidor de agua, á lo menos en todos los servicios (doméstico, industrial y público), en donde se encuentre desperdicio. Los medidores deben ser propiedad y conservados por la corporación que suministra el agua.

**Derecho mínimo.** A fin de estimular el *uso* liberal del agua, al mismo tiempo atenuando el deseo de *desperdiciarla*, y evitando una economía indebida (que conduce al desaseo), á cada consumidor debe cobrársele periódicamente un derecho mínimo, suficiente para cubrir ampliamente toda el agua de que él probablemente pueda usar y gozar.

El Sr. Freeman estima el costo medio de los medidores domésticos, para Nueva York y Brooklyn, por lo común de 5-8 pulgadas y 3–4 pulgadas, con unos pocos de tamaños más grandes, en $12.50 cada uno, y el costo de instalación, trabajando sistemáticamente y en grande escala, en $2.50, ó sean $15 cada uno. Él supone que la duración media del medidor doméstico ordinario, de un buen tipo, bien cuidado, y con reparaciones oportunas y renovación de las partes gastadas, es de « no mucho menos de 20 años »; y los gastos anuales como sigue :

| | Providencia, R. I. Aprox. | Nueva York. Se suponen. |
|---|---|---|
| Interés sobre el costo del medidor y colocación... | $.50 | $.45 |
| Depreciación y renovación del medidor (supuesta duración de 20 años)..... | .75 | .75 |
| Conservación y reparaciones, prueba y recomposición..... | .46 | .70 |
| Anotación de medidores y cómputo de cuentas, etc. | .42 | .60 |
| Costo anual total, por medidor..... | $2.13 | $2.50 |

**Agua gratis para defenderse del fuego.** En las ciudades, se da algunas veces á los manufactureros un suplemento de agua gratis, por especiales conexiones, para usarla sólo contra el fuego, garantizando no emplearla con otro objeto, y la ciudad pone un medidor en la conexión para conocer cualquier uso ilícito.

**El agua para el uso de una ciudad no debe tomarse del mismo fondo del estanque,** por que se llevaría los sedimentos, que no sólo dañan el agua, sino producen obstrucciones en la corriente. Debe esto tenerse en cuenta al fijar la capacidad necesaria del estanque, considerando el agua que se halla debajo del nivel de la toma como perdida. Cuando las circunstancias justifican el costo, sería bueno encorvar la parte del tubo matriz en el estanque, y proveerlo con válvulas á diferentes alturas, para tomar el agua de la capa de agua más pura en el estanque. En vista de esto, la torre de las válvulas generalmente tiene estas válvulas comunicando con el agua del estanque, y por este medio no se da entrada á la torre sino al agua limpia, y de ésta pasa á los tubos para la ciudad. Este esmerado sistema es, sin embargo, pocas veces practicable. Estas válvulas deben ser manejadas por empleados de guardia.

**Art. 1. Estanques.** En estanques de tierra, de alguna importancia, para almacenar agua á profundidades moderadas, para ciudades, parece que la experiencia no permite **dimensiones** menores de 3 metros de ancho en la parte superior; talud interior 2 en 1, talud exterior 1½ en 1. Se han adoptado en algunos casos de 4.50 á 6 m con taludes interiores de 3 á 1 y exteriores de 2 á 1. Algunas veces ambos taludes se hacen de 1½ en 1. La superficie del agua debe mantenerse por lo menos á 1 metro bajo la parte superior del terraplén, y más si está expuesto á oleajes. En un estanque grande, con una brisa moderada, se llegaron á formar olas hasta de 1 metro. Se usa algunas veces un muro pequeño, ó una palizada cerrada, *w*, fig. 37, que sirve como defensa contra las olas. La parte superior yel talud exterior deben estar protegidos, por lo menos, con césped. Para mantener la parte superior seca debe redondearse un poco, ó tener una inclinación hacia el exterior. Deben suprimirse y limpiarse cuidadosamente las partes blandas fangosas y toda materia vegetal en toda la base de los terraplenes; esta limpieza se hace hasta donde el suelo es impenetrable al agua, con el fin de que no se puedan formar filtraciones *debajo* de los terraplenes. Con este objeto y en malos terrenos se establece una hilera doble de pilotes de palastro ó un muro enterrado de mampostería de concreto hasta una profundidad adecuada y á lo largo del pie del talud

interior. Si hay manantiales de agua debajo de la base, deben taparse y desaguarlos con cuidado hacia otra parte por medio de tubos. El terraplén debe hacerse por capas, un poco cóncavas hacia el centro y que no pasen de 30 centímetros de grueso; y deben excluirse cuidadosamente todos los troncos de árboles, piedras ó cualquier otro material extraño, como granzón *puro*, arena, esquistos micáceos, etc., que puedan producir filtraciones. Estas capas de tierra deben ser pisadas, lo que es tanto más fácil de hacer cuanto más suaves sean los taludes. Debe procurarse que las capas no sean de distintas clases de tierra y unirlas muy bien entre sí. Esto se logra algunas veces haciendo traficar mucho y en todas direcciones sobre cada capa un rebaño de ganado y hasta de ovejas, á más del tráfico de las carretas. No recomendamos los rollos pesados porque tienden á producir grietas entre las capas.

La tierra arenisca es un material excelente, quizás el mejor. Los materiales más escogidos deben colocarse en el talud más cerca del agua: y comprimirlos con especial cuidado en esta parte, para evitar que el agua pueda filtrarse en la parte interior del terraplén y debilitarlo. No está demás cubrir la parte baja del terraplén exterior *b*, fig. 37, para disminuir el peligro de que el agua de lluvia lave el terraplén, y para disminuir también la rapidez de su descenso.

Si al fondo del estanque corresponde un suelo poroso, ó una roca rajada, por donde el agua pueda escaparse, debe cubrirse cuidadosamente con greda pisada en una capa de 40 á 80 centímetros, la cual á su vez se protege con una capa de granzón, ó de concreto, según las circunstancias.

Los estanques construídos según las dimensiones que acabamos de fijar, y con cuidado, *pueden* conservarse en buen estado durante un período de tiempo indefinido, pero deben tomarse las **precauciones** *adicionales* que siguen si resultaren daños serios por algún defecto. El talud interior hasta la parte superior debe cubrirse con una capa de piedras en seco de 40 á 45 cm de grueso y colocadas con sumo cuidado, como protección contra la acción del agua y de los animales, como ratas, etc., que pueden minar el terraplén. Estos animales, según creemos, principian á minar debajo del agua. Si los taludes están más escarpados que de 2 en 1, las capas de piedra en seco están expuestas á resbalar. Será mucho mejor, pero por supuesto más costoso, colocar las piedras en cemento hidráulico, ó mejor todavía, sobre una capa de concreto de algunos centímetros de espesor, especialmente si debajo de la capa de concreto hubiese una capa de greda pisada de 40 á 80 centímetros de grueso, extendida sobre la cara del talud; esto con el principal objeto de proteger el talud interior del contacto del agua. Si estas condiciones se realizan, basta para una completa seguridad que los taludes tengan una inclinación de 1½ á 1. Debe tenerse mucho cuidado en consolidar la parte inferior del talud interior, para evitar que el agua allí se filtre y ablande la tierra minando por la parte baja las capas de piedras superpuestas. Hacia la parte superior debe tenerse cuidado con los efectos de destrucción producidos por el frío, hielo, lluvias y olas. Los taludes interiores muy inclinados no sólo evitan que se disloquen ó desacomoden las piedras, sino que aumentan la estabilidad del terraplén, á causa de que la presión del agua (que siempre obra en ángulo recto contra el talud) se hace más vertical y comprime el terraplén sobre su base con más fuerza que cuando no hay agua sobre él. Algunas veces las patas de ambos taludes, interior y exterior, se protegen con un pequeño muro de sostenimiento hecho de concreto.

Muchos ingenieros, para evitar filtraciones, sea en el terraplén ó debajo de él, construyen un muro de mezclote amasado de arcilla y tierra bien pisados, *p*, fig. 37,

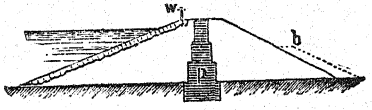

Fig. 37.

impenetrable al agua, que llega desde la parte superior hasta algunos decímetros bajo la superficie de la tierra. Este muro no debe tener menos de 1.50 á 2.50 metros en su parte superior, y debe ensancharse hacia abajo por medio de escalones (y no por taludes) en proporción de 1 de espesor por 3 ó 4 de profundidad. Otros ingenieros se oponen á esta clase de muros pisados, y afirman que la filtración debe evitarse haciendo los taludes interiores y el fondo del estanque impermeables, por medio de greda pisada, concreto, ó cubriéndolos con una capa de piedras colocadas

en cemento, como se ha dicho. Arguyen que si el terraplén está bien construído, por sí mismo constituye un muro pisado en toda su extensión.

**Cerca de San Francisco, Cal, hay dos estanques de terraplenes de tierra,** construídos en 1864, uno tiene 28.95 m de alto, 7.92 m en la parte superior; el talud interior 2.75 por 1; el exterior 2.5 por 1.

El otro tiene 28.°6 m de alto, 7.62 m en su parte superior; el talud interior 3.5 á 1; el exterior 3 á 1. En ambos el muro de tierra pisada llega á 14.32 m bajo su base. No hay revestimiento de piedras.

**Es difícil evitar bajo una fuerte presión que el agua penetre á distancias considerables por los intersticios** que resultan donde la tierra está en contacto con roca lisa, madera ó metal, como, por ejemplo, en los tubos de hierro colocados bajo los terraplenes del estanque; y lo mismo puede ocurrir bajo las bases de los terraplenes que descansan sobre roca lisa. Debe tenerse un cuidado especial en que la tierra usada en estos puntos no sea porosa, que esté muy compacta á lo largo de los filones ó intersticios, procurando que no queden en línea recta, sino que se alternen ó crucen. En el caso de roca ó mampostería, en los intersticios debe hacerse una especie de reborde con piedras y cemento.

Se acostumbra, y es prudente, dividir los estanques en dos partes, de modo que mientras se usa el agua de una división, el agua de la otra decanta todos sus sedimentos y se purifica. También sirve para usar una parte mientras se limpia la otra. Se necesitan algunas veces muchos días y hasta 2 ó 3 semanas, según la profundidad del estanque, para que se asiente completamente el agua cuando contiene partículas muy finas en suspensión. Deben colocarse una ó dos escaleras hasta el fondo del estanque.

**Del fango en los estanques.** Los estanques de la Comp. *New River, London, Ingl.*, se dejaron sin limpiar durante 100 años, y en este tiempo se depositó un fango de 2.40 m de alto, es decir, más ó menos, 2½ centímetros por año. En Filadelfia se depositan más ó menos 6 milímetros por año en las aguas del río Schuyklil y 25 en las del río Delaware. En San Luis, Misuri, más ó menos de .90 m á 1.20 m por año!

En los estanques de poca profundidad se desarrolla mucha vegetación, y en los de mucha profundidad, en las orillas, especialmente durante la estación cálida. Cuando estas plantas se pudren dañan el agua.

**Las aguas que corren por pantanos** no son á veces potables, como sucede, por ejemplo, en algunos parajes del río Concord, en Massachusetts, que han sido declaradas venenosas por el eminente ingeniero hidráulico, Loammi Baldwin, de Boston.

La construcción de un estanque grande y profundo es, no tan sólo muy costosa, sino muy arriesgada, pues á pesar de la mayor vigilancia y cuidado es casi imposible impedir las filtraciones, y éstas suelen no ser visibles durante meses y aun años. En los casos de rotura, sobre todo cerca de una ciudad, puede producir grandes pérdidas de vidas y de propiedades. Si el agua encuentra una vía y se forma una corriente, tendrá gran fuerza de destrucción.

**Art. 1a. Estanques de depósito.** El total rendimiento anual de una corriente puede ser más que suficiente para suministrar el agua á cierta población; pero puede suceder, sin embargo, que no se haga uso de ella con aquel objeto, porque en verano se seque casi por completo y, además, porque las lluvias y las nieves derretidas producen en otras estaciones crecientes que dan mucha más agua de la requerida, y que se desperdicia. Un estanque de depósito sirve para recoger y conservar este exceso de agua, y usarlo durante las sequías del verano, igualando así el abasto de agua en todo el año. Cuando la localidad lo permita, se logra esto construyendo una represa á través de la corriente, para formar un lado del estanque, mientras que las faldas de las colinas que rodean la corriente forman los otros lados. La corriente entra en este estanque por su extremo superior. Cuando la corriente pueda agotarse durante las largas sequías del verano, la experiencia demuestra que la *capacidad* del estanque debe hacerse igual á la provisión de 4 á 6 meses, según las circunstancias. Durante la construcción de la represa se debe hacer un ramal para que pase la corriente sin dañar la obra. Si la represa se construye exactamente como la fig. 37, toda de tierra, sería fácilmente destruída por la corriente en caso de que el estanque llegase á llenarse tanto que el agua pase sobre su borde. Para impedir esto se puede, por medio de una mampostería, ó por cajones llenos de piedras trituradas, ó de otra manera, hacer que toda, ó parte de la represa, sirva como *vertedero*. O por canales (abiertos ó por entubados) á cada extremo de la represa, y sobre el suelo natural, á un nivel que pueda dar salida al exceso de las crecientes antes de que lleguen éstas á pasar por encima

del borde de tierra de la represa. Además de éstos, y de los tubos que lleven el agua á la población, debe existir una salida, con válvula ó compuerta á nivel del fondo del estanque, para que se pueda sacar toda el agua en caso de reparaciones ó de limpieza. Las bocas de los tubos para la ciudad deben estar protegidas por rejas, para impedir la entrada de peces, etc.

**Para facilitar las reparaciones ó la renovación de todas las válvulas, etc., que están bajo el agua**, los extremos de los tubos ó alcantarillas encajados en el estanque pueden estar rodeados por cajas ó cámaras impermeables, que para el servicio se dejan abiertas hacia el estanque y se cierran en caso de reparaciones. Se puede llegar á ellas entrando por el otro extremo, después que haya salido el agua. En el caso de que la salida sea al través de una larga extensión de tubos y que no se pueda entrar en ella, se puede hacer una abertura especial con este objeto en el tubo mismo cerca de la orilla exterior del terraplén y mantenerla cerrada cuando no hay reparaciones. A veces, la mejor manera de llegar á estas válvulas es levantando sobre ellas una *torre de válvulas* hecha de mampostería. Ésta es una cámara hueca, vertical, impermeable, semejante á un pozo, pero situada cerca de la base del talud interior, con sus cimientos en el fondo del estanque, desde donde se levanta la torre á través del agua hasta su superficie. Esta cámara está provista de válvulas ó compuertas generalmente abiertas hacia el estanque, pero que se pueden cerrar en caso de reparaciones. Así construída, los obreros pueden bajar por la torre con escaleras, entrando por la parte superior.

A veces las salidas para el exceso de agua de las crecientes, así como las de limpieza, se colocan sobre el nivel del fondo del estanque. Para que éstas puedan funcionar en caso de creciente repentina nocturna, etc., deben estar provistas de válvulas automáticas, que se abren por sí mismas cuando la creciente sube demasiado. Esto se puede lograr asegurándolas á boyas, las cuales, al subir el nivel del agua, las abren tirando de ellas. Todas estas salidas deben ser suficientemente amplias para dar paso á los obreros. De ninguna manera se deben hacer en el cuerpo de tierra de la misma represa, sin que estén apoyadas en bases de mampostería que lleguen á cimientos sólidos; de otra manera estarían expuestas á romperse al asentarse el terraplén. Es, generalmente, más seguro hacerlas en firme, en el suelo natural, cerca de uno de los extremos de la represa. Sus válvulas, si son sencillas, deben estar situadas hacia la extremidad interior del estanque, de ese modo las salidas se mantienen generalmente libres facilitando su inspección; pero es mejor tener dos válvulas, para usar una mientras se repara la otra, y en este caso se puede colocar una á cada extremo. En los estanques que se llenan por medio de bombas, no se requieren precauciones contra las inundaciones; porque las bombas se pueden parar cuando se hayan llenado lo suficiente. Los estanques grandes de provisión inundan generalmente mayor ó menor cantidad de terrenos que deben comprarse. Estos estanques al interceptar el agua corriente evitan frecuentemente las crecientes de primavera que perjudican los terrenos más bajos. Si hay molinos río abajo de la represa, quedan privados del agua para moverlos, si no se les destina parte de la almacenada en el estanque. El agua que se aplica para **compensar** la pérdida de una corriente natural, se llama **agua de compensación**, y el estanque, **estanque de compensación**.

**Art. 1 b. Estanques de distribución.** Frecuentemente un valle á propósito para un estanque de provisión, no se halla sino á una distancia grande (de muchos kilómetros algunas veces) de la ciudad; entonces, es conveniente construir también otro estanque más pequeño que el de provisión cerca de la ciudad y á una altura tan grande como las circunstancias lo permitan; pero siempre más bajo que el estanque de provisión. Éste se llama, para distinguirlo, estanque de *distribución*, porque el agua, después de haber llegado á él por *tubos surtidores que la traen* del estanque de provisión, sale de aquél para ser distribuída, en diferentes direcciones por la ciudad, en la tubería de las calles. Este estanque pequeño debe contener agua suficiente para algunos días por lo menos, y mejor para algunas semanas. La extremidad de los tubos surtidores debe estar provista de una llave para suspender cuando se quiera la entrada del agua que viene del estanque de provisión. Estas precauciones permiten que se hagan reparaciones á lo largo de los tubos surtidores, sin privar á la ciudad del agua durante este tiempo. En vista de estas reparaciones, como también con el fin de poderlos limpiar, estos tubos deben estar provistos **de llaves de desagüe** en varios puntos bajos de su longitud entre los dos estanques, especialmente en aquellos puntos donde se pueden desaguar en vertientes naturales. Al abrir estas válvulas, la fuerza del agua se lleva el sedimento, y deja el tubo libre para inspeccionarlo.

**Al calcular los diámetros de los tubos** para surtir de agua una ciudad,

es necesario tener en cuenta, que la mayor parte del producto del agua durante las 24 horas, se gasta en realidad durante 8 á 12 horas; y por consiguiente, la capacidad del tubo debe ser tal, que supla la cantidad necesaria para un día en mucho menos de 24 horas. También, durante los meses cálidos de verano, se gasta mucha más agua que en los meses de invierno, y esto hace necesario un diámetro mayor aún.

(*N. del T.* — Esto sucede solamente en países donde las diferencias de las estaciones es muy notable. En climas análogos al nuestro (Venezuela) no pasa esto.)

**Art. 2. Sistemas de tubos de distribución en las ciudades.** El autor no conoce ninguna regla práctica para calcular el diámetro de los tubos en estos sistemas. Las varias complicaciones que envuelve hacen de poco ó ningún valor las investigaciones puramente científicas. Después de mucha vacilación nos atrevemos á dar las siguientes reglas que son puramente empíricas, basadas sobre las observaciones, que han llegado á nuestro conocimiento.

*Regla* 1. *Cuando en ningun punto del sistema de tubos de distribución en las calles, la carga ó la distancia vertical bajo la superficie del estanque, comparada con la distancia horizontal del estanque, es menor de* 9.47 *m por kilóm, entonces la población de una ciudad dada en la última columna de la Tabla A, puede surtirse abundantemente para todos los usos, sea por un solo tubo del diámetro interior de la* 1ª *columna, ó por* 2, 3, *etc., tubos de los diámetros que se indican en las otras columnas.* Estos diámetros se han dado con una aproximación de 3 milímetros más ó menos. El gasto por habitante se supone ser de 60 galones (227 litros) por día *.

(*Obs. del T.* — Suponemos que se trata de galones de los Estados Unidos, de 3.78 litros.)

**TABLA A.** (Original.)

(*N. del T.* — La hemos convertido al sistema métrico.)

| Número de tubos. | | | | | | | | Población. |
|---|---|---|---|---|---|---|---|---|
| 1 | 2 | 3 | 4 | 6 | 8 | 12 | 24 | |

* Para apreciaciones rápidas y aproximadas, nada más útil ni más práctico que estas dos tablas del autor. Continúese leyendo hasta la aplicación de la Tabla B, y lo que falta del art. 2, porque lo que sigue está tan íntimamente ligado á la Tabla A, que la completa. *(N. del T.)*

(*Obs. del T.* — Cuando se quiera calcular la tubería para surtir de agua una población, pero dándole á cada habitante *más ó menos* de los (60 galones) 227 litros que supone la tabla, también es útil ésta, procediendo así:

Multiplíquese el número de habitantes por el número de litros que se quieran dar y divídase por 227; tómese el número que resulte como población para entrar en la Tabla A, y los tubos que ella indica servirán para surtir la población dada con los litros que se deseaban.

Ej.: Se quiere surtir con cuatro tubos una población como la de Caracas (Venezuela), que tiene 100,000 habitantes, con 160 litros por habitante: Tendremos: $100{,}000 \times 160 \div 227 = 71{,}748$. Búsquese en la tabla A, en la columna *Población*, el número más próximo á 71,748, que es 77,565, y, como se ve en la columna 4, con 4 tubos de 412 mm se surtiría la población. Es claro que se supone la carga de 9.47 m por kilómetro.

Más adelante la tabla B, también original del autor, da el modo de hacer el cálculo para otras cargas.)

Será bueno también aumentar además uno ó dos centímetros para cada diámetro (según la clase de agua) por obstrucciones y sedimentos.

El agua después de llegar á la ciudad por uno ó más tubos matrices, debe distribuirse por las calles, por medio de tubos pequeños que se ramifican de los tubos mayores. El diámetro de estos tubos más pequeños también puede hallarse con la Tabla A, así: Si una calle con sus callejones, etc., contiene 6,000 personas, más ó menos (y la proporción de la carga, como antes se dijo, no es menor de 9.47 m por kilóm en cualquier punto) vemos entonces por la tabla que un tubo de 254 mm es suficiente. Aconsejamos no usar tubos de un diámetro menor de 150 mm en cualquier calle de la ciudad.

**Los tubos matrices que se cruzan deben estar conexionados en algunas de sus intersecciones**, para dar al agua una circulación más libre por todo el sistema; si se quita el agua provisionalmente cerrando las llaves para alguna reparación ó se la disminuye por un gasto excesivo, el servicio se mantiene siempre con la corriente de agua de las otras tuberías.

**Evítense los extremos de tuberías cerrados**, porque el agua en ellos se vuelve sucia y malsana.

*Regla* 2. *Con los mismos diámetros, pero con cargas distintas á la de* 9.47 *m por kilóm, supuesta por el autor en la Tabla A, se surtirán poblaciones que estén con las poblaciones del cuadro A, en la proporción que indican los números que se hallan en la columna* 3 *de la Tabla B. O dicho de otro modo: para hallar los diámetros de los tubos que surtan las mismas poblaciones dadas en la última columna de la Tabla A,* **pero con diferentes cargas**; multiplíquese el diámetro dado en la Tabla A, por el número correspondiente en la columna 4 de la Tabla B, enfrente de la nueva carga en la columna 1.

**TABLA B.** (Original.)

| Columna 0. | Columna 1. | Columna 2. | Columna 3. | Columna 4. |
|---|---|---|---|---|
| Carga en metros por kilómetro. | Carga en pies por millas. | Relación de la carga comparada con la de la Tabla A. | Proporción en que están las poblaciones. | Diámetros proporcionales para suplir las poblaciones en la Tabla A. |

| 23.662 | 125 | 2.5 | 1.59 | .83 |
| 28.395 | 150 | 3.0 | 1.73 | .80 |
| 37.860 | 200 | 4.0 | 2.00 | .76 |
| 47.324 | 250 | 5.0 | 2.25 | .73 |
| 56.790 | 300 | 6.0 | 2.46 | .69 |
| 75.720 | 400 | 8.0 | 2.83 | .66 |
| 94.650 | 500 | 10.0 | 3.18 | .63 |

(*Obs. del T.* — Hemos hecho, como siempre, en los ejemplos y en esta tabla, las modificaciones necesarias para que puedan usarse en el sistema métrico.)

**Ejemplo.** Por la tabla A observamos, que con la carga de 9.47 m por kilómetro (en ella supuesta) un tubo de 762 milímetros) suplirá una población de 91,580; pero con tres veces esa carga ó 150 pies por milla (como 28.4 m por kilómetro), véase tabla B; encontramos por la columna 3 (tomando el número enfrente á la presión nueva 28.39) que el mismo tubo surtirá á 1.73 veces tantas personas ó 91,580 × 1.73 = 158,433 personas. Pero si con esta carga mayor deseamos surtir solamente 91,580 personas, entonces hallamos en la columna 4, Tabla B, enfrente á 1.73), que debemos disminuir el diámetro del tubo de 762 mm hasta 762 × 0.80 = 610 mm.

También después que el agua haya llegado á la ciudad por el tubo de 762 mm de la Tabla A, si queremos distribuirla por ocho ramales ó tubos más pequeños, vemos por la sexta columna, Tabla A, que cada uno de ellos debe tener á lo menos 333 mm de diám. De estos ocho tubos, otros más pequeños pueden ramificarse en las diferentes calles transversales, callejones, etc. Al apreciar el gasto necesario para cualquier tubo principal de una calle, debemos agregar evidentemente lo que se requiera para las calles transversales á la calle principal y aquéllas deben ser alimentadas por dicho tubo.

Si ciertas partes limitadas de un sistema de tubos de una ciudad tiene una carga considerablemente menor en relación al resto de los tubos, entonces puede ser conveniente proveerla con tubo especial, separado, y de mayor diámetro, que saldría directamente del estanque mismo ó de uno de los tubos matrices que llevan el agua á las partes bajas de la ciudad.

Debe tenerse presente que aumentando los diámetros se puede obtener un gasto tan abundante como se quiera, compensando así, *en cuanto al volumen*, la carga grande; pero el agua no sube entonces á tanta altura en los tubos secundarios como para abastecer los diferentes pisos de las casas, etc.

Con los diámetros y carga de la tabla A, el agua con un gasto ordinario no subirá á la altura de la superficie del agua en el estanque, y si hay un gasto extraordinario y al mismo tiempo en muchas partes del sistema como en el caso de un incendio

extenso ó durante los meses cálidos del verano, quizá no sube ni á la mitad de aquella altura.

**Art. 3. Las siguientes reglas ó condiciones han dado muy buenos resultados para evitar la formación de concreciones en los tubos de agua** y la consiguiente obstrucción. Antiguamente en Boston, los tubos de hierro fundido de 4 pulgadas (10 centímetros) de diámetro, se tapaban en 7 años, y á los de mayor diámetro se les redujo éste considerablemente en el mismo tiempo.

Pero más tarde, y durante ocho años en que se usó este charol, no se formaron concreciones *.

**Reglas para la aplicación del charol de brea mineral á tubos y fundiciones construídos para el Departamento de Aguas de Filadelfia, bajo las condiciones siguientes:**

*Primero.* Todo tubo debe estar enteramente arreglado y limpio, libre de tierra ó arena, que se adhiera al hierro en las partes mohosas y deben usarse cepillos duros para quitarles el último polvo.

*Segundo.* Ningún tubo debe tener ninguna parte oxidada cuando se aplica el charol. Si el tubo no puede sumergirse inmediatamente después de haberse limpiado, debe dársele una mano de aceite de linaza para preservarlo hasta que esté listo para el charol, y éste no debe aplicarse después que haya principiado la oxidación.

*Tercero.* La brea mineral se hace de alquitrán de hulla, por medio de la destilación, hasta que haya salido toda la nafta, y el material se haya hecho inodoro. La destilación se hace hasta que la brea tenga la consistencia de la cera. Se recomiende mezclarla con 5 ó 6 por ciento de aceite de linaza. La brea que al enfriarse se vuelva dura y quebradiza, no sirve para esto.

*Cuarto.* Después de haber obtenido la brea propia para el efecto, debe calentarse en un envase adecuado, á una temperatura de 149° C, y debe mantenerse á esta temperatura durante el tiempo de la inmersión. El material se pondrá más espeso y deteriorará después que se haya sumergido un número de tubos; entonces se agrega con frecuencia brea fresca; y algunas veces debe extraerse del envase su contenido viejo; y llenarse de nuevo con brea fresca; el sobrante será duro y quebradizo como la brea ordinaria.

*Quinto.* Ningún tubo debe sacarse del envase de brea caliente, hasta que no haya alcanzado 149° C. Entonces puede sacarse lentamente y ponerse sobre varas de madera para que gotee.

Todos los tubos de 50 cm ó más de diámetro, deben quedar á lo menos treinta minutos en el fluído caliente para alcanzar aquella temperatura, y probablemente por más tiempo cuando haga frío.

*Sexto.* La aplicación del charol debe hacerse á satisfacción del ingeniero en jefe del Departamento de Aguas, y el material estar sujeto en todo tiempo á su examen é inspección, para ser rechazado por él si no satisface las condiciones exigidas.

*Séptimo.* No se pagará lo que cuesta la aplicación del charol sino en los tubos que están en buen estado y satisfacen á todas las condiciones antes de aplicarles el charol.

*Octavo.* Ningún tubo debe sumergirse sin que el inspector autorizado haya examinado si está limpio y libre de oxidación, y lo haya sometido á la prueba del martillo. Entonces puede sumergirse y después se pasa á la prensa hidráulica, para hacer la prueba de la presión requerida.

*Noveno.* Si está bien aplicada, la capa de charol después que esté fría debe estar rígida y muy adherida al tubo, y no ser quebradiza ni tener tendencia á desconcharse. Cuando el charol no se haya aplicado bien á un tubo, sea por defecto del material, herramientas ó manipulación, no debe pagarse; si se desconcha, ó parece que puede desconcharse, debe limpiarse en su interior antes de charolarlo nuevamente.

**Art. 4.** Los tubos se colocan siguiendo la configuración de las calles en el sentido vertical. Las partes superiores de los tubos no deben estar nunca á menos de un metro bajo la superficie de la calle; y en tubos de 7 cm el agua se ha helado algunas veces aun á esta profundidad.

---

* El Sr. Braccket, de Boston, nos informa (1892) que allá se forman tubérculos en los tubos no charolados hasta un espesor como de 18 milímetros, lo que hace poco útiles ó inútiles los tubos de 10 centímetros para los casos de incendio; pero que, no obstante, no ha observado ninguna interrupción total durante los veintitrés años que lleva en el Departamento del Ingeniero Municipal. También dice que hasta los tubos charolados después que están enterrados diez ó quince años, se corroen en la superficie interior.

(*Obs. del T.* — En nuestros climas templados basta para tubos de pequeño diámetro que su parte superior esté 60 centímetros bajo la superficie del suelo.)

**En Filadelfia, en 1885, había como 1,262 kilómetros de tubos en las calles**; ó 1,770 metros para cada 1,000 habitantes. La población era de 860,000 y vivían en 150,000 edificios más ó menos. **Berlín**, 1887-8, tenía 1,400,000 habitantes en 20,000 casas (70 personas por casa término medio). Consumo medio por persona=64 lit por día, máximo 90 lit; mínimo 47 lit; todo aproximado; había 25,000 medidores de agua en uso.

**Ninguna acción galvánica** ha sido observada donde los tubos de plomo ó cobre están unidos á los de hierro fundido. Ningún tubo de menos de 15 centímetros debe colocarse en una ciudad; y cuando se empleen que sea solamente para distancia de algunos centenares de metros *. La insuficiencia de ellos se nota principalmente en casos de incendio. Un mínimo de 20 centímetros es mejor. No hay más filtraciones en el invierno que en el verano; excepto cuando se revientan los *tubos de servicio* porque se hiela el agua en ellos.

Pisando bien la tierra alrededor de los tubos, se excluye el aire, y se evita mucho la oxidación.

Los tubos de agua se corroen por las filtraciones de gas.

## PESO DE TUBOS DE HIERRO COLADO

**Como se usan en Filadelfia** y probados con la prensa hidráulica á una presión interior de 21 kilogramos por centímetro cuadrado. En esta tabla está incluída la campana.

Los tubos deben hacerse de un hierro gris, duro y fuerte, fundido de manera que puedan taladrarse y cortarse fácilmente; y todos los que tienen más de 7 cm de diám deben fundirse verticalmente, con la campana hacia abajo. Se permite una diferencia de 5%, en más ó en menos del peso teórico, por las irregularidades imposibles de evitar en la fundición. Los tubos se hacen con 4 ó 5 cm de exceso en longitud sobre 3.66 m, para que colocados midan 3.66 m de la boca *l*, fig. 38, de una campana á la boca de la otra.

| Diámetro. | Espesor. | Peso por tubo. | Diámetro. | Espesor. | Peso por tubo. | Diámetro. | Espesor. | Peso por tubo. |

| mm. | mm. | kilog. | mm. | mm. | kilog. | mm. | mm. | kilog. |
| 76.2 | 7.94 | 71.668 | 406.4 | 16.0 | 599.632 | 914.4 | 23.81 | 1965.815 |
| 101.6 | 9.53 | 95.709 | 508.0 | » | 750.221 | 914.4 | 26.99 | 2205.305 |
| 152.4 | 11.11 | 174.635 | 508.0 | 17.46 | 815.536 | 914.4 | 30.16 | 2433.910 |
| 203.2 | » | 208.656 | 762.0 | 20.62 | 1502.710 | 1219.2 | 28.58 | 3302.969 |
| 254.0 | 12.7 | 302.551 | 762.0 | 22.82 | 1637.423 | 1219.2 | 34.93 | 3931.177 |
| 304.8 | 14.3 | 407.775 | 762.0 | 25.4 | 1798.091 | 1219.2 | 38.10 | 4253.677 |

*Obs. del T.* — En la tabla que agregamos á continuación, los espesores de los tubos son los siguientes: De 40 á 70 mm de diámetro, van aumentando desde 7 hasta 8.5 mm; de 75 y 80, son de 9 mm; de 90 á 162, son de 10 mm; de 200 y 250, son de 12 mm; de 300 á 400, son de 14 mm; de 400 á 500, son de 16 mm; de 600, son de 18 mm; de 700 á 1,000, son de 22 mm; y de 1,100 á 1,500, varían de 25 á 28 mm.

Siendo $e$ el espesor del tubo en metros; D, el diámetro del tubo, y $n$, la presión en atmósferas, á la cual se ensayan los tubos, la fórmula del espesor es:

Tubos colados horizontalmente, $e = 0.010 + 0.0020\ Dn$.
» » verticalmente, $e = 0.008 + 0.0016\ Dn$.

* *N. del T.* — Esto puede hacerse en las grandes ciudades, porque en ciudades de poca población y donde ésta está muy esparcida, hay que recurrir hasta á tubos de 5 centímetros de diámetro. Además, en nuestros climas no hay el temor de que, á causa del pequeño diámetro, el agua se congele.

Los siguientes tamaños de **tubos para agua, de hierro forjado con soldaduras solapadas,** los hace la Compañía Nacional en McKeesport, Pa. Un extremo de cada tubo está provisto de su unión. El peso por metro incluye el peso del plomo en la unión. El peso del plomo, por unión es el que se requiere para echarlo derretido en aquélla al colocar los tubos, ó el plomo que se requiere por un solo lado.

| Diámetro interior en milímetros..... | 50 | 75 | 100 | 125 | 150 | 200 | 250 | 305 | 406 |
|---|---|---|---|---|---|---|---|---|---|
| Peso por metro en kilogramos..... | 2.88 | 5.61 | 7.82 | 10.91 | 13.02 | 19.63 | 25.40 | 37.37 | 70.92 |
| Plomo para cada junta en kilogramos.... | .28 | .68 | .96 | 1.47 | 1.59 | 2.60 | 2.72 | 3.97 | 7.25 |

Los tubos se someten á una prueba de presión de 35 kilogramos por centímetro cuadrado. Están provistos con una capa de estaño ó asfalto, ó, si se desea, primeramente estañados y después cubiertos con una capa de asfalto.

El proceso de estañar consiste en « incorporar, sobre y entre las partículas del hierro, una liga de metal no corrosivo compuesto en su mayor parte de estaño ». La superficie formada así no se cuartea con golpes ni doblando el tubo, sea frío ó caliente.

La junta ó unión, es de hierro fundido, y tiene concavidades internas que reciben y sujetan los bordes exteriores en cada extremo del tubo.

La junta se llena entonces de plomo derretido de la manera ordinaria (véase pág. 712) sea con collares de greda, ó por medio de una laña ó abrazadera especial hecha para el efecto.

Esta laña se parece á la pieza de unión, fig. 39, con la diferencia que aquélla consiste en dos piezas semicirculares unidas por bisagras, y provistas de dos mangos, semejantes á un exprimidor de limones con un agujero en un lado, para echar el plomo derretido. Esta unión forma una superficie interior lisa con el tubo en la junta, disminuyendo así en parte la resistencia á la corriente que presenta el hierro fundido.

En los casos donde se hace necesario los cambios frecuentes, la unión se compone de dos piezas sujetadas en sus pestañas con pernos.

**El hierro forjado para tubos** tiene la gran ventaja sobre el hierro colado de ser más liviano y más flexible. El poco peso facilita su manejo, y resulta más económico *el metro lineal* á pesar de que su costo por *tonelada* es, más ó menos, 25 por ciento mayor. No están expuestos á romperse durante el transporte por torpe manejo y pueden doblarse hasta un ángulo de 25°. No requieren ser fundidos expresamente para formar estos ángulos; hay máquinas para doblarlos, que pueden

manejar dos hombres. Una máquina cambiando los dados, puede usarse para todos los tamaños de tubos. Estos tubos se hacen en piezas de 4.57 m á 5.49 m en lugar de 3.66 m que tienen los de hierro fundido, así es que se emplean **menos juntas por kilómetro.**

La Compañía provee « lañas especiales » de servicio y taladros (aparatos con terraja, etc.) **para conectar los tubos de las casas á los tubos principales de las calles.** Esto puede hacerse, como se hace con el taladro de Payne, estando el tubo principal bajo la presión del agua. Esta laña es una pieza de hierro fundido en forma de silla, la cual se asegura al tubo antes de hacer el taladro, por medio de un perno en forma de U, y queda permanentemente fijo después de taladrarse el tubo. Entre la laña y el tubo se calza un anillo de plomo. Aquélla tiene un agujero cilíndrico provisto de roscas, en las cuales se atornilla el tubo, llaves, etc., suministrados por la Compañía para hacer *la toma*. El aparato de taladrar tiene un barreno que pasa por el orificio cilíndrico de la laña, y taladra el tubo.

La Compañía también suple máquinas para cortar tubos y piezas especiales, como para hacer reducciones y también cruces, etc., todo de acuerdo con las uniones y diámetros de los tubos que se van á conectar.

**Art. 5. Los tubos de hierro forjado se oxidan** mucho más pronto que los de hierro fundido.

**Un tubo de gutapercha**, de 3 mm de espesor y 18 milímetros de diámetro interior, **ha resistido** con seguridad á una presión interna de más de 17.58 kilogramos por centímetro cuadrado, igual á más ó menos 175 mets de carga. Dicho tubo tan sólo se hinchó un poco con la presión de más ó menos 24 kilogramos por centímetro cuadrado. En 1851, un tubo de esta materia, de 64 milímetros de diámetro interior y 12 milímetros de espesor y de 412 mets de largo, fué sumergido en el East River, N. Y., para llevar el agua de Craton á la isla de Blackwell. El tubo lo sostuvieron en el fondo con pesos, y no dió un resultado satisfactorio debido al rozamiento causado por las corrientes de la marea y al daño sufrido con las anclas arrastradas por las embarcaciones que pasaban. Con un forro de lona se evitó la primera causa de daño, pero no la última. Este tubo fué reemplazado por otro de hierro forjado en 1870.

**Tubos de hierro y cemento patentados** por la Compañía de Tubos de Agua y Gas de Jersey City, N. J. Estos tubos están formados de hierro en planchas remachadas y cada tubo se sumerge en una capa de una mezcla caliente de alquitrán mineral y asfalto. Después se revisten con una capa de cemento hidráulico. Esta capa alcanza un espesor de 15 mm en un tubo de 300 mm de diám y hasta 25 mm en los de 500 mm de diám. Se hacen estos tubos hasta de .91 m de diámetro. Se colocan en un lecho de mezcla de cemento y se cubren enteramente con éste. Se los provee de todo lo necesario para hacer las conexiones que después puedan necesitarse, y para las ramificaciones de tubos en la ciudad. Más de 2,000 kilómetros están en uso en varias ciudades, y algunos tienen ya 35 años; parece que han dado muy buen resultado. No se forman obstrucciones en estos tubos como en los de hierro. Hay muchas razones para suponer que son duraderos. Haciéndose las zanjas, la Compañía de Jersey City suple los tubos y los coloca (incluyendo el cemento).

A. Wychoff y Son, Elmira, N. Y., hace **tubos de madera para agua.** Para una presión de 1 kg por cm cuad, ellos suplen tubos simples de 9 á 18 cm en cuadro, en el exterior, y de 2½ á 10 cm de diámetro interior; y tubos redondos, de 2½ á 40 cm de diámetro interior, provistos de una capa exterior de cemento asfaltado. En sus extremidades, tanto los tubos cuadrados como los redondos están forrados con láminas de hierro. Para presiones de 2 á 11 kg por cm cuad, á los tubos redondos de madera, antes de darles la capa de cemento, se los envuelve con unos aros de hierro en espiral, aplicados por medio del vapor, pasando antes por una preparación de alquitrán mineral. Los aros están tan apretados, que penetran entre la madera hasta formar una sola superficie. Las extremidades están envueltas doblemente, y entonces se aplica la capa de cemento asfaltado. Estos tubos se han usado extensamente y con buen éxito tanto para agua como para gas. Se proveen con lo necesario para empatarlos y conectarlos.

**Los tubos para agua, de trozos de roble y de pino taladrados,** colocados en Filadelfia hace 50 á 60 años, están casi todos enteramente sanos, y todavía servibles, excepto en los casos en que se pudre la madera blanca del exterior. Quitando esta parte, muchos de ellos se han colocado otra vez. Comprimiendo *bien un poco de greda* alrededor de los tubos de madera, se evita el contacto del aire

y aumenta mucho su durabilidad. Es, al contrario, muy desfavorable un medio suelto y poroso como la arena ó tierra.

**Los tubos de papel betuminado** hechos bajo una gran presión, se han usado tanto para agua como para gas. No están tan expuestos á quebrarse como los de hierro fundido, y su peso no es sino la mitad más ó menos. Con un diámetro interior de 125 milímetros y 12 milímetros de espesor han resistido á una presión de 15 kilogramos por centímetro cuadrado; igual á una carga de agua de 150 metros más ó menos.

**Costo de la tubería de agua y de su colocación.** Las siguientes cifras se deducen de un cuadro bondadosamente suministrado por el Sr. Allen J. Fuller, superintendente general (Oficina de las Aguas, Filadelfia). Ellas representan condiciones medias para tubería recta, colocada en el suelo, en esa ciudad. El costo, en cualquier caso dado, puede diferir considerablemente de esas cifras, según las circunstancias. « La colocación » incluye todo movimiento de materiales, después de su entrega en el terreno, para colocarlos en la zanja, hacer conexiones, calafateo, etc. Los calafateadores principales reciben $2.50, los otros $2, y los peones $1.75 por día de 8 horas. (*N. del T.* — Hemos dejado estos cálculos y costos, porque dados estos valores de jornal y materias primas, es muy fácil deducir los que corresponderán á otros países conociendo los jornales y precios para estos últimos.)

El costo del material se calcula como sigue: Fundiciones de tubos, 1.2 centavos; plomo, 5 centavos; empaquetadura, 3½ centavos; combustible, .27 centavos por libra; acuñar, nivelar, 5½ centavos por metro. Agréguese para llaves de retención, bocas de ramales, de incendios, fundiciones especiales, reempedrado, perjuicios, sueldos de caporales, costo de herramientas, etc. Para presupuestos brutos, que cubran instalaciones, excavaciones en roca, y algunas adicionales requeridas por la zanja, deterioro de herramientas y reempedrado ordinario, pero sin incluir perjuicios, nuevo pavimento de asfalto ó caballetes, el costo en el cuadro puede aumentarse como sigue:

| | | | | | | |
|---|---|---|---|---|---|---|
| Diámetro del tubo... | 100 | 150 | 200 | 250 | 300 | 400 á 1,200 mm. |
| Agréguese..... | 80 | 70 | 65 | 60 | 50 | 40 por ciento. |

*N. del Trad.* — Esta tabla y las dos anteriores han sido reconstruídas con las unidades métricas conservando los precios en pesos fuertes americanos (dólares).

**Art. 6. Empalmes de tubos de hierro fundido.** Modelo de Filadelfia. La distancia *d*, entre el tubo y la campana es casi uniforme para todos los tamaños de tubos, variando solamente de 3 mm para tubos de 100 mm, á 10 mm para tubos de 750 mm. La profundidad de la campana *mn* varía de 75 mm en un tubo de 100 mm, á 100 mm en un tubo de 750 mm. Las pequeñas pestañas circulares *s*, *m*, *s'*, *m'* en el macho del tubo, que entra en la campana del otro tienen como 6 mm

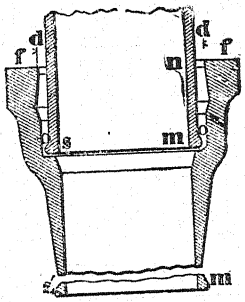

**Fig. 3b.**

Esta fig. está trazada en una escala de $\frac{1}{16}$.

de alto más ó menos, para evitar que el material con que se calafatea la junta, pueda penetrar al tubo. Se calafatea primero con estopa sin alquitrán bien apretada hasta 3 ó 5 centímetros y sobre ésta se echa el plomo derretido, encerrado para evitar que chorree, con una faja ó anillo de greda puesto alrededor de la campana. Después el plomo se compacta por medio de un martillo de calafatear.

El plomo derretido se echa por un orificio que se deja en la greda en el lado superior del tubo. En tubos gruesos se dejan dos orificios adicionales, uno en cada lado del tubo, y se echa el plomo primeramente por estos dos orificios empleando dos hombres, uno en cada lado y simultáneamente. Después se tapan estos orificios con greda; cuando el plomo ya vaciado se ha endurecido, los dos hombres echan el plomo por el orificio de la parte superior hasta llenar la junta. Es necesario proceder así, porque el peso grande del plomo derretido botaría el anillo de greda.

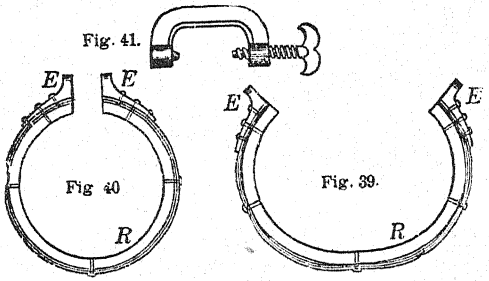
El agua que contiene la greda suele congelarse con el frío, y ponerla tan dura que no puede usarse. También esta agua que contiene la greda está expuesta, en todo tiempo, á convertirse en vapor por el calor del plomo, y á veces este vapor sale é « infla » la greda, saliéndose el plomo.

**Art. 7. Los « cinturones » * patentados**, de Watkins, para soldar tubos, evitan estas dificultades y hacen innecesario el anillo de greda. Consisten en un anillo R, figs. 39 y 40, de sección transversal cuadrada, y hecho de capas alternativas de lona y caucho. El anillo está forrado por una ó más tiras de acero delgado elástico que están remachadas al anillo de distancia á distancia, como se ve. EE son unos codos de hierro remachados á las tiras de acero. Se coloca el « cinturón » alrededor del tubo, cerca de la campana, en la posición de la fig. 40, y sujetada flojamente por el tornillo de presión, fig. 41, cuyas dos puntas entran cada una en una concavidad pequeña de los codos EE. Entonces se hace entrar el « cinturón » por medio de un martillo hasta que llegue á la punta *f*, de la campana, fig. 38, y se aprieta algo el tornillo para hacer que toque el « cinturón » al tubo; se coloca ahora un poco de greda enfrente de la abertura de los dos codos EE, y la junta está lista para vaciar el plomo en ella. Después de endurecido el plomo, se quita el « cinturón », y se puede usar entonces en otra soldadura. Uno de ellos sirve sin romperse para soldar hasta algunos centenares de juntas. Usando estos « cinturones » no se necesita, por su

---

*N del T.* — No sabemos que en español tenga este aparato nombre especial; adoptamos el de « *cinturones* ».

puesto, el trabajo de los hombres que preparan los anillos de greda. Al quitar el



« cinturón », se encuentra el plomo liso, no siendo necesario cortarlo para emparejarlo, como muchas veces es preciso hacer cuando se trabaja con greda.

**Art. 8. Como otro preventivo para que ninguna parte de la soldadura penetre en los tubos**, se coloca un anillo de plomo en la junta antes de estopear el tubo. Este anillo de plomo es de un diámetro tal, que se le puede empujar exactamente por el espacio *d*, fig. 38, entre la boca y la campana, y de un tamaño suficiente para rodear exactamente el tubo de agua. Se le empuja lo más posible en el espacio angosto anular *oo*, fig. 38. Después se estopea y se vacía el plomo como de ostumbre.

**Art. 9. En la junta flexible de John F. Ward**, fig. 42, para tubos de hierro fundido que se colocan al través de los lechos irregulares de los ríos, etc., una parte, *ao*, de la campana B está torneada con exactitud para formar la zona media de una esfera cuyo centro es C; y el borde ó filo *mm* del lado exterior de la boca S se construye para formar una zona angosta, esférica, que corresponda con exactitud á la anterior. El plomo se echa cuando á cada dos tubos adyacentes se los hace descansar sobre una embarcación ó balsa para que estén en línea recta ó casi recta. El plomo ocupa el espacio *mn* pintado en negro y queda fijo en su lugar en la boca del tubo S dentro del espacio anular *dd*. Tan pronto como se llenan las juntas,

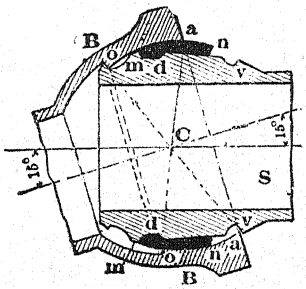


*Fig. 42*

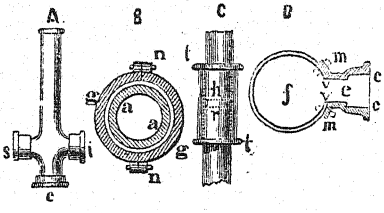
las balsas se mueven hacia adelante, y los tubos que son de pequeñas dimensiones se sumergen sin más cuidado en el agua á poca profundidad. Un aparato apropiado se usa para sumergir los tubos grandes en aguas profundas sin que las juntas hagan gran esfuerzo. La junta permite una desviación de 15°; pero una desviación mayor expone á rajarse la campana y se la evita por los bordes *oo* de la campana y *vv* del macho. En algunos casos sería conveniente usar una draga para disminuir las irregularidades bruscas del suelo emparejando el fondo del río previamente. Más de

treinta tuberías provistas de estas juntas ó uniones, se han colocado con muy buen éxito, y con diámetros hasta de cerca de 1 metro.

**Art. 10.** En las figs. 43, A es un tubo en cruz; es decir, un tubo que tiene además de la campana *c*, en una punta, dos más *s*, *i*, en las cuales pueden conexionarse tuberías que conducen á direcciones opuestas, como sucede en las calles que se cruzan. Si se omite sea *s* ó *i*, el tubo se llama de **single brench** (adoptamos **ramal simple**). El tubo es más fuerte cuando las dos campanas *s*, *i*, se hallan cerca de sus extremos, que cuando están en el centro. En una tubería larga y para trabajar más ligero, se ponen frecuentemente á diferentes obreros á soldar tubos en diferentes partes de la línea, y cuando dos extremos de las tuberías que se vienen soldando se acercan á una distancia tan pequeña que no cabe un tubo completo para empatarlos, se unen como en *r* y *h*, fig. C, es decir, se usa un **sleeve** (adoptamos **tambor**) *tt* de hierro, el cual se pone primero sobre una parte del tubo, y (después de haber colocado el otro tubo) se corre hacia atrás hasta la posición que ocupa en la figura, dejando en su centro tapada la unión de los dos tubos. Los tambores se hacen generalmente de 30 cm de largo, del mismo espesor que el tubo; y su diámetro interior es suficiente para permitir la soldadura usual de estopa y plomo. La soldadura debe hacerse, por supuesto, en ambos extremos del tambor.



Figs. 43.

**Art. 11. Cuando ocurra una hendedura** en un tubo *aa*, fig. B, que ya está en uso, entonces se la compone por medio de *una brida* de hierro fundido *gg*, dividida en dos partes y asegurada con pernos en *mm*. Ésta se usa como el tambor que precede. El anillo blanco en la figura es la soldadura de plomo. Si la rajadura es demasiado grande ó en un estado que no puede remediarse con *una brida*, se rompe el tubo en pedazos y se derriten las juntas de plomo en las puntas, para que se puedan sacar. Entonces, como no se puede colocar un tubo nuevo entero, porque no cabe, se sustituyen con dos piezas cortas, una con un extremo macho y la otra con un extremo hembra. Una punta de cada pieza entra en los tubos ya colocados, mientras que las otras dos, que probablemente quedan apartadas algunos centímetros, se cubren con el tambor *tt*, fig. C.

Algunas veces se pueden componer provisionalmente las hendeduras envolviéndolas con lona enteramente saturada con pintura de albayalde; y bien apretadas al

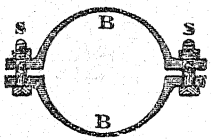


Fig. 44.

tubo por medio de flejes de hierro, delgados ó con alambre. O con una brida más angosta de hierro delgado, hecha de dos partes, BB, fig. 44, y unidas por pernos de tornillos, SS. Estos anillos son útiles también para reforzar tubos que se consideran en peligro de rajarse.

**Art. 12. Para conectar un tubo, e, fig. 43, á otro, f, que está ya en uso**, pero que no está dispuesto con tal objeto, se puede taladrar el tubo *f*, y fijar una pieza *e*, por medio de tornillos, en dos ó más taladros hechos en el tubo. Si el tubo nuevo es tan grande, que si se hace circular el taladro *vv*, resulte demasiado ancho, puede hacerse en *óvalo*, con su diámetro mayor en la dirección del *largo* del tubo *f*. En este caso la pieza *e* será oval en parte, pero redonda en *cc*.

**Art. 13. Válvulas de aire.** El aire es propenso á recogerse gradualmente en los puntos más altos de las curvas verticales de los tubos de alimentación; y si no tiene salida produce una obstrucción más ó menos fuerte en la corriente. Esto puede evitarse por medio de válvulas de aire, fig. 44 A. Este aparato consiste en una caja de hierro fundido *ccdd*, asegurada al tubo matriz *mm*, por medio de tornillos que pasan por las planchas *dd*. Tiene una tapa *gng*, asegurada por medio de tornillos *tt;* en la parte superior hay una abertura *n*, para la salida del aire de adentro. En esta caja hay un flotador *f*, que puede ser un envase cerrado de hojalata ó cobre, ó de

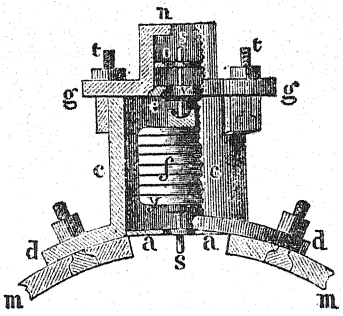

Fig. 44A.

capas de corcho, como se ve en la figura. Este flotador tiene un eje ó varilla *ss* que lo atraviesa y pasa por los orificios *aa* y *o* que permiten al flotador subir y bajar libremente; pero evitan que se mueva lateralmente. Cuando el tubo *mm* está vacío, el flotador está bajo y su base *y* descansa sobre *aa*. Una válvula *v* está fija al eje *ss*, y sube y baja con el flotador. Suponiendo que el tubo *mm* esté vacío, y por consiguiente el flotador y la válvula bajos, entonces, al entrar el agua en el tubo, ésta también sube á la caja y la llena hasta *e*, levantando el flotador y la válvula, obstruyendo la abertura *v* y evitando la salida al aire libre. Ahora, el aire llevado por el agua, por ser más liviano que ésta, sube naturalmente al punto más alto que encuentra. Por consiguiente, si este aire llega á la abertura *aa*, subirá por ella hasta llegar á *e*, donde la válvula cerrada le empide pasar más adelante. Así sucesivamente están subiendo partes de aire, que con el tiempo se acumulan en un grado tal, que comprime el agua hacia abajo y la hace salir de la caja. Sucediendo esto, el flotador que está sostenido por el agua solamente, también baja, y arrastra la válvula *v* hacia abajo. El aire acumulado se escapa instantáneamente al aire libre por las aberturas en *v* y *n*, y el agua en el tubo *mm*, sube instantáneamente otra vez á la caja, llevándose el flotador, y cerrando así nuevamente la válvula *v*. Esta válvula y su asiento *e*, están forrados de bronce, para evitar la oxidación y un mal ajuste. El todo está protegido por una tapa de hierro ó madera al nivel de la calle

**Ya en las poblaciones no se usan las válvulas de aire en los tubos**; las llaves de incendio á distancia de 150 m entre sí, más ó menos, las reemplazan. Estas llaves, colocadas, lo más posible, en las partes superiores de las curvas en la tubería, se usan para lavar las calles, y como se abren frecuentemente con tal fin, permiten también la salida del aire acumulado.

**La salida del aire comprimido por una válvula de aire, ú otro orificio, ha hecho reventar algunas veces los tubos matrices de las calles**; porque el escape es instantáneo, y las columnas de agua á ambos lados de la válvula se unen con gran fuerza chocando una contra otra y produciendo una reacción contra los tubos.

**Cámaras de aire.** Se da movimiento al agua en una tubería por medio de golpe, hacia adelante, del émbolo de una bomba de simple efecto; pero durante el movimiento del émbolo hacia atrás, el agua se detiene en su movimiento. Por lo tanto, el golpe próximo hacia adelante tiene que poner de nuevo en movimiento toda la columna de agua; y la fuerza que debe ejercerse por la bomba para producir este movimiento del agua, es mucho mayor que la que sería necesaria si el movimiento anteriormente producido se hubiese conservado durante el golpe de émbolo hacia atrás. La adición de una cámara ó depósito de aire asegura la conservación de este movimiento, y por lo tanto produce una gran economía de fuerza; además de que disminuye el peligro de que se revienten los tubos con tantos golpes de ariete. La cámara de aire consiste solamente en una caja de hierro alta y fuerte, herméticamente cerrada, asegurada fuertemente por medio de pernos á la parte superior de los tubos, colocada en la inmediación y más adelante de la bomba, y comunicándose libremente con los tubos por medio de una abertura en su base. Está llena de aire. El golpe hacia adelante de la bomba no solamente mueve el agua á lo largo de los tubos, sino también la hace entrar en la parte inferior de la cámara de aire por una abertura en la base de ésta, comprimiendo así el aire que contiene. Pero durante el golpe hacia atrás, este aire comprimido, libre ya de compresión por la bomba, se dilata y ejerce presión sobre el agua en los tubos, manteniéndola en movimiento hasta el próximo golpe hacia adelante; y así se continúa. Una cámara de aire también actúa como un *colchón de aire* (preferimos como un resorte), que permite al émbolo aplicar su fuerza al agua gradualmente, preservando así tanto á los tubos como á la bomba de choques violentos. Sin embargo, el aire en la cámara es absorbido y arrastrado gradualmente por el agua, y entonces cesa su acción como regulador. Para evitar esto, debe introducirse más aire en la cámara, de tiempo en tiempo, por medio de una bomba de aire impelente. En una bomba de *doble efecto* no es tan indispensable la cámara de aire como en una de simple efecto. No hay regla especial para el tamaño ó capacidad de las cámaras de aire. En la práctica parece variar de 5 á 50 veces el de la bomba; con una altura igual á 2 ó tres veces el diámetro.

Se usa algunas veces **un tubo vertical** en lugar de la cámara de aire (véase arriba). Es un tubo alto, abierto al aire en su parte superior, y en libre comunicación con los tubos de agua en su parte inferior, lo mismo que la cámara de aire. La parte superior ha de estar **más alta que el punto más alto** donde la bomba ha de llevar el agua por la tubería; porque de otro modo el agua se derramaría por la parte superior. El área de su sección transversal debe ser *á lo menos* igual al área del tubo, ó de los tubos que siguen y conducen el agua; pero es algunas veces mejor darle mucho mayor diámetro, porque un tubo vertical abierto, si la bomba deja de trabajar por algunas horas, puede servir entonces (y especialmente en una población pequeña) *como un estanque*. El tubo vertical debe ser cilíndrico, y no cónico; porque si se forma hielo grueso sobre el agua en uno cónico, una presión repentina hacia arriba producida por la bomba puede romperlo. Los tubos verticales en conexión con las tuberías de agua, en Filadelfia, son de una altura de 37 á 52 metros, y de 1.50 m de diámetro; están hechos de hierro de calderas remachado, de un espesor de 1 cm cerca de su base, y de ½ cm en su parte superior. No están protegidos contra la inclemencia del tiempo, ni están provistos de vientos, sino que se mantienen en su posición por su propio peso, aunque á veces están expuestos á vientos fuertes.

**Art. 14. Los tubos para surtir las habitaciones** se hacen de plomo y de un diámetro interior de 1 á 1½ centímetros. Están en conexión con los tubos

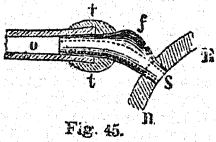

Fig. 45.

grandes de las calles *nn*, fig. 45, por medio de un **suncho ó tubo corto de latón** dibujado aquí como en ¼ parte de su tamaño natural. Las líneas de puntos muestran su diámetro, de 1 centímetro más ó menos. Este suncho cónico entra á martillo en un orificio cilíndrico del tubo principal en *s*. El tubo de plomo *o* está soldado en *t* á la otra punta del suncho y metido como 3 ó 4 centímetros. Con el

espesor mayor dado al suncho, en *f*, resulta de una forma especial y permite hacerlo entrar á martillo en el tubo mayor. El tubo y la soldadura se ven en sección longitudinal. Además de la llave de retención empatada con cada tubo de servicio, y á sus ramificaciones por toda la casa, hay otra llave subterránea, con la cual las autoridades municipales pueden quitar el agua en caso de que no paguen los derechos; y otra más, por la cual el latonero puede quitar el agua durante las reparaciones en los tubos del interior de la casa. **Los tubos de hierro galvanizados** se usan mucho para el servicio de las casas, especialmente para agua caliente, porque están menos sujetos á la dilatación y contracción que producen filtraciones.

**Art. 15. Las llaves de la Compañía de Aguas** se conectan en el tubo por una máquina especial, fig. 46. La gran ventaja de aquellas llaves sobre el suncho,

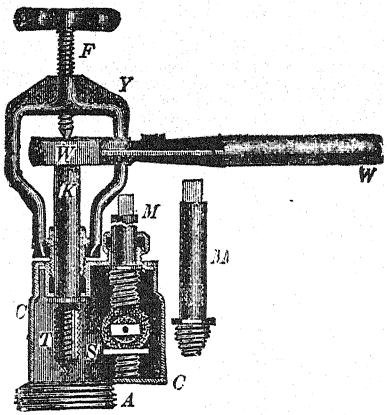

Fig. 46.

fig. 45, **consiste en que pueden conectarse en un tubo cuando éste. está lleno de agua y con presión.** Además, como ellas entran en el tubo por una rosca de tornillo, no tienen peligro de ser empujadas hacia afuera por la presión del agua. Están provistas de una llave de retención, la que se cierra mientras la llave de la toma se conecta en el tubo; y después se deja generalmente abierta.

**Las máquinas para taladrar y enroscar los taladros en los tubos,** y para insertar estas llaves, se hacen de varias formas. La de la fig. 46 es una fabricada por **Wálter S. Payne and Cy.**, Fostoria, Ohio. Cada una de estas máquinas trae un número de planchas de hierro fundido maleable que no se ven en la fig. y que sirven para los diferentes diámetros de los tubos con los cuales puede usarse. Se asegura esta plancha al tubo por medio de una cadena puesta alrededor de él, y se aprieta la cadena con perno y tuerca.

El cilindro de bronce ó latón grueso CC (en el cual se inserta primero el macho de la terraja del taladro T, y la llave S) se asegura entonces en la plancha por medio del tornillo A. La llave está atornillada provisionalmente á un mandril M. Este mandril y el eje del taladro K pasan por cajas de estopas (de hierro fundido). Por medio de una manigueta, no mostrada en la figura, la cabeza del cilindro da vuelta (mientras el cilindro mismo queda fijo) hasta que el taladro T y la llave S, están en sus puestos respectivos, como se ve en la figura. Cuando la cabeza del cilindro llega á su puesto, se para por medio de una uña en el interior del cilindro. El taladro se halla ahora inmediatamente sobre el centro de un gran orificio circular en la base del cilindro CC, y sobre otro orificio semejante que tiene la plancha que va sobre el tubo en el lugar donde se quiere taladrar. Se empuja hacia abajo hasta tocar dicho tubo. La *carraca* WW se pone ahora sobre la cabeza cuadrada del taladro K; y el marco Y con su tornillo F se ponen en la posición que indica la figura; moviendo ahora la *carraca* se taladra el tubo y se hace la rosca. Si el agua en el tubo tiene presión, sale del tubo por el taladro hecho y llena el cilindro.

Si ahora se cambia la posición del fiador de la carraca W y se vuelve á trabajar con ella, el macho del barreno sale ahora del orificio, pero se queda en el cilindro. Ahora se da vuelta á la cabeza del cilindro para cambiar las posiciones de S y T; una agarradera en el interior del cilindro impide á la cabeza dar más vueltas que las requeridas para poner la llave inmediatamente encima del taladro hecho. Por medio de la carraca, puesta ahora sobre la cabeza cuadrada del mandril M, la llave S (*cuya válvula debe estar cerrada*) se atornilla en el orificio del tubo, pero sólo lo suficiente para evitar que siga saliendo el agua del tubo, cuando se quita la máquina. Ahora la llave se atornilla firmemente por medio de una manigueta que encaja sobre la cabeza cuadrada de la misma llave.

El mandril M se hace de dos partes (que se atornillan una en la otra) para que su parte superior pueda quitarse y no estorbe á la carraca mientras se taladra. Tiene dos ó tres roscas diferentes, para servir á diferentes tamaños de llaves. Se suplen también diversas llaves para usar con la misma máquina.

La máquina puede trabajar en cualquiera dirección, y por consiguiente usarse para taladrar el tubo en cualquier punto de su circunferencia.

Después de conectada la llave, el tubo de servicio se asegura á ella por medio de una tuerca de empate con la rosca, como se ve en la figura.

**Art. 15a. La cúpula neumática**, figs. 46*a* y 46*b*, inventada por Mr. N. Monroe Hopkins, de Wáshington, son para evitar que se revienten los tubos al helarse el agua.

En tubos no protegidos, el agua al congelarse es expande transversalmente y revienta el tubo. La cúpula colocada en el tubo, como se ve en la fig., y á inter-

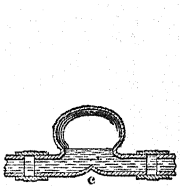

Fig. 46 *a*. Fig. 46 *b*.

valos de 3.60 m, permite la expansión del hielo hacia cada cúpula, donde comprime el aire allí encerrado. En la cúpula horizontal, los dos planos inclinados, *c*, en su parte inferior, compelen á las dos columnas de hielo hacia la cúpula, evitando que se compriman entre sí.

Con el objeto de asegurarse de que las cúpulas en un sistema de tubos (como los de una casa, industria ó puente) no se queden sin aire por la acción de la corriente, se coloca después de ellos un aspirador á la entrada del sistema; el aspirador consiste esencialmente en una contracción del tubo, que aumenta la velocidad del agua en ese punto y produce una succión del aire á través de una válvula colocada con ese objeto (véase medidor Venturi, pág. 566). El aire así introducido, es llevado á lo largo del tubo, en burbujas, entre la superficie del agua y la parte superior del tubo, las que son retenidas por las cúpulas. Cuando, al cerrar una llave, etc., se detiene la corriente, el exceso de presión cierra la válvula. Se han hecho ensayos muy estrictos en tubos anchos y estrechos (10 cm y 18 mm) protegidos por estas cúpulas, y siempre han resultado eficaces para evitar la ruptura.

**Art. 16. Las llaves de retención** que se abren verticalmente, figs. 47 y 48, se colocan en la tubería de la calle á distancias de 100 á 300 mets unas de otras. Se usan para quitar el agua de cualquiera sección durante las composiciones ú otros casos; y el agua de estas secciones se bota por tubos de desagüe. Hay mucha diferencia en los detalles de unas á otras según los diferentes fabricantes.

Las figs. 47 y 48 muestran una llave hecha por *Chapman Valve Mfg Co., Indian Orchard, Mass.* La válvula *v* está fundida en una sola pieza. Estando baja, como en las figs., cierra el tubo. Como en otros modelos, se abren verticalmente por medio de un tornillo D que hace penetrar la válvula á la caja de hierro fundido BB, dejando, cuando se la hace subir, una abertura de todo el diámetro del tubo. El tornillo se mueve por medio de una llave de mano que se ajusta á su cabeza cuadrada *h*. El tornillo D no puede moverse verticalmente porque se lo impide el reborde ó collar C.

Las dos fundiciones principales que componen la caja ó la cubierta están unidas

por pernos que atraviesan una plancha saliente, *g*. Las caras de unión de las fundiciones son muy lisas, y se inserta una tira delgada de plomo entre ellas para evitar

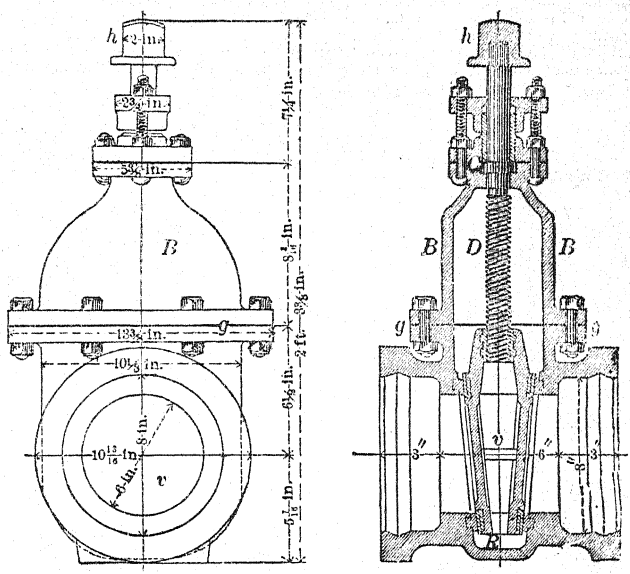

**Fig. 47.** Fig. 48.

(*N. del T.* — Para las medidas sobre la figura, recuérdese que una *in* (inch = pulgada) equivale á 25.4 mm y un *ft* (foot = pie) equivale á 305 mm.)

las filtraciones. La cavidad R admite pequeñas partículas de materias extrañas que de otro modo podían llegar á impedir que la válvula cerrara perfectamente. Los asientos de la válvula están revestidos con metal de *Babbitt* *. En la parte superior de la caja, el mango del tornillo pasa por una caja llena de estopa, que evita la filtración del agua en este punto.

(*N. del T.* — La tabla que sigue es la que trae el autor, convertida al sistema métrico.)

* *N. del T.* — Compuesto de 50 partes de estaño, 1 de cobre y 5 de antimonio.

**Art. 17.** En la fig. 49 se ve un aparato de estos **con el tornillo exterior** para subir y bajar la válvula. Aquí el tornillo D no da vuelta si no está asegurado á la válvula, y sube y baja con ella movido por la rueda W, en cuyo centro se halla una tuerca por la cual pasa aquél. La tuerca está fija en la rueda, y está dispuesta para que no pueda moverse verticalmente.

**Art. 18. Una llave de cuatro tubos** ó **cuatro vías**, figs. 50 y 51, se coloca en la intersección de dos tuberías matrices, cuyos cuatro extremos se aseguran

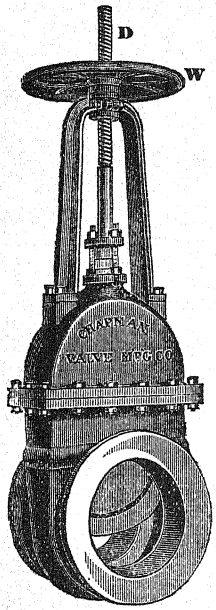

Fig. 49

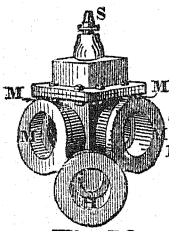

Fig. 50

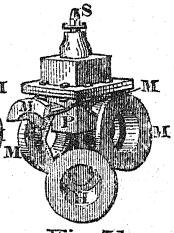

Fig. 51

respectivamente á las cuatro aberturas MMMM. En el fondo hay otra abertura que está en conexión, por medio de un codo H, con tubos que van á una boca de agua para incendios situada al lado de la acera. Véanse los arts. 20 y 21. Dos ó más aberturas pueden mandarse hacer, si se quiere; para suplir tantas bocas de agua como sean necesarias. Todas estas aberturas se abren y se cierran al mismo tiempo, subiendo ó bajando la válvula compuesta P, por medio de una llave aplicada á la cabeza cuadrada S del tornillo. Lo mismo que en las figs. 47 y 48, da vuelta el tornillo pero sin subir ni bajar, y la llave sube y baja en el tornillo mismo.

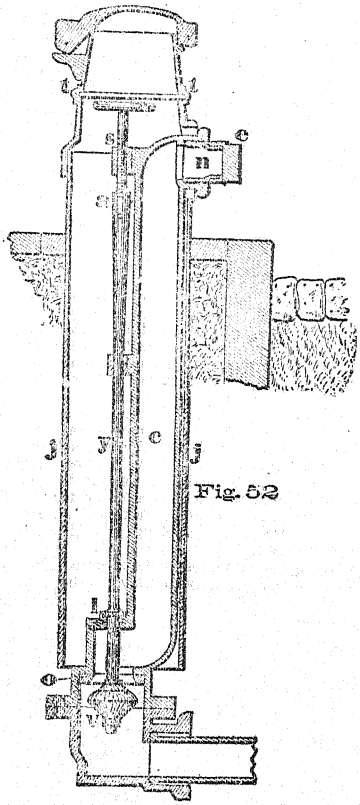
Como todo sedimento se escapa por la abertura en el fondo, que conduce á la boca de incendio, la llave no está expuesta á ser obstruída por esta causa. La boca para incendios, como está alimentada por ambos tubos matrices, obtiene una presión de agua mayor de la que se lograría, si estuviese alimentada por un tubo solamente.

**Art. 19.** Cualquiera que sea la forma ó clase de llave, está protegida, en su unión con el tubo, **por una caja que la contiene**, hecha generalmente de madera ó de hierro fundido, cuadrada, de sección horizontal menor arriba que abajo. La caja está abierta en el fondo, pero tiene una tapa movediza de hierro al nivel de la calle. Se quita la tapa cuando se quiere abrir ó cerrar la llave ó inspeccionarla. Dos de los lados opuestos de la caja tienen, por supuesto, aberturas para el pasaje y conexión de los tubos á la llave. Deben cerrarse muy lentamente, sobre todo las grandes,

de otro modo la violenta detención de la corriente en los tubos expondría á éstos á reventarse y á las llaves mismas á romperse. Como precaución contra esto, las cajas que cubren las válvulas se refuerzan con unas molduras salientes que se hacen en la fundición.

Ya no se usan las llaves de aire automáticas, fig. 44 A, en las partes altas de la tubería para dejar salir el aire. Las bocas de agua para incendios suplen su efecto. El radio para curvas horizontales en tubos matrices, no debe ser menor, si es posible, de 12 veces el diámetro del tubo; se les da el mayor radio que permite el ancho de la calle; generalmente de 15 m. Las bocas para incendios, figs 52, etc., se colocan, lo más posible, en las partes más altas de las calles, para que sirvan también para lavar las calles y para el escape del aire acumulado; el término medio son 8 para cada 2 kilómetros de tubo, ó una para cada cuadra edificada.

**Art. 20. La fig. 52 representa una boca de agua para incendios.**



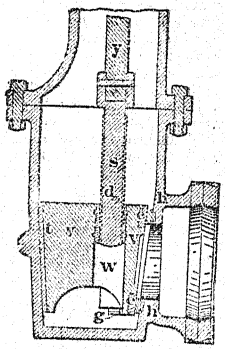


Fig. 53

La válvula *v* se hace de suela bien comprimida á martillo; y cuando se cierra, se ajusta contra un asiento de bronce ó latón en forma de anillo, que está asegurado en su puesto por una soldadura de plomo. Se abre la válvula haciéndola bajar por

el tornillo *s*, el cual, por medio de una articulación giratoria en *a*, puede dar vueltas sin que gire el eje de la válvula *y*. Si la válvula *v* está cerrada, después de haberse usado la llave de incendio, la cámara *c* queda llena de agua, expuesta á congelarse con el frío y romper el aparato. Pero, cerrando la válvula, levantamos el pestillo *l*, del eje, y de este modo se escapa el agua por la abertura en *l*, y se pierde corriendo por el suelo, por la parte inferior del cilindro vacío *jj* que envuelve el aparato.

La parte superior *t* de la caja de la boca de incendio está fundida en una sola pieza con la cámara *c*.

La tapa *e* se atornilla sobre la cajeta *n*.

**Art. 21. En las bocas de incendio de Chapman**, figs. 53, 54 y 55, hechas por *the Chapman valor Co*, **la válvula** *v es corrediza*. El vástago *y*, fig. 53, en que está fijo el tornillo *s*, no puede ni subir ni bajar á causa de un collar fijo en su parte

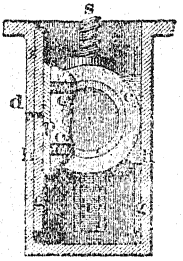

Fig. 54.

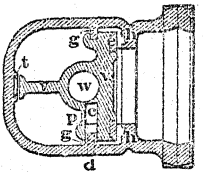

Fig. 55

superior, y confinado en una ranura circular. Cuando se da vuelta al vástago y al tornillo, la válvula se mueve hacia arriba y hacia abajo sobre el tornillo, admitiendo ó excluyendo, de este modo, el agua en la boca de incendio. La válvula corre sobre dos guías *gg*, fundidas en una sola pieza en los dos lados *verticales* del aparato. El borde circular, en el contacto con la caja del aparato, está cubierto con un anillo de bronce *ee*, que descansa contra un anillo igual, hecho de metal de *Babbitt*, embutido en la caja del aparato.

**El agua** que queda en la caja de la boca de incendio después de cerrarse la válvula, **se sale** por un agujero cilíndrico *d*, de 1 cm más ó menos, taladrado al través de la guía *g* y la caja *h*. Este agujero está á una altura tal, que quede exactamente sobre la parte superior de la plancha suelta *p*, cuando la válvula está cerrada como en la fig. 53. Esta plancha está en una ranura vertical, á un lado de la fundición de la válvula, y está comprimida contra el lado de la caja *h*, por dos resortes espirales, confinados en dos concavidades *cc*, de la fundición de la válvula. Cuando la válvula empieza á subir, el agujero, *d*, se cierra por la plancha *p*, y queda así hasta que la válvula se cierra de nuevo enteramente.

**Taladros de ensayo.** Las figs. 1 y 2 muestran un instrumento para **taladrar tierra, greda, arena y granzón**, aunque estén muy duros y aun helados. No

Fig. 1.

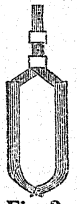

Fig. 2.

perfora roca dura ni piedras grandes sueltas. Se compone de dos segmentos cilíndricos de planchas de hierro SS llamadas « vainas », y cuyas aristas cortantes

inferiores están guarnecidas de acero. Estas aristas sobresalen (como se ve en la figura) á los lados del taladro, y hacen el pozo más ancho que el taladro mismo, de modo que éste no se atraque en él. Las dos aristas cortantes están equidistantes de la línea central del instrumento, y esto asegura una perforación recta y vertical. En *a* el taladro está sujeto á la extremidad inferior de una barra vertical de taladros compuesta de un número de barras de hierro de 37 mm en cuadro, ó tubos de 62 mm y de 3 á 4.5 m de longitud, unidos en sus extremidades por medio de un encaje cuadrado. En la parte superior de esta barra hay un gancho con movimiento giratorio, por el cual el aparato entero está colgado en un mecate, que pasa por encima de una polea en la parte superior de una grúa ó trípode y hacia abajo á un tambor movido por un torno y un engranaje. Por medio de este torno y del mecate se suspende el taladro y su barra (la cual al principio tiene una sola pieza) sobre la perforación que se hace. Luego se baja dicho taladro hasta el suelo; y por medio de una palanca fija á la barra, dos hombres ó un caballo le imprimen al taladro un movimiento de rotación horizontal. El gancho giratorio situado en la parte superior de la barra permite esta rotación sin que se tuerza el mecate. La forma del taladro es tal, que este movimiento rotatorio lo hace penetrar en la tierra á manera de tornillo, y el hombre que maneja el torno durante la perforación, no tiene sino que mantener el mecate tenso, para que de este modo impida que el taladro penetre demasiado ligero y se atraque. Con ocho revoluciones más ó menos se llena de tierra el taladro. Entonces se levanta por medio del torno á un metro más ó menos sobre la superficie, y soltando y quitando entonces el anillo *b*, el taladro se abre como unas tenazas, y cae la tierra extraída en un cajón de madera, que se ha colocado encima de la perforación. Después se sigue taladrando como antes. Cuando la perforación haya llegado á una profundidad de 3 m más ó menos, debe agregarse una segunda barra en la parte superior de la primera. Para hacer esto, el taladro, y la primera barra se levantan algunos centímetros, se coloca en el suelo un ligero andamio de tablas alrededor de la barra y luego se fija á ésta un reborde que la sostiene en el andamio, mientras se quite el gancho giratorio y se agrega la segunda barra, en cuya punta superior se fija el gancho giratorio, y clavando ésta hasta que su extremidad inferior puede asegurarse á la superior de la primera barra. Hecho esto, se estira el mecate, se baja el taladro al fondo de la perforación y se principia nuevamente. Del mismo modo se añaden las barras necesarias de tiempo en tiempo, según lo requiera el descenso del taladro.

Estos taladros se hacen de 15 á 20 cm de diám, ó más grandes por encargo especial. Si se quiere, puede hacerse la perforación de 60 á 90 cm de diámetro, fijando al taladro un ensanchador. Este taladro hará perforaciones hasta de 30 m ó más de profundidad, á razón de 1.20 á 6 m por hora. Saca piedras del tamaño de su semidiámetro. En terrenos secos se vacía un balde de agua en la perforación cada vez que se saca el taladro.

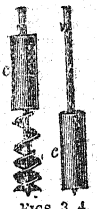
Puede emplearse ventajosamente en la perforación de los hoyos para **pilotes**, y algunas veces, **en lugar de hincar las estacas de madera** con el martinete, puede ser mejor enterrarlas (con la punta cuadrada hacia abajo, si se prefiere así) en perforaciones hechas con este instrumento, apretando la tierra alrededor de ellas después. Así se librará á las casas contiguas y cercanas, de la vibración y perjuicio producido por un martinete.

Si se encuentra **arena, fango, ó granzón suelto** al hacer la perforación, se ensancha aquélla 10 cm más y se colocan tablas forrando la excavación, las cuales se hacen penetrar á través de la arena ó granzón, y luego se extrae esta arena ó granzón por medio de una **bomba de arena**. Esta bomba se compone de un cilindro de hierro hueco de 12½ cm de diám por 75 cm de largo, más ó menos, con una válvula en su pie, que se abre hacia arriba. Este cilindro se baja hasta el fondo de la perforación; se cubre con agua hasta .60 á 1.20 m y se le da con la mano un movimiento rápido hacia arriba y hacia abajo, de 10 á 15 cm de amplitud y por 20 ó 30 veces, durante las cuales la bomba se llena de arena, y se saca entonces fuera De 3 á 6 m de altura de fango, ó arena, etc., pueden extraerse por hora de una perforación de 15 á 45 cm de diámetro. La bomba se usa también para extraer tierra, etc., de una perforación hecha en un suelo muy compacto. **El precio** de un taladro perforador con su cabrestante, barrenos, mecates, bomba de arena, etc., etc., completo, es más ó menos $175. El taladro pesa de 67 á 90 kg, según el tamaño. Los barrenos de 37 mm en cuadro, 5 kg por m. El cabrestante, 70 kg.

El perforador de arena, figs. 3 y 4, lo mismo que la bomba de arena descrita, se emplean entre tubos, con el mismo fin. El cilindro hueco de hierro C, de 25 cm de diámetro × 75 cm de largo, se desliza verticalmente en la barra. Al taladrar, la arena que está debajo y la que rodea al cilindro mantiene á éste en la posición

indicada en la fig. 3. Seis revoluciones de la barra y tornillo llenan el cilindro de arena. Luego se levanta la barra. Ésta hace entrar primero el tornillo dentro del cilindro como en la fig 4, y una válvula situada en el pie del tornillo cierra el fondo del cilindro, é impide que la arena se salga cuando se saca el taladro. La barra es un tubo abierto en ambas extremidades. Esto permite la introducción del aire libre evitando la resistencia producida por la sección al sacar el taladro. A éste se le comunica movimiento de rotación y se saca del mismo modo que el taladro de tierra descrito arriba. Precio, $30.

También se **usa un taladro** de acero de 5 á 10 cm de diám, para reconocimientos; tiene .60 m de longitud, sirve para perforaciones de 8 á 15 cm de diám y de 3 á 15 m de profundidad. Perfora greda, arena ó granzón fino, y saca muestras de todas estas substancias. Se le da vueltas por medio de llaves ó palancas, con fuerza de hombres ó de caballo. Véase también pág. 728.



FIGS 3, 4.

FIG 5.

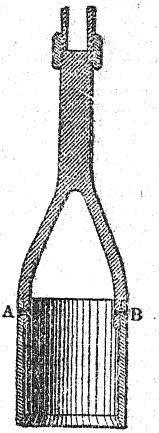


FIG 6.

**La perforadora cuya sección vertical se ve en la fig. 6,** y su sección transversal horizontal en la fig 5, es muy útil para **hacer á la mano perforaciones de poca profundidad á través** de greda, granzón, etc. El taladro mismo se compone de un cilindro de acero de resortes, de 7 á 10 cm de diámetro y de 10 á 13 cm de alto, con sus lados de 6 mm de espesor, con una abertura vertical (véase la fig. 5) en toda su altura, cortada al sesgo en el pie, para producir un filo cortante, como se ve en la fig. 6. En la parte superior está remachada ó soldada una pieza de hierro forjado en forma de V invertida, la cual, por medio de un encaje que tiene en su extremidad superior, se atornilla á un tubo de gas que le sirva de mango, y al cual se agregan otros, según vaya haciéndose la perforación.

Ésta se hace con dos hombres que agarran el mango, y teniendo verticalmente el instrumento, lo hacen entrar en el suelo levantándolo y dejándolo caer repetidas veces en el mismo lugar. A medida que el instrumento golpea el suelo, la forma sesgada de su filo cortante lo hace abrirse ligeramente, y cuando al levantarlo se suprime la presión hacia abajo, recupera su forma anterior cerrándose lo que se había abierto y recoge la tierra que entra en él. El instrumento se llena pronto, y los hombres, viendo que ya no entra con facilidad, lo sacan fuera para vaciarlo. La calidad de su contenido á diferentes profundidades (medida ésta á lo largo del mango), se anota.

En seis días de á ocho horas 3 hombres (uno de ellos descansando á intervalos) empleando uno de estos taladros, hicieron 20 perforaciones de 2.80 m de profundidad media, en marga, granzón greda y esquisto micáceo descompuesto, al costo de 72 centavos por metro. Salario ó jornal por día y por hombre, $2

Para trabajos en marga, greda ó arena no movediza, cualquier herrero bueno puede hacer un **taladro de tornillo que sirva** con sólo darle la forma de un

tirabuzón de .60 m de largo y con 6 vueltas completas de 15 cm diám á una barra de hierro ó acero de 2½ cm en cuadro, con su parte inferior formada de un filo cortante vertical, que sobresalga más ó menos 10 mm de la espiral del tornillo, para disminuir el frotamiento. Este instrumento sacará muestras completas, pero requiere un torno ú otro modo sencillo de levantarlo, cuando el tornillo está lleno.

## POZOS ARTESIANOS

Las perforaciones verticales profundas, de 15 á 20 cm diám, como se requieren para pozos artesianos ó para pozos de aceite, y exploraciones de minas, se hacen levantando y dejando caer repetidamente un barreno ó mecha pesada de hierro, fig. 1, pág. 727, con un filo cortante de acero. Después de cada golpe de la mecha se le da á ésta un pequeño movimiento horizontal de rotación, para hacer que la perforación sea redonda. El largo de la arista cortante de la mecha es algo mayor que el diámetro de ésta, y de este modo se hace la perforación suficientemente grande para impedir que la mecha se atraque. La mecha es la última pieza que figura en la serie de barras de hierro y acero, etc., unidas con tornillos por sus extremidades. Este conjunto de útiles varía en longitud de 7 á 18 m, según el tamaño y profundidad del pozo, la dureza de la roca; su diámetro general (más arriba del filo cortante) es de 2 á 5 cm menos que el del pozo. Su peso es de 360 á 1,800 kg. La pieza superior es siempre el portacuerda (véase la fig. 4), al cual se sujeta la punta inferior del **cable**. Este cable pasa al salir del orificio á una **palanca horizontal**, la que, por medio de una máquina de vapor ó fuerza animal, se tiene constantemente en movimiento alternativo de arriba abajo. Todo con el filo cortante de la mecha en la extremidad inferior, se levanta y se deja caer alternativamente de .60 á 1.20 m de alto y de 30 á 50 veces por minuto; de este modo se perfora la roca ó la tierra. Se conserva constantemente el hueco con 1 á 3 m de agua para facilitar la perforación y la extracción del material triturado. Después que la perforación llega donde hay agua, se puede continuar taladrando, aun cuando se llene de agua el pozo; pero una altura grande de agua disminuye la intensidad de la *fuerza de los golpes*. Debe darse una disposición conveniente para aflojar el mecate á medida, que el instrumento desciende. Una pinza horizontal está fija al mecate, y el hombre encargado de manejarla, dándole vuelta, tuerce el cable, y de este modo **da un movimiento de rotación horizontal** á la mecha, igual, más ó menos, á la quinta parte de una revolución entera, después de cada golpe, hasta que se hayan hecho de 6 á 8 revoluciones enteras en una sola dirección. Entonces invierte el movimiento, y hace un número igual de revoluciones, en el mismo tiempo, en dirección opuesta.

Después de haber barrenado á algunos metros de profundidad, se saca todo fuera del pozo, por medio del cable, para poder *extraer el material triturado* que se ha acumulado en la perforación. Esto se hace por medio de una **bomba de arena.**

**Los pozos se hacen generalmente de 15 á 20 cm de diámetro.** Para diámetros menores de 15 cm, los instrumentos son tan delgados, que están expuestos á romperse dentro de un pozo hondo.

El mismo aparato se usa **para perforar la tierra encima de la roca** antes de que se llega á esta última. Esto se llama « escardar » (*spudding*). En este caso debe impedirse que las paredes del pozo se derrumben. Al efecto se coloca un tubo de hierro forjado de un diámetro tal, que ajuste bien en la perforación y de 6 mm de espesor, y se empuja hacia abajo de tiempo en tiempo á medida que avance la excavación. El tubo se hace bajar por medio de un mazo pesado de roble, ó de otra madera dura, de 35 ó 45 cm en cuadro y de 3 á 4.5 m de largo. Este mazo se fija á una extremidad de la punta inferior del mismo cable que durante la perforación sostiene el instrumento. Varias veces se levanta y se deja caer sobre la cabeza del tubo, el cual está protegido por un **casquete** de hierro fundido. El pie del tubo está provisto de un anillo de acero con filo cortante. Cuando el tubo ha penetrado lo más que puede, se retira el mazo de la punta del cable, se sustituye por el instrumento y se principia nuevamente á perforar dentro del tubo.

Dicho tubo está formado de porciones de 2.40 á 5.40 m de longitud, y la perforación del pozo y colocación de aquél se efectúan alternativamente hasta que se llegue á la roca y el pie del tubo haya penetrado algunos centímetros dentro de ésta; lo suficiente para excluir la arena movediza ó el agua de la superficie.

**Si se encuentra arena movediza**, se saca el instrumento y se emplea la bomba de arena dentro del tubo.

**Para ensanchar las perforaciones ó para enderezar** las que estén torcidas, etc., se reemplaza la mecha por instrumentos especiales, tales como ensanchadores, etc.

Es necesario tener especial cuidado en aceitar bien **todas las superficies de rozamiento.** La polea situada en la cabeza de la grúa y las ruedas del piñón de la máquina deben aceitarse bien cada dos ó tres horas.

**En tiempo muy frío ó muy húmedo debe construirse un caney de tablas ordinarias,** ó un cobertizo de lona, de 2.4 m de altura más ó menos, para proteger los hombres contra la intemperie; y si se emplea máquina de vapor, debe cubrirse la correa con 2 ó 3 tablas que le sirvan de techo; pues cuando se moja se resbala.

La descripción que sigue está basada en las máquinas construídas por la Pierce Well Supply Co.

**Para perforaciones de 60 á 300 m de profundidad,** se usan **máquinas de taladrar portátiles,** que se pueden maniobrar con fuerza de vapor ó de sangre. En estas máquinas, el cable se extiende desde el instrumento y fuera del pozo, hasta pasar sobre una garrucha colocada en la cabeza del árbol de madera; desciende otra vez, y de allí, por intermedio de una polea fija al pie del árbol, va á un cilindro donde está enrollada. A este cilindro está fija una rueda dentada y una palanca para aflojar el cable á medida que desciende el aparato.

**El árbol tiene un gozne** á la altura de 1.8 m de su extremo inferior, de modo que su parte superior puede ponerse horizontal, cuando se traslada la máquina de un punto á otro. Cuando la máquina está trabajando, el árbol está sostenido en su posición por puntales de madera, sujetos con pernos en su parte superior, y sus extremidades inferiores fijas al burro de taladrar, que se compone de un andamio fuerte, de 2.70 m de largo, .90 de ancho y 1.2 de alto, colocado al pie del árbol, el cual contiene la palanca que suspende y deja caer el cable, el cilindro en que está enrollado el cable, el eje y la excéntrica que maneja la palanca, etc. El operador permanece parado al pie del árbol, y por medio de palancas de pie y de mano á su alcance, regula todos los movimientos de la máquina. Una de estas palancas gobierna la rueda de retención que regula el desarrollo del cable. Imprimiendo á la rueda de engranaje un movimiento de un diente á otro, baja el cable y la mecha 6 mm.

El operador, moviendo una corredera con su pie, aprieta hacia abajo la palanca principal, fuera del alcance de la excéntrica, y detiene de este modo el movimiento del cable y del perforador. Por medio de otra palanca puede engranar el cilindro del cable al eje motor principal, para que el cable se arrolle en el cilindro, y levante el perforador y lo saque del pozo. Otra palanca mueve un tambor pequeño, sobre el cual está enrollado un mecate liviano, que sujeta la bomba de arena. Todas estas operaciones se ejecutan por la misma fuerza (caballo ó vapor, según el caso) que trabaja sin interrupción; haciendo el hombre diferentes cambios para engranar y desengranar las diversas partes de la máquina con el eje motor principal, etc.

**Una de estas máquinas portátiles requiere** dos caballos ó un pequeño motor de vapor, un hombre para atenderla y otro para manejar la máquina, vaciar la bomba de arena, cambiar las piezas del taladro, etc. La máquina puede llevarse en una carreta de campo por cualquier camino ordinario. Dos hombres la pueden descargar, armar y principiar á perforar en dos horas; y á menos que se prefiera la fuerza de vapor, los dos caballos empleados en su transporte pueden suplir la fuerza motriz. La máquina puede desarmarse y meterse otra vez en el carro en el término de dos horas. Las figs. 1 á 4 muestran **los útiles empleados con estas máquinas.**

La fig. 1 es la **mecha de taladrar** (escariador) (*drilling bit*). El filo tiene 15 cm de largo y la mecha de 75 á 90 cm, y pesa 45 kg más ó menos. Su parte superior se atornilla en el pie **del mango de taladro,** fig. 2, que se hace de hierro redondo de 7½ cm diámetro, de 3.6 m de largo y pesa 150 kg. Su aplicación es la de un peso, que comunica una fuerza adicional á los golpes de la mecha.

Su parte superior se atornilla en el pie de la sonda de percusión (*drill-jars*), fig. 3, cuya parte superior se atornilla al cable. **Si la mecha se atraca por cualquiera causa dentro del pozo,** el operador detiene el movimiento del instrumento y afloja el cable, 30 cm más ó menos. Esto permite que el eslabón superior U de la sonda de percusión, fig. 3, se deslice hacia abajo en la ranura S inferior. Principiando entonces nuevamente con el movimiento de vaivén, el golpe adicional producido por la pieza U contra la parte superior del eslabón S, afloja el aparato.

Estas máquinas se hacen de diferentes tamaños para perforaciones hasta de 60 á 300 m de profundidad. El juego de instrumentos pesa de 360 á 1,000 kg, y la

máquina completa, incluyendo instrumentos, cable, árbol, etc., de 1,000 á 2,000 kg. Su precio es de $700 á $1,500, no incluyendo el de la fuerza motriz. Los tamaños más pequeños pueden manejarse con fuerza animal. Una máquina para fuerza animal de 1 caballo pesa 360 kg más ó menos, y su precio es de $75. Una máquina de vapor pesa 700 á 1,600 kg y vale de $150 á $300.

**Para pozos de 300 á 900 m de profundidad**, se usa una máquina fija con su balancín, semejante á las empleadas en las regiones de petróleo de Pensilva-

FIG 1.

FIG 2.

FIG 3.

FIG 4.

nia. Se levanta una grúa cuadrada piramidal, de 23 m de alto, 6 m en cuadro en su base y 1.2 m en cuadro en su parte superior. Cada una de las cuatro piernas de sus ángulos se construye de tablones de 5 × 20 cm y 5 × 25 cm, unidas de manera que formen una pieza angular de 25 × 25 cm y 2 pulgs de grueso. Estas piernas están unidas por piezas horizontales y verticales de madera. El balancín es de madera de 7.8 m de largo, de 30 cm de ancho, y 65 cm de grueso en su centro, donde gira por medio de muñones colocados en la parte superior de un poste de madera de 45 cm en cuadro y de 3.60 m de alto, llamado « Samson post ». La base de este poste está ensamblada en el quicio principal de la máquina, que tiene 45 cm de ancho por 60 cm de grueso.

La fuerza motriz es una máquina de vapor de 15 caballos, la cual por medio de una correa, polea, manivela y biela obrando sobre el balancín, le comunica el movimiento de vaivén. En la otra extremidad del balancín, é inmediatamente sobre el pozo, está suspendido, por medio de un gancho, un tornillo graduador. Este último se compone de dos barras de hierro de 15 × 50 mm más ó menos y 1.5 m de largo, colgando con 5 cm de separación y unidas por sus partes superiores, en cuyo punto

tienen un anillo suspendido del gancho del balacín. En las puntas inferiores de las barras y entre ellas hay un manguito de tuerca, por la que pasa un tornillo de 1.5 m de largo, el cual en su punta inferior tiene una cabeza que sostiene un eslabón giratorio. Éste agarra el cable de 5 cm de diámetro, de cuya extremidad inferior está suspendido el perforador. Éste, para una perforación de 600 m, está compuesto de una barrena de acero de .90 á 1.20 m de largo, con peso de 90 á 180 kg; de un mango de hierro redondo de 10 á 12 cm de diám y de 7 á 9 m de largo, con peso de 500 á 1,000 kg; de una sonda forrada de acero de 2.40 m de largo, 260 á 300 kg; una barra de inmersión de hierro redondo del mismo diámetro que la del mango de 3.60 á 4.50 m de largo, que pesa de 260 á 500 kg; y un encaje de cable de .75 m de largo, pesando 90 kg. Largo total del juego de piezas, de 15 á 18 m; peso total, 1,350 kg; y para una perforación de 20 cm en la roca más dura, 1,800 kg. **La barra de inmersión** se agrega como peso adicional, y de este modo ayuda á introducirse el cable entre el agua. Para extraer objetos que se hayan caído casualmente en el pozo, se usan **instrumentos especiales.**

**El cable del taladro está enrollado** á un tambor, y durante la perforación, pasa flojamente por sobre la polea situada en la parte superior de la grúa, y de allí á la parte inferior del tornillo de graduación en la extremidad del balancín. A medida que la perforación avanza, el hombre encargado de maniobrar le da vuelta al tornillo de graduación y al cable, para cambiar la posición del barreno después de cada golpe.

Cuando vaya á sacarse el instrumento de la excavación, se quita el cable de las lañas del tornillo de graduación y se arrolla en el tambor, el cual para este fin se engrana con la máquina de vapor, quitando al mismo tiempo la barra de conexión del manubrio, de modo que el balancín quede sin movimiento. Como en las máquinas portátiles, la bomba de arena se saca por medio de la misma fuerza que hace la perforación.

**6½ m³ de madera en bruto**, se llevan más ó menos para la grúa, balancín, quicios, etc., y como 2 m³ más para un caney que cubra la caldera, la máquina y la correa.

En roca calcárea de dureza ordinaria, **una máquina como la descrita** perfora más ó menos 45 cm por hora, en las circunstancias más favorables. Para el trabajo de la máquina **se requieren dos hombres**, el uno para atender á la caldera, afilar las barrenas, etc., y el otro para maniobrar la máquina.

**En la máquina Pierce**, para taladros de prueba, exploraciones mineras y pozos, se empujan los tubos con un martillo de hierro, como los de hincar estacas, pero cubierto con madera dura, en el extremo bajo con que golpea; el martillo se mueve con un *winch* de mano. Los tubos tienen de 1.5 á 3 m de largo; después que se ha enterrado cada tubo, se introduce agua á presión con una bomba de mano, hasta el fondo del agujero, por medio de un tubo que se agita de arriba abajo; el agua hace salir á la superficie el pantano, la arena y el granzón. Las máquinas pequeñas introducen tubos de 5 á 7½ cm de diám; las grandes, de 5 á 20. Las máquinas son desmontables, sus partes pesan de 5 á 30 kg. Cuatro tubos derechos, que sostienen una polea de hierro, obran como guías del martillo; sus extremos, forrados en hierro, entran en unas cavidades. Los martillos están compuestos por secciones que se atornillan juntas; en las máquinas pequeñas se les da así un peso de 45 á 90 kg, y en las grandes, de 45 á 900 kg. Los barrenos pueden hacerse á una profundidad de 30 á 120 m. Estas máquinas han sido muy usadas por la comisión del Canal Istmico de Nicaragua. Si se desea, las máquinas pueden suministrarse con herramientas especiales para taladrar roca, y con bombas de arena para sacar lodo, arena, pedazos de minerales, etc.

# MÁQUINAS PARA TALADRAR ROCAS

**Art. 1.** La roca se taladra mucho más rápida y económicamente con **máquinas de taladrar** que con taladros de mano, con tal que la obra sea de tal magnitud, que justifique los gastos de instalación. Perforan en cualquiera dirección, y pueden emplearse muchas veces en lugares donde es imposible barrenar á la mano. Son movidas directamente por el vapor; ó por aire comprido en un « recipiente », por medio del vapor ó fuerza hidráulica, y de allí llevado á los taladros por tubos de hierro.

El aire es la mejor fuerza motriz para taladrar en túneles y pozos, porque, escapándose después de haber funcionado en los taladros, contribuye á la ventilación

**Art. 2. Estos taladros son de dos especies : taladros de rotación y taladros de percusión.** En los primeros, la barra del taladro se compone de un tubo largo que gira alrededor de su eje. La extremidad de este tubo, templado de tal modo que forme una arista cortante anular, se mantiene en contacto con la roca, y al rotar practica una perforación cilíndrica, dejando generalmente un cilindro (alma) sólido en el centro. Este corazón ocupa el anillo central (*core-barrell*).

Art. 8. La barra del taladro avanza hacia adelante ó dentro del agujero, á medida que prosigue la perforación. La piedra triturada se extrae de la cavidad por medio de un chorro de agua continuo, que se dirige al fondo de ella por la cavidad central de la barra del taladro, y que saca fuera dichas trituraciones á través del angosto espacio comprendido entre la parte exterior de la barra del barreno y las caras de la perforación.

**En los taladros de percusión**, la barra del taladro es maciza, y su acción es como la del taladro giratorio.

**Art. 3. En el taladro rotatorio Brandt** (europeo) la arista cortante de la extremidad de la barra del taladro tubular está provista de dientes de acero templado. Está comprimido contra la roca por una presión hidráulica enorme, y hace sólo de 5 á 8 revoluciones por minuto.

**Art. 4. El taladro de diamante** es la única forma de taladros rotatorios para roca usados extensamente en América. La barra de este taladro se compone de un número de tubos unidos rígidamente en sus extremidades por medio de manguitos interiores hueces.

**Art. 5. La barrena ó mecha del taladro**, fig. 1, se llama mecha de anillo. En su arista cortante hay incrustados « **diamantes** » como se ve en la figura. Éstos están dispuestos de tal manera, que sobresalen ligeramente á ambas orillas, tanto interior como exteriormente. De este modo resultan espacios anulares entre el alma y el anillo central (*core-barrell*), y entre este último y las paredes de la perforación. Estos espacios permiten la entrada y salida del agua empleada en sacar la piedra triturada, y al mismo tiempo impide que el alma de piedra se atraque en el anillo, y éste en la perforación.

Fig. 1

*Mecha de anillo.*

Fig. 2

*Anillo elevador.*

Fig. 3

*Cabeza de taladro.*

**Art. 6.** Inmediatamente encima de la mecha de anillo se atornilla el anillo elevador (*core-lifter*), fig. 2, al anillo central (*corre-barrell*). Consiste el anillo elevador en un tubo de 20 cm de largo más ó menos y del mismo diámetro exterior que el anillo central. En el interior es ligeramente cónico, con la base del cono hacia arriba, y provisto de un anillo R, con dientes en el interior, é igualmente cónico. Cuando se está taladrando, el anillo se une al alma estrechamente y se separa del cilindro exterior; pero cuando el taladro cesa de funcionar, y la barra de taladro se principia á levantar, este anillo es cogido y levantado por el cilindro exterior; y

por causa de su forma en bisel, está comprimido fuertemente contra el alma de la roca, la cual se rompe en su parte inferior por la fuerza que levanta la barra del taladro.

**Art. 7.** Esta fuerza se suple por un **tambor de cable** (torno) fijo á la parte superior del andamio que sostiene el taladro, y maniobrado por la misma máquina que pone en movimiento rotatorio á la barra del taladro. El cable pasa del tambor hacia arriba á una polea situada en la parte superior de una grúa, y de allí hacia abajo á la extremidad superior de la barra del barreno. La altura considerable de la grúa permite que puedan sacarse unidos en una sola pieza, 12 ó 15 m de barra de taladro.

**Art. 8.** Encima del anillo elevador (*core-lifter*) se halla el **anillo central** (*core-barrell*). Éste está formado de un tubo de hierro forjado de 2.4 á 4.8 m de largo. En su lado exterior hay ranuras en espirales, que permiten que el agua y la piedra triturada puedan ascender y salir de la perforación; y algunas veces tiene diamantes incrustados en su exterior, para evitar que se gaste prontamente. La mecha del barreno, el elevador y el anillo central son de un diámetro exterior uniforme, un poco menor que el diámetro de la perforación. El diámetro exterior de la barra del barreno varía de 46 mm más ó menos para un anillo central de 50 mm hasta á 137 mm para uno de 300 mm.

**Art. 9.** Cuando no se desea conservar intacto el corazón ó alma del taladro, puede usarse una **cabeza de taladro**, fig. 3, en lugar de la mecha de anillo, fig. 1. Ésta consiste en una mecha maciza (excepto la que tiene perforaciones para que salga el agua) y está armada con diamantes, algunos de los cuales sobresalen á su circunferencia.

**Art. 10.** La barra de taladro da de **200 á 400 revoluciones** por minuto. **La máquina** que le comunica el movimiento de rotación se compone generalmente de dos cilindros, fijos ú oscilatorios, actuados por vapor ó aire comprimido, y trabajando en ángulo recto entre sí. Por medio de manubrios dan vuelta á un eje, que comunica su movimiento, por medio de un engranaje cónico, á la barra del barreno. Esta está dispuesta para que baje á medida que avanza la perforación, ya sea por otro **engranaje cónico** movido por la misma máquina, ó por estar fijo á una cruceta de cabeza que conecta los vástagos de émbolos de 2 **cilindros hidráulicos**, siendo los vástagos de los émbolos paralelos á las barras de los barrenos.

**Art. 11.** El barreno de diamante **hace perforaciones perfectamente circulares en líneas rectas y en cualquiera dirección, hasta grandes profundidades**, no siendo raro una de 90 á 450 m. Con la circunstancia de extraer el cilindro central (alma) de la roca **en pedazos de 3 á 5 m sin quebrarlas**; lo cual nos muestra las condiciones y estratificación de la roca perforada, tan útil en perforaciones de reconocimientos, de minas, etc., etc. Se consiguen también de tamaño suficiente para hacer perforaciones de 15 á 37 cm de diámetro, para **pozos artesianos**. La redondez de sus perforaciones permite el empleo de revestimientos de casi el mismo diámetro que el de la perforación; y su dirección recta es ventajosa cuando es necesario usar una bomba.

**Art. 12.** En roca blanda una mecha ó barrena puede perforar 60 ó más m sin amolarla; pero en roca muy dura, dichas mechas se gastan en 3 m ó menos. En 1883-4 un barreno de diamante hecho por la *Am'n Diamond Rock Boring Co* con peso por todo de 640 kg más ó menos, y de un costo de $2,800 próximamente, perforó en 1,428 horas de trabajo efectivo, 53 pozos de 2 pulgs de diámetro, haciendo un total de 2,788 m lineales. Profundidad media de las perforaciones, 52.6 m. **Término medio** de perforación, 1.95 m lineales por hora. Máximo por h, 3.8 m. **Costo medio total**, $1.95 por m lineal más ó menos. La roca era en su mayor parte calcárea, con algún cuarzo y piedra arenisca. Las perforaciones se hicieron en ángulos que variaban de 0° á 45° con la vertical.

Como un término medio aproximado podemos decir que **en la roca ordinaria**, tal como granito, piedra calcárea y arenisca dura, estos taladros pueden hacer perforaciones profundas de 5 á 7½ cm de diámetro, á razón **de 60 ó 75 cm por hora**, á un costo de **$3 á $6 por metro.**

**Art. 13.** Estos taladros se hacen de muchos tamaños **muy diferentes**, y montados de diverso modo, según la obra que se ejecuta. Los precios de catálogo para algunos tamaños de los más usados, son como sigue.

| Diámetro de la perforación. | Profundidad mayor de perforación. | H. P. de la caldera. | Precio. | |
|---|---|---|---|---|
| | | | Perforadora. | Bomba. |
| Milímetros. | Metros. | | $ | $ |
| 65 | 1,219 | 25 | 4,000 | ..... |
| 50 | 477 | 15 | 2,500 | 3,400 |
| » | 305 | 14 | 1,900 | 2,800 |
| 40 | 183 | 10 | 1,400 | 1,900 |
| » | 122 | á la mano. | 425 | ..... |

**Art. 14. En máquinas de taladrar de percusión** la barra del barreno está fuertemente impelida contra la roca **por la presión del vapor ó del aire comprimido**, que actúa sobre un émbolo, P, fig. 4, que se mueve en un cilindro CC, figs 4 y 5, y da 300 golpes de émbolo más ó menos por minuto. La rotación de la barra del barreno se hace automáticamente, como se explica en el art. 27.

**Art. 15. El cilindro** CC, se puede deslizar longitudinalmente en la **pieza** SS, fig. 5, á la cual está sujeto, la que está fija á su vez sobre una trípode, á otro sostén (véanse arts. 18 y 19) que soporta toda la máquina.

**Art. 16. La barra del barreno**, R, que corresponde á la del taladro giratorio está sujeta por medio del mandril K á la extremidad de la varilla del émbolo O. Se principia la perforación con una barra de barreno corta, y con el cilindro tan distante de la perforación como la extensión de la armadura S lo permita. A medida que la mecha penetra en la roca, el cilindro está impulsado hacia adelante, sea automáticamente ó á la mano (véase art. 28), hasta donde lo permita el largo de la armadura. Entonces se para el taladro, cerrando la válvula del vapor *, é invirtiendo el movimiento del aparato de alimentación, el cilindro corre hacia atrás. Se quita entonces la barra del barreno corta y se sustituye con una más larga, repitiendo el procedimiento.

**Art. 17**. Como á medida que se taladra se gasta el filo de la mecha reduciendo así su diámetro un poco, **la perforación se hará, por supuesto, cónica** ó de un diámetro ligeramente menor en el fondo que en su parte superior. La segunda mecha debe por consiguiente tener un diámetro ligeramente más pequeño, por ejemplo 1½ á 3 mm menos, la tercera debe ser menos que la segunda. Por otra parte, en perforaciones profundas, la barra del barreno estará raras veces en línea perfectamente recta, de modo que la mecha, en lugar de percutir siempre en el mismo lugar describe un círculo, y de este modo hace más ancha la perforación.

**Art. 18**. La armadura S, en que se desliza el cilindro, está dispuesta de manera tal que puede fijarse por medio de ganchos á una **trípode**, fig. 5, ó á una **barra ó columna**, á lo largo de la cual puede resbalar. La columna, cuando está horizontal, puede descansar sobre dos pares de patas, ó puede fijarse en cualquiera posición por medio de abrazaderas á los lados opuestos de una ranura angosta, ó contra el piso ó techo de una cuba, etc., en cuyo caso una de sus extremidades está provista de un tornillo que sobresale para hacer que las dos extremidades de la columna ejerzan una presión firme contra las paredes opuestas de la roca. En todo caso, los soportes del taladro están ajustados de manera que puedan perforar en cualquiera dirección.

**Art. 19**. Frecuentemente se fija el taladro á un **brazo corto por medio de ganchos**, cuyo brazo á su vez está sujeto á una columna, y sobresale de ella en ángulo recto. Al brazo puede hacérsele cambiar de posición vertical en la columna y también girar alrededor de ella tomando cualquiera posición. Esta disposición da al taladro un grado mayor de movilidad y le permite hacer perforaciones en una extensión mayor sin mover la columna.

**Art. 20**. En los túneles, uno ó más taladros pueden montarse sobre un **carro de taladros**, que corra sobre una línea de carriles de ferrocarril, colocados longitudinalmente dentro del túnel. Sobre estos carriles el carro se lleva donde se va á perforar. El ancho de la vía debe ser tal, que admita debajo del carro de taladrar una vía más angosta. Sobre esta vía angosta corren carros para sacar las piedras voladas en las explosiones. En este país se usan los carros de taladros menos que en Europa.

★ Para evitar repeticiones, usaremos la palabra **vapor** para significar tanto *vapor como aire comprimido.*

**Art. 21.** La presión aplicada á los cilindros de los taladros de percusión es generalmente de 4 á 5 kg por cm cuad más ó menos. **Un taladro hace en una hora** una perforación de 25 á 50 mm de diámetro y de 1 á 3 m de profundidad, según la calidad de la roca y el tamaño de la máquina, al precio **de 33 á 30 centavos por m lineal**, pagando los trabajadores á razón de $1 por día. **Es necesario afilar las mechas** á cada .60 ó 1.20 m que se perforen. Un herrero con un ayudante puede afilar y componer las mechas para 5 ó 6 máquinas.

**Art. 22.** Las mechas tienen muchas formas diferentes, variando con la naturaleza de la obra que se va á ejecutar. En roca dura uniforme se emplean mechas de dos filos cortantes, que forman una cruz de brazos iguales en ángulo recto. Para roca en capas ó filones, los brazos de la cruz son iguales, pero forman dos ángulos agudos y dos obtusos, como en la letra X. En roca blanda, se da algunas veces al filo cortante la forma de la letra Z.

**Art. 23. Cada taladro requiere** un hombre para su manejo. Dos ó tres hombres se requieren para mudar de un lugar á otro los tamaños más pesados. Un hombre puede atender á un compresor de aire pequeño y su caldera.

**Art. 24.** Las figs. 4 y 5 representan el taladro de percusión « **Eclipse** », de la *Ingersoll Rock Drill Co.*, N. Y. La fig. 5, muestra el taladro, montado (como casi siempre) sobre una trípode. La fig. 4 es una sección longitudinal del cilindro, de la cámara, de la válvula y del émbolo.

**Art. 25.** El cilindro C, está provisto en ambas puntas de una **almohadilla** de goma elástica N, para amortiguar los golpes del émbolo, el cual está expuesto, en todos los taladros de percusión, á golpear contra cualquiera de las cabezas del cilindro. El lado de la almohadilla más próximo al émbolo está protegido por una plancha delgada de hierro. Las almohadillas tienen que renovarse de tiempo en tiempo.

**Art. 26. La válvula** V tiene la forma de una devanadera. El perno B pasa flojamente por su centro y le sirve de guía. El vapor de la caldera entra en la caja de vapor, y ocupa todo el espacio comprendido entre los dos rebordes de las extremidades de la válvula, con excepción de *u*. El vapor empuja la válvula alternativamente de un extremo de la cámara al otro, según que uno ú otro punto esté libre de la presión por estar ó no, en comunicación con la cámara vacía E, por medio de los pasadizos DD' y FF'. D y D' están en comunicación con los extremos de la caja de vapor por pasadizos que no se ven en la figura; mientras F y F' comunican, por pasadizos semejantes, con la cámara vacía E. El émbolo tiene un canal anular, LL', en su alrededor. Cualquiera que sea la posición del émbolo, uno de los pasadizos D ó D' está siempre, por medio de este canal, en comunicación con su pasadizo correspondiente, F ó F', que comunican con la cámara vacía. De este modo uno ú otro extremo de la cámara de la válvula está siempre en comunicación con el aire libre; y la válvula está cerrada hacia ese extremo por la presión del vapor que la rodea, entrando aquél al cilindro, C, por el otro extremo.

**Art. 27.** La rotación del émbolo, y con ella la de la barra del barreno, se efectúan así : La barra cilíndrica de acero A, provista de ranuras en espirales, y llamada **barra estriada**, pasa á través de la **tuerca estriada** H y maniobra dentro de ella; dicha tuerca está fija firmemente á la extremidad del émbolo, y tiene ranuras espirales correspondientes á las de la barra estriada. Dicha barra está fija, en su extremidad superior, á la rueda dentada J dispuesta de tal manera, que cuando se efectúa el golpe de émbolo hacia abajo, la tuerca estriada H, actuando sobre las ranuras ó estrías de la barra estriada, comunica á esta barra, y por ella á la rueda dentada, un movimiento rotatorio alrededor de su eje común. El peso del émbolo y su fuerza al moverse son tales, que comunican fácilmente rotación á la rueda dentada sin girar el mismo. De este modo se impide que la mecha gire al golpear. Pero cuando el émbolo sube, la tendencia de la tuerca estriada es comunicar rotación á la barra estriada y á la rueda dentada en la dirección *opuesta:* pero este movimiento está impedido por los dientes de la rueda dentada, y la barra estriada permanece *estacionaria*, mientras que el *émbolo, el vástago del émbolo y la mecha giran* sobre su eje común.

**Art. 28. El tornillo de alimentación** M está provisto en su parte superior de un anillo ó collar, Q, en la armadura fija. De este modo se impide que se mueva longitudinalmente, cuando se le da vuelta por medio de un manubrio fijo en su parte superior. La parte inferior del tornillo gira en una tuerca T, fija al cilindro, que se mueve longitudinalmente al dar vueltas al manubrio. Los taladros grandes están frecuentemente provistos de un **sistema de alimentación automática**, además del manubrio de mano. En este sistema, cuando el cilindro se mueve hacia

adelante, y en consecuencia el émbolo avanza hasta cerca del límite de su carrera, el émbolo ejerce presión contra un tope inclinado dentro del cilindro cerca de su extremidad. El movimiento de este tope, por medio de una pieza exterior, que corre á lo largo del cilindro, está provisto en su parte superior de una pieza que comunica

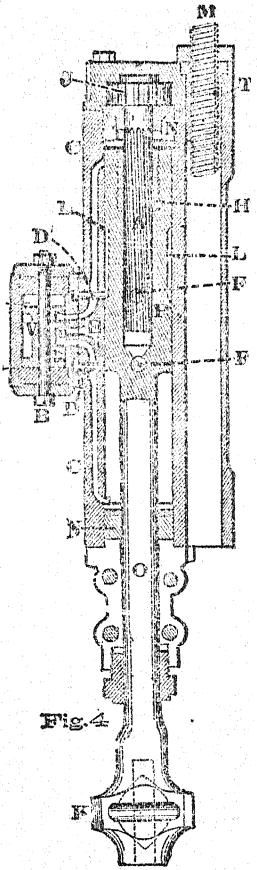

Fig. 4.

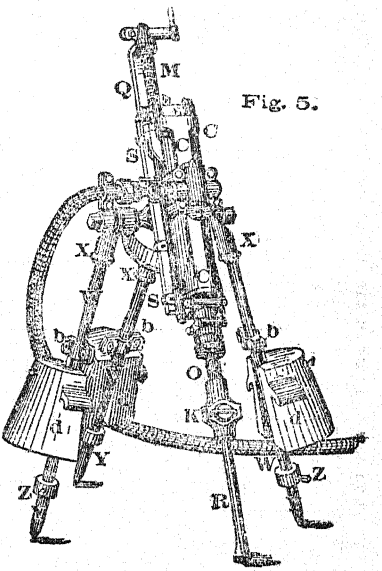

Fig. 5.

movimiento rotatorio á una rueda dentada fija al tornillo de alimentación. Cuando se desea, la alimentación automática puede desengranarse, y hacerla á la mano por medio del manubrio.

**Art. 29. Las piernas de la trípode** se componen de tubos de hierro forjado WW. Sus extremidades superiores están atornilladas en cajas XX. En sus partes inferiores reciben las barras cónicas puntiagudas de acero YY, de .60 á .90 m de largo más ó menos. Estas piernas pueden alargarse ó acortarse, por medio de los tornillos de presión ZZ, graduando así la distancia á que las barras YY pueden

entrar. Las abrazaderas *bb*, tienen ganchos en forma de L unidos á ellas. Sobre estos ganchos cuelgan **los pesos** *dd*, que sujetan la máquina contra la reacción de las percusiones hacia arriba.

**Art. 30.** La tabla siguiente da las dimensiones principales de estos taladros, con **los diámetros y profundidad de perforaciones**, á los cuales se adapta cada uno de ellos. El tamaño H se usa para trabajos submarinos, de túneles y cortadas grandes en roca. G y F se usan para túneles, nivelaciones de calles, pedreras y en trabajos de cloacas. E, D y C para trabajos ordinarios de minas. B sirve sólo para trabajos muy sencillos. Al solicitar datos acerca del valor de estos taladros y compresores, dese la descripción más amplia posible (acompañando un croquis) de la obra que va á hacerse, exponiendo su estado actual y lo que se quiere hacer. Dígase si el trabajo está en la superficie ó debajo de tierra; á qué distancia debe llevarse el vapor ó el aire comprimido; la profundidad de las perforaciones que van hacerse, y la clase de roca, etc. Los barrenos de percusión se venden sin restricciones con respecto á la naturaleza y extensión del trabajo, para el cual se van usar.

* De la parte superior de la mangueta del manubrio alimentador, hasta el extremo inferior de la carrera del émbolo.

** Para tener el máximo de perforaciones horizontales, redúzcase una cuarta parte.

*** La máquina A está montada sobre una pequeña armadura.

**Art. 31. Las máquinas de taladrar de diferentes fabricantes varían principalmente** en el modo de actuar la válvula. Algunas de ellas son movidas por **vapor**, como la « Ingersoll Eclipse », art. 26. En otras la válvula se pone en movimiento por medio de una **palanca ó reborde** que penetra en el cilndro para así llegar al contacto del émbolo, que la mueve en cada carrera. Como estas carreras de émbolo se hacen con gran fuerza, algunas 300 veces por minuto, el juego de válvulas está sujeto á un deterioro muy grande.

**Art. 32.** En el barreno «**Pequeño gigante**», fabricado por la **Rand Drill Co.**, la válvula V, fig. 6, se desliza hacia adelante y hacia atrás en la misma dirección del movimiento del émbolo, por el reborde T.

**Art. 33. La misma fábrica** vende los taladros « **Economizer** » y « **Slugger** », en los cuales, como en el « Ingersoll Eclipse », la válvula se pone en movimiento por el vapor, pero bajo un principio enteramente diferente. En estos dos aparatos no existe ningún vapor comprimido (*steam cushion*) contra el cual pueda chocar el émbolo en su carrera hacia abajo, y de este modo, toda su fuerza se aplica y consume más completamente sobre la roca. El cojín de vapor comprimido que se acumula detrás ó encima del émbolo cuando éste hace su carrera hacia atrás, es formado por el vapor exhausto. Ambas máquinas suspenden la entrada del vapor antes del fin de la carrera del émbolo, usándolo por expansión. En la carrera de émbolo hacia abajo la « Economizer » corta el vapor primero que la « Slugger » y por esta razón se llama así.

**Art. 34.** En el taladro « Burleigh » mejorado, la válvula V, fig. 7, es movida por

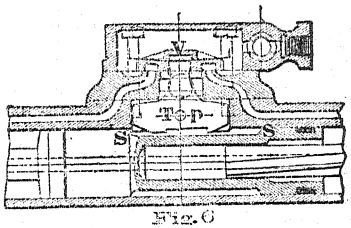

Fig. 6

medio de *dos* palanquitas TT' que están empujadas alternativamente por las extremidades del émbolo P.

**Art. 35.** En el taladro « Dynamic », inventado por el profesor De Volson Wood, la válvula, fig. 8, está adherida á un émbolo de válvula V, fig. 8, que se mueve hacia adelante y hacia atrás por el vapor, actuando alternativamente sobre sus dos

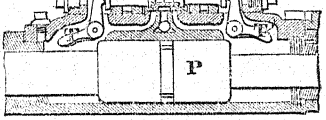

**Fig. 7.**

extremidades. La entrada de este vapor está regulada por una pequeña válvula auxiliar *a*, en cuya parte posterior se encuentra una proyección que ajusta en una ranura en espiral que se ve en el tarugo *n*. Este tarugo está continuamente comprimido hacia abajo (según la posición de la fig. 8) por el vapor que lo comprime en su parte superior, pero es levantado en cada carrera de émbolo por la superficie cónica del émbolo, P, que lo comprime en su pie. De este modo, el tarugo sube y baja continuamente, llevándose la válvula *a*. Dándole vuelta al tarugo, por medio del mango ajustador *s*, se hace que la proyección de la válvula ocupe un punto más alto ó más bajo en la ranura espiral, y de este modo puede variarse la carrera del émbolo, ó limitarla á una parte del cilindro.

En este taladro, diferente del Ingersoll, art. 27, el **émbolo tiene un movimiento rotatorio** en su carrera hacia abajo. **El vástago**, *o*, **del émbolo es**

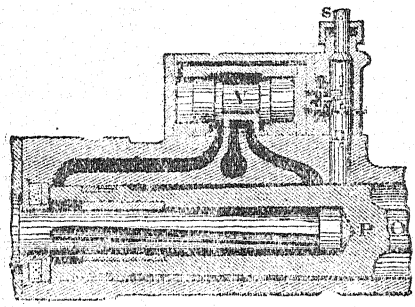

Fig. 8

**más liviano que en los otros taladros.** Éste presenta mayor superficie y por tanto tiene mayor fuerza.

Las piernas de la trípode son de barras de hierro y su longitud puede graduarse aumentándola ó recortándola.

**Art. 36.** El taladro de mano « **Pierce** » es un taladro de percusión. Se maneja por un manubrio, que hace girar un disco de 60 cm de diámetro más ó menos. Este disco tiene una hendedura ó muesca semicircular, en la cual actúa el brazo que levanta la barra del barreno. Este brazo, al levantarse, comprime un resorte enroscado, el cual, en la carrera hacia abajo del émbolo, empuja la mecha contra la roca. Una bola de hierro con peso de 13 kg ó más, se envía con cada máquina. Esta bola puede atornillarse sobre la parte superior de la barra del taladro, para dar mayor fuerza á los golpes de la mecha. Puede usarse la bola sin el resorte desengranando este último.

Este taladro da, más ó menos, 40 golpes de 25 á 30 cm por minuto, y hace las perforaciones de 18 á 62 mm de diámetro. Puede arreglarse de manera que perfore á una profundidad de 9 m ó más. Está provisto de una rueda ó mollejón de esmeril para afilar las mechas, la cual se mueve por medio del manubrio, desengranando al efecto el disco.

**El taladro está montado** sobre un andamio rectangular de dos patas de 1.5 m de alto por .60 m de ancho, hechas de tubos de hierro. En la parte superior de este andamio está sujeta una tercera pata, y al ajustarla puede variarse el ángulo que forma la barra del barreno con la vertical. Semejante á los otros taladros de mano de percusión, este taladro deja de trabajar con ventaja cuando dicho ángulo excede de 45° más ó menos.

**Art. 37. Acanaladura.** Consiste ésta en practicar cortes largos, profundos y angostos en la roca. De este modo pueden sacarse bloques grandes de piedras sin volarlas y sin temor de fracturarlas. Esto se hace ordinariamente ejecutando una hilera de perforaciones á unos 3 cm de distancia unas de otras, y luego rompiendo los espacios intermedios por medio de un cincel sin filo. Esto se llama acanaladura á cincel. Con este objeto se monta una máquina de taladro á vapor sobre una barra horizontal sostenida por dos pares de patas. La barra horizontal está colocada sobre la línea donde se va á perforar, y el barreno se desliza sobre ella de una perforación á otra. Al emplearlo así, se desengrana el aparato de rotación, de manera que el filo del cincel mantenga su posición en la línea de perforaciones.

**Art. 38. La máquina de acanalar de patente de Saunders,** de la Compañía Ingersoll, se compone de una máquina de taladrar roca, que tiene en lugar de la mecha ordinaria de taladrar, un juego de instrumentos compuestos de cinceles, uno al lado del otro, formando así un instrumento cortante de 17 cm de largo por 18 mm de ancho más ó menos. Este instrumento tiene tantos filos cortantes (cada uno tiene un largo igual al ancho del cincel) como cinceles hay en él. La máquina está sostenida por un carro, que se mueve sobre carriles paralelos

a canal que se va á cortar. Por supuesto, que el instrumento no tiene movimiento de rotación, sino que la barra estriada A, fig. 4, se emplea para mover el carro más ó menos una pulgada después de cada percusión. Durante la percusión no se mueve el carro. Bajo circunstancias favorables **esta máquina ha cortado de 7 á 9 m cuad** de canal en un día de 10 horas de trabajo. **Su peso,** incluyendo el carro, es de 2,250 kg.

El instrumento está provisto de una válvula, por la cual, cuando se desea, **puede cerrarse** el vapor del émbolo en su carrera hacia abajo; de modo que la percusión puede hacerse con el *peso* del émbolo, vástago y mecha solamente.

**Art. 39.** La Compañía Ingersoll tiene un método especial, ideado por el Sr. W. L. Saunders, I. C., **para barrenar y volar las rocas debajo del agua**, aunque estén cubiertas de fango á considerable altura.

**Art. 40. Los compresores de aire** para taladros de roca, como los hechos y usados en los E. U., son generalmente máquinas horizontales de acción directa. Es decir, que los ejes de los cilindros de vapor y aire son horizontales, y que el vástago del émbolo pasa directamente del cilindro de vapor al cilindro de aire. Un volante está fijo al vástago del émbolo por medio de un manubrio y barra de conexión. Algunas veces la máquina de vapor está separada del compresor, y se transmite la fuerza al último por medio de correas ó engranajes: puede emplearse de la misma manera fuerza hidráulica. El aire es impelido dentro de un receptáculo compuesto generalmente de un cilindro (de .90 á 1.20 m de diám) de planchas de hierro, y que tiene una longitud de 1.5 á 3.66 m.

Si el cilindro de aire está dispuesto de modo que deje entrar el aire en una sola carrera del émbolo, y lo impela al receptáculo en la carrera de retorno, se llama **máquina de simple acción**. Cuando en cada carrera deja entrar el aire y o lanza al receptáculo, se llama de **doble acción**. Cuando el compresor no tiene ri no un solo cilindro, se llama **sencillo**, y si tiene dos compresores sencillos, es **doble** (*duplex*). **Las válvulas** pueden ser **válvulas de tubo,** fijas por resortes y movidas por la misma presión del aire, ó **válvulas de corredera,** actuadas por medio de excéntricas y barras de conexión, como en las máquinas de vapor.

La compresión del aire desarrolla **calor,** y éste se hace desaparecer, haciendo circular agua fría por el émbolo de aire y por cubiertas que envuelven el cilindro de aire, ó inyectándola en dicho cilindro en forma de irrigación. O ambos métodos pueden usarse al mismo tiempo.

**Art. 41.** La siguiente lista parcial de los compresores de Clayton, formada con datos recibidos de los fabricantes, muestra las **dimensiones** y **trabajo** que efectúa cada uno de ellos. Damos también una lista de los **receptáculos** hechos por ellos.

## COMPRESORES DE AIRE DE DOBLE ACCIÓN DE CLAYTON.

Los receptáculos están provistos de manómetros de bronce, de indicadores de cristal de nivel de agua, de válvula de seguridad, de válvulas de escape, llaves de prueba, rebordes y conexiones para alimentación automática.

# TRACCIÓN

**Tracción sobre caminos carreteros y canales,** ó la fuerza que se necesita para arrastrar por ellos vehículos y botes.

La siguiente tabla da (con aproximaciones tolerables) la fuerza en kg por toneladas que se necesita para arrastrar por caballos un coche ó diligencia con pasajeros, por la pendiente del camino (buen camino) Holyhead de Inglaterra, determinado por medio de un dinamómetro. El peso entero era de 1½ tonaladas; pero en la tabla se dan los resultados por toneladas. Por la naturaleza de tales experiencias no es posible alcanzar gran exactitud.

(*Obs. del T.* — Hemos convertido los ejemplos y la tabla del autor al sistema métrico.)

| Pendiente. | A 6,437 metros por hora. | A 9,656 metros por hora. | A 12,874 metros por hora. | A 16,093 metros por hora. |
|---|---|---|---|---|
| | kilogramos. | kilogramos. | kilogramos. | kilogramos. |
| 1 en 15½ | 95.25 | 97.97 | 102.06 | 108.86 |

| Horizontal. | 34.47 | 36.28 | 38.56 | 41.27 |

Los resultados siguientes apreciados en su mayor parte con el mismo instrumento son también en kilogramos por tonelada, con un carro de cuatro ruedas á paso, lento, en un plano á nivel y la vía en buena condición.

Sobre un pavimento de cubos de piedra, de 15 á 24 kilogs por tonelada métrica.

Sobre una vía macadanizada de pequeños pedazos de piedra, de 28 á 34 kilogramos por tonelada métrica.

Sobre una vía de cascajo, 64 kilogs por tonelada métrica.

Sobre una vía pavimentada con piedras pequeñas, 21 á 34 kilogs por tonelada métrica.

Sobre piedra picada en lecho de concreto, 21 á 34 kilogs por tonelada métrica.

Sobre vías de tierra común, 90 á 136 kilogs.
Sobre una vía entablada 14 á 23 kilogs.

**La fuerza de tracción de un caballo disminuye á proporción que aumenta su velocidad**, y quizá dentro de ciertos límites, de 1½ á 6 km por hora, esta disminución está en razón inversa con ella. De este modo el término medio de la tracción de un caballo, sobre una *superficie á nivel*, tirando por espacio de 10 horas al día, se puede suponer aproximadamente como sigue. (*Obs. del T.* — Al convertir esta tabla hemos puesto números sin fracciones y aproximados, porque bastan para la práctica y son más fáciles de retener en la memoria.)

| Metros por hora. | Kilogramos de tracción. | Metros por hora. | Kilogramos de tracción. |
|---|---|---|---|
| 1,200..... | 151 | 3,600..... | 50 |
| 1,600..... | 113 | 4,000..... | 45 |
| 2,000..... | 90 | 4,400..... | 41 |
| 2,400..... | 76 | 4,800..... | 37 |
| 2,800..... | 65 | 5,600..... | 32 |
| 3,200..... | 57 | 6,400..... | 28 |

Si trabaja * durante un número menor de horas, su tracción puede aumentar á proporción que disminuyen aquéllas; por ejemplo, para 5 horas por día, la tracción á 4,000 met por hora será de 90 kg.

Cuando sube una pendiente, su fuerza disminuye rápidamente porque tiene que suspender una parte de su propio peso (cuyo término medio es como de 450 á 500 kg), el cual puede apenas sobrellevarlo sin otra carga en una pendiente de 5 á 1.

En una pendiente semejante debe ejercer una fuerza igual á 199 kg por tonelada, es decir, de 90 kg por los 450 kg de su propio peso. Suponiendo que en un pedazo á nivel de buen camino tuviese al arrastrar un carro cargado que pese con carga y todo una tonelada, que ejercer una tracción de 27 kg; entonces al subir un pendiente de 4° (es decir, de 1 en 14.3), tendría una tracción de 70.72 kg para el peso de la tonelada, y de 30.39 kg para su propio peso, 101.11 kg por todo. Un caballo puede ejercer *por algunos minutos* hasta el doble de su tracción regular sin gran fatiga. Estos cálculos demuestran que en una pendiente de 4°, un caballo mediano se fatiga bastante cuando arrastra una carga total de una tonelada, y se le debe permitir por consiguiente andar al paso, y descansar á cortos intervalos. La carga justa para un caballo solo, con un carro, á un paso variable, en buen orden y trabajando 10 horas por día en un camino ordinario, onduloso, es como de media tonelada, además del carro, que tiene como media tonelada más. Con dos caballos y el mismo carro, el peso solo puede ser como de 1½ toneladas.

*Advertencia.* Como la acción de la gravedad es la misma en los caminos buenos que en los malos, se desprende que **se hacen más dificultosas las pendientes mientras mejor sea el camino**. Así, en una pendiente de 2°, es decir, de 3 1/2 por ciento, y teniendo en cuenta tan sólo el peso, se requiere una tracción de 35.38 kg por tonelada; que es como 10 veces la de un ferrocarril á nivel con velocidad de 9,655 metros por hora; pero es casi igual á la requerida en un camino común á nivel y á la misma velocidad. Por tanto (hablando así al poco más ó menos) se necesitarían 10 locomotoras en lugar de 1; pero sólo 2 caballos en lugar de 1.

Una pendiente de 1 en 35, ó 2.80 por ciento, ó de 1°38′ es la mayor pendiente en que pueden trabajar caballos bajando un camino sólido y plano á un trote ligero y sin peligro. De ella no debe, por tanto, pasarse sino cuando sea absolutamente necesario.

**En los canales y otras aguas**, el líquido como medio resistente hace las veces del rozamiento en los caminos á nivel; pero es distinto al rozamiento; su resistencia varía como los cuadrados de la velocidad, á lo menos desde la velocidad de 2 kilómetros por hora, hasta la de 13 kilómetros por hora. A proporción que la velocidad desciende, la resistencia disminuye más, y más rápidamente: se trata del caso en que el cuerpo en movimiento flota en parte sobre la superficie ó se sumerge enteramente. Al remolcar á lo largo de canales estancados, etc. la velocidad es generalmente de 1.5 á 4 km por hora, y para cargas en mas usado de

* *N. del T.* — Para nuestra clase de caballos carecemos de experiencias que nos den este dato; pero de seguro que es mucho menor, puesto que los caballos americanos son más grandes, dobles y mejor enrazados que los nuestros, y por tanto mucho más fuertes.

2.4 á 3.2 km. Se necesita menos fuerza para remolcar un bote con una velocidad de 2 kilómetros por hora donde no hay corriente, que á 1¼ por hora contra una corriente de ¼ de kilómetro porque en el último caso el bote tiene que *ser subido* por el plano inclinado que produce la corriente.

La fuerza que se requiere para remolcar un bote á lo largo de un canal, depende en *gran parte* de las áreas comparativas de las secciones transversales del canal y de la parte sumergida del bote. Cuando la anchura del canal en la línea de flotación es por lo menos 4 veces la del bote, y el área de su sección transversal por lo menos de 6¼ veces la de la sección transversal de la parte sumergida del bote, el remolque á velocidades usadas en los canales será casi tan fácil como en aguas más anchas y profundas. Con menos dimensiones se hace más difícil. (D'Aubuisson.) Depende mucho también de la forma de la proa y otras partes del bote, y de la proporción entre el largo, su anchura y profundidad. Por consiguiente, se ve que el solo peso de la carga no es un elemento de tanta importancia en estos casos, como lo es en tierra. El asunto es sin embargo muy complicado para tratar de él aquí. Morin dice que los constructores navales estiman la resistencia de los buques de vela y de los vapores en el mar sólo como de 2½ á 3½ kg por metro cuadrado de sección transversal sumergida, cuando la velocidad es de 3,200 metros por hora. Es mucho mayor en canales.

**En la navegación del Schuylkill de Pensilvania**, que es un canal mezclado con aguas de flujo y reflujo, para 173 kilómetros, la carga regular de 3 caballos ó mulas es un bote de muy buena construcción, sin quilla, como de 30 m de largo; con baos de 5.33 m y 2.43 m de profundidad de bodega, que cala 1.68 m cuando está cargado *. El peso del bote es como de 65 toneladas; carga 175 toneladas de carbón; peso total 240 toneladas, á 80 por caballo ó mula. En el viaje de descenso con los botes cargados, los animales trabajan durante cuatro días *remolcando* (excepto en las represas) por espacio de 18 horas de las 24 del día, excediendo en mucho á los límites concedidos generalmente para esfuerzos continuos.

En las secciones del canal (en que tiene 18.29 m la línea de flotación, y 1.83 m de profundidad, la velocidad es de 2,815 metros por hora, y en los estanques profundos y anchos, 3,200 metros más ó menos.

En el viaje de subida con los botes, de 65 toneladas, vacíos, la velocidad media es como de 4 km por hora. Los botes vacíos traen como 45 cm de agua, y frecuentemente continúan sin descansar día y noche en todo el trayecto de 173 km. Los animales tienen generalmente dos ó tres días de descanso á cada fin de viaje; pero quedan muy maltratados al fin de la estación.

Si nuestra suposición anterior, de 65 kg de tracción de un caballo á razón de 2.800 metros por hora, es correcta, la tracción de los botes cargados en las secciones del canal es $\frac{65}{80 \text{ toneladas}} = 0.81$ kg por tonelada.

El inteligente ingeniero y superintendente del *Sch. Nav., James F. Smith*, dió como resultado de sus propias y extensas observaciones, que uno de estos grandes botes cargados (240 toneladas por todo) sin fatigar los animales puede ser arrastrado por todo el canal durante 10 horas al día como sigue : por un caballo ó mula á razón de 1,600 metros; por 2 animales á razón de 2,400 metros, y por 3 á razón de 2,800 metros por hora. Cuando se emplean cuatro animales, la ganancia de tiempo es muy insignificante. En una época de rivalidad entre los boteros, uno de ellos empleó 8 caballos, pero con ellos no pudo pasar de 4 km por hora. Dos ó más caballos juntos no pueden, trabajando por horas, halar tanto como cuando trabajan separadamente.

Si nuestra pequeña tabla anterior de la tracción de un caballo á diferentes velocidades por 10 horas, es correcta, entonces la tracción de los anteriores botes cargados de carbón (240 toneladas) en las secciones del canal de navegación, es como sigue : La última columna da la tracción en kg por m cuadrado del área de la sección transversal sumergida donde es mayor; á saber : como de 8.83 metros cuadrados.

(*Obs. del T.* — Damos á continuación la tabla que trae el autor convertida al sistema métrico.)

| Caballos. | Mets por hora. | | Kg por tonel. | Kg por m². |
|---|---|---|---|---|
| 1..... | 1,600 | $\frac{113}{240}$ | .47 | 12.83 |

* **Valor de los botes**, en 1884 (Canal Schuylkill), como $1,800. Reparaciones anuales como $85. Los botes duraban de 16 á 20 años. Longitud como 31 m; bao de 5.33 m; calado de .45 m á 1.68 m; capacidad 180 toneladas; peso como 58 toneladas; velocidad con 3 mulas, 2,800 metros por hora.

| | | | | |
|---|---|---|---|---|
| 2..... | 2,400 | $\frac{152}{240}$ | .63 | 17.08 |
| 3..... | 2,800 | $\frac{195}{240}$ | .81 | 21.96 |

| 3 (subiendo). | 4,000 | $\frac{135}{65}$ | 2.10 | 61.01 |

**En el canal Lachine**, Canadá, de 36.75 m de ancho en la línea de flotación, 24.38 m en el fondo y 2.74 m de profundidad en la compuerta, 6 caballos remolcaron con facilidad goletas cargadas.

Antes del ensanche del **canal Erie** * sus dimensiones eran 12.19 m en la línea de flotación, 8.53 m de fondo y 1.22 m de profundidad de agua. El término medio del peso de los botes era como de 30 toncladas. Con 75 toneladas de carga, ó un total de 105 toneladas, fueron remolcados por dos caballos á razón de 3,200 m por hora, lo cual da, según nuestra tabla (114 ÷ 105) una tracción de cerca de 1.09 kg por tonelada. Los botes eran como de 24.38 m de largo, con baos de 4.27 m, y calaban como .99 m cuando estaban cargados; por consiguiente, la tracción, según nuestra tabla, sería como de 27.82 kg por metro cuad de sección transversal sumergida. Mientras que para botes de 82 toneladas cargados en un canal más pequeño (casi tocando los botes el fondo), la tracción á 2,800 mets sería de 1.59 kg por tonelada. También da 27.83 kg por metro cuadrado de sección sumergida.

# FUERZA ANIMAL

**Art. 1.** En lo que se refiere á caballos, este asunto se ha tratado ya por separado bajo el encabezamiento precedente de « Tracción ». Todas las apreciaciones que se hagan á este respecto serán hasta cierto punto vagas, debido á las diferentes resistencias y velocidades entre animales de la misma especie, así como al grado de educación ó expedición que tengan para cualquier trabajo especial. Las autoridades en la materia difieren mucho en este punto, y algunas veces se expresan de una manera tan indefinida, que arrojan duda respecto á sus opiniones. Esperamos, sin embargo, que se encuentre el cálculo que sigue tan aproximado á los términos medios prácticos, como lo permite la naturaleza del caso con nuestros imperfectos conocimientos actuales. Supongamos un caballo medianamente educado, que no pese menos de media tonelada, bien tratado y bien mantenido. Dicho caballo trabajando 10 horas por día á razón de 4,000 m por hora, en un camino bueno y *á nivel*, tal como el andén de un canal, ó un andén circular de caballos **, **puede ejercer un tiro continuo de 45.35 kg (100 libras)**.

Ahora bien, 4,000 m por hora equivalen á 66.66 m por minuto, ó á $3^2/_3$ pies (1.11 m) por segundo ; y como 10 horas contienen 600 minutos, su trabajo de un día, halando constantemente nive con dicha velocidad, asciende á

$$600 \times 66.66 \times 45.35 = 1{,}813{,}818 \text{ kilográmetros por día;}$$

ó como 50 kilográmetros por segundo ***. Lo cual significa que ejerce fuerza suficiente durante el día para *suspender*, á 1 metro de altura, 1,813,818 kg, ó sean 181,381 á 10 m.

---

* Extensión como 584 km ; precio $12.30 por metro lineal. El canal ensanchado tiene 21.33 m, 12.80 m ; y 2.13 de agua ; y cuesta el ensanche $35.40 por metro lineal.
El precio de los diferentes canales de Pensilvania varía de 14 á 31 dólares el metro lineal.

** Para hacer que un caballo trabaje con facilidad en **un andén circular**, el diámetro de éste no debe ser menor de 7 á 9 m, ó mejor aún, como de 11 m.

*** **Un caballo de fuerza (nominal)**, son 33,000 pies-libras (4,562.33 kilográmetros) por minuto; éste es el valor del caballo asignado por Boulton y Watt á las máquinas

Puede ejercer esta fuerza ya por *tracción* (*remolcando* o *halando*) ó ya *levantando* ó ***suspendiendo*** pesos. Si tiene que suspender una pequeña carga á una gran altura la maquinaria por medio de la cual lo hace debe estar dispuesta de tal modo que se pueda ganar velocidad con lo que se pierda en fuerza (así se dice vulgarmente aunque impropiamente). Sea que suspenda el gran peso á una pequeña altura ó un peso pequeño á grande altura, empleará siempre la misma cantidad de fuerza. La experiencia demuestra que entre los límites de 5 á 10 horas por día (permaneciendo la velocidad la misma), **puede aumentarse el tiro de un caballo casi en la misma proporción en que disminuye el tiempo**. De modo que cuando trabaja de 5 á 10 horas diarias, dicho aumento será como se muestra en la tabla que sigue. Por consiguiente, puede hacerse la cantidad total de 1,813,818 kilográmetros de trabajo por día, ya trabaje el caballo 5, 6 ú 8, etc., horas por día *. Esto, por supuesto, supone que realmente trabaje *todo el tiempo* sin pararse.

**Tabla del tiro á nivel de un caballo, á razón de 4,000 m por hora.**

| Horas por día. | Kilogs. | Horas por día. | Kilogs. |
|---|---|---|---|
| 10 | 45.36 | 7 | 64.80 |
| 9 | 50.40 | 6 | 75.60 |
| 8 | 56.70 | 5 | 90.72 |

**La experiencia nos demuestra también que, para velocidades comprendidas entre 1,200 m y 6,400 m por hora, su esfuerzo ó tiro estará en razón inversa de su velocidad.** Así á 3,200 m por hora, para las 10 horas del día, el tiro será

| metros | metros | | kilogs | kilogs |
|---|---|---|---|---|
| 3,200 | : 4,000 | = | 45.36 | : 56.70 |

A 2,400 m serían como 75 kg.

Por tanto, en este caso también la cantidad de trabajo diario permanece la misma §, y entre todos los límites anteriores de horas y velocidad, se puede tomar prácticamente como 13,200,000 pies-libras (1,824,930 kilográmetros) por día, ó 22,000 pies-libras (3,041.56 kilográmetros) por minuto de un día de 10 horas. Pero eso no significa que el caballo puede efectivamente en la práctica trabajar sobre pesos en esta proporción, porque generalmente una parte de su fuerza se emplea en vencer el *rozamiento* de la maquinaria que pone en movimiento, y, además, la naturaleza del trabajo puede requerir que el caballo se pare frecuentemente; de modo que en un *día de trabajo* de 8 á 10 horas, puede no haber *trabajado* efectivamente más de 5, 6 ó 7 horas.

Como cálculo aproximado, despreciando algo por la pérdida de fuerza en vencer el rozamiento de la maquinaria de suspensión, y el peso de las cadenas, cubos, etc., podemos decir que **el trabajo útil diario de un caballo levantando pesos**

---

que ofrecen en venta, y en esta inteligencia los compradores que deseen sustituir vapor por caballo no sufrirán contratiempo alguno. Este valor supuesto puede llevarse á la práctica aplicando un caballo fuerte que trabaje diariamente á razón de 8 á 10 horas por día; pero como la máquina puede trabajar sin pararse durante meses, días y noches, lo cual no podría hacer un caballo, es claro que el caballo de vapor ó de una máquina puede efectuar mucho más trabajo que cualquier otro caballo. Por consiguiente, muchos objetan el término « caballo de fuerza » aplicado á las máquinas; pero desde luego que todo el mundo comprende su significado, y como dicho término es conveniente, no es en efecto objetable. Boulton y Watt quieren decir que una máquina de un caballo es la que efectúa en un momento cualquiera el trabajo de un caballo muy fuerte. Un caballo *mediano* no haría sino 22,000 pies-libras** (3,041.56 kilográmetros) por minuto.

* Es claro que aun cuando el *día de trabajo* sea el mismo, la hora ó el minuto de trabajo variarán con el número de horas asignadas al día de trabajo. Debe recordarse que *un día de trabajo* de un número de horas dado no implica absolutamente en todos los casos un número de horas de *trabajo efectivo*, sino que comprende las interrupciones y paradas.

§ **Esta advertencia sobre la velocidad no se refiere á las cargas remolcadas en el agua.** Así, si el tiro á razón de 2 millas por hora es de 125 libras (56.70 kg), y á 4 millas de 62 1/2 libras (28.29 kg), *en tierra* arrastrará pesos en esta proporción; pero al *remolcar* un bote *en el agua* á su mayor velocidad, tiene que vencer la resistencia aumentada del *agua misma*, la cual á 4 millas es mucho más del doble que á 2 millas; probablemente *cuatro* veces mayor. Por tanto, á 4 millas, sobre un canal, el tiro de 62 1/2 libras (28.39 kg) no sería suficiente para *una carga* mitad de la que podría arrastrar con el tiro de 125 libras (56.70 kg) á 2 millas.

** *N. del T.* — Para convertir pies-libra; en kilográmetros, multipliquese aquéllas por .138255.

**por medio de una grúa común**, es como de 10,000,000 de pies-libras (1,382,525 kilográmetros). Esto es, que él suspenderá un equivalente de 10,000,000 de libras netas de agua, mineral, etc., á un pie (ó sean 1,382,525 kilogramos á 1 metro de altura). La carga que él puede suspender de un golpe, incluyendo cadenas, cubos y las pérdidas por rozamiento será tanto mayor que su propia fuerza cuantas veces el diámetro del andén del caballo sea mayor que el del tambor de la grúa, y su velocidad estará en razón inversa. Su fuerza directa propia variará con el número de horas diarias que sea necesario que trabaje, según la tabla anterior. Con este dato se puede eligir el tamaño de los cubos, de los cuales debe haber por lo menos dos, de modo que el que está abajo, vacío puede llenarse mientras se vacía el de arriba, á fin de economizar tiempo. Lo mismo cuando el trabajo se hace por hombres.

**Art. 2. Un trabajador práctico tirando por medio de una cuerda sobre sus hombros en un camino á nivel**, ó empujando por delante de sí en un andén circular una barra horizontal, con una velocidad de 2,400 m á 4,800 m por hora, ejerce como la sexta parte de la fuerza de un caballo, ó sean 304,156 kilográmetros por día, ó 506.92 kilográmetros por minuto, de días de 10 horas de trabajo efectivo.

Pero los trabajadores tienen que trabajar frecuentemente bajo circunstancias menos ventajosas para la aplicación de sus fuerzas que cuando halan ó empujan de la manera indicada; y en dichos casos no pueden hacer tanto por día. Así, por ejemplo, al darle vuelta á un torno, la inclinación constante del cuerpo y el movimiento de los brazos es más fatigante. **El tamaño de un torno no debe exceder de 18 pulgadas (45 cm)** ó el radio de un círculo de 3 pies (91 cm) de diámetro; así un trabajador puede ejercer una fuerza como de 16 libras (7.25 kg) á una velocidad de 2½ pies (75 cm) por segundo, ó 150 pies (45.71 m) por minuto dando muy cerca de 16 vueltas por minuto, á 8 horas por día. Debe calcularse como una cuarta parte por los descansos cortos. Si se toman *los días de trabajo* á razón de 8 ó 10, etc., horas, se debe descontar generalmente de ellas una quinta parte para dichos descansos. Según los datos precedentes, una hora de *trabajo* de 60 minutos de *remolque efectivo* sería, empleando el sistema métrico :

kilogramos metros minutos
$$7.25749 \times 45.7192 \times 60 = 19{,}908.40 \text{ kilográmetros.}$$

y deduciendo la quinta parte dará como 16,000 kilográmetros por hora incluyendo descanso

En la práctica debe hacerse, sin embargo, otra deducción por el rozamiento de la máquina y por el peso de las cadenas elevadoras; y en caso de elevar agua, piedra, mineral, etc., también por el peso de los cubos. Como término medio aproximado, podemos suponer sólo 100,000 pies-libras (13,825 kilográmetros) de trabajo útil por hora; esto es, que **un hombre con una grúa suspenderá efectivamente un equivalente á 100,000 libras de agua, ó mineral, etc., á 1 pie de altura por hora, incluyendo descansos (13,825 kilogs á 1 metro de altura)**. Esto es, 230.42 kilográmetros por minuto en días de 10 horas, incluyendo los descansos. Por tanto, en un día de 10 horas de trabajo suspendería 138,250 kilográmetros á 1 metro, **ó justamente la décima parte de lo que haría un caballo con una grúa en el mismo tiempo**. Hemos visto anteriormente que cuando se remolca en un camino á nivel, se puede, á paso cortos ejecutar como la sexta parte del trabajo diario de un caballo. Puede también moverse la grúa con mayor fuerza hasta con 30 ó 40 libras (13.6 ó 18 kg); pero lo hará más despacio, efectuando el mismo trabajo diario. Con una grúa, como las destinadas á caballos, pero menos pesada con dos ó más tobos, un trabajador práctico suspenderá en un día de trabajo de 10 horas, de 165,903 y 193,554 kilográm respectivamente. En un aljibe ó foso de poco fondo se pierde más tiempo en vaciar los tobos (porque se suben mayor número de tobos) que en uno profundo; pero el profundo requiere mayor peso de cuerda; para economizar tiempo en todas estas operaciones deberá haber por lo menos dos tobos, para llenar el vacío mientras se vacía el lleno. También es mejor emplear dos ó más hombres para izar al mismo tiempo con palancas colocadas á los extremos del eje; y los hombres trabajarán con más facilidad si se colocan tornos en ángulos rectos. Cada palanca ó manubrio debe ser suficientemente largo para dos ó tres hombres. Se debe emplear un hombre más para vaciar los baldes. Éste debe alternar con los izadores. Las mismas observaciones son aplicables en algunos de los casos siguientes.

Con una rueda de pies ó de escalones un trabajador práctico hará como 40 por

ciento más de trabajo diario que con un torno; ó en un día de trabajo * de 10 horas, incluyendo descansos, hará como 1,400,000 pies-libras (193,554 kilográm). Y puede hacer esto, sea que trabaje en la circunferencia exterior de la rueda, subiendo sobre los escalones á nivel de sus ejes, ó caminando dentro de ella cerca de su parte inferior. En ambos casos obra con su peso, generalmente, 130 á 140 libras (58.96 á 63.50 kg), y no con la fuerza muscular de sus brazos. Cuando se encuentra á nivel de los ejes, su peso obra más directamente que cuando se halla en la parte inferior de la rueda; pero en el primer caso tiene que ejecutar un trabajo lento y fatigoso parecido al que se ejerce al subir una escalera continua; mientras que en el segundo es simplemente como si tuviera que ascender un plano inclinado muy poco sensible, lo que puede hacer más rápidamente, durante horas, con una fatiga relativamente pequeña, y esta rapidez compensa la menor acción directa de su peso. Por tanto, en cualquiera de los dos casos, como lo ha demostrado la experiencia, él ejecuta casi la misma cantidad de trabajo diario. Las ruedas de pie ó escalera deben ser de 5 á 25 pies (1.52 m á 7.61 m) de diámetro, según la naturaleza del trabajo. Son movidas generalmennte por varios hombres á la vez y pueden á veces emplearse para clavar estacas, como también para suspender agua, piedras, etc.

**Por medio de una buena bomba común**, adecuadamente proporcionada, un trabajador práctico elevará en un día de 10 horas de trabajo como 1,000,000 pies libras (138,252.52 kilográmetros) netos de agua **.

**Trabajando con un balde liviano ó con un achicador**, puede sacar como 200,000 pies-libras (27,650.5 kilográm) netos de agua. **Con balde y cigoñal** (*swape*) (una palanca larga oscilando verticalmente, y con un peso en un extremo que equilibre al balde colgado en el otro, usado á menudo en cisternas del campo), de 600,000 á 800,000 (de 82,951 á 110,602 kilográm).

En el último tiene solamente que tirar hacia abajo el balde vacío y suspender así el contrapeso. **Por medio de dos baldes suspendidos en los extremos de una cuerda sobre una polea**, hará de 500,000 á 600,000 (de 69,126 á 82,951 kilográm). En este caso trabajan los baldes tirando la cuerda á la mano.

**Por medio de un tímpano, tambor ó dado** ***, movido por una rueda de pie, hará como de 1,200,000 á 1,400,000 (de 165,903 á 193,554 kilográmetros).

**Con una rueda Persa §, una bomba de cadena, una cadena de cubos ‖, ó un tornillo de Arquímedes**, movidos por una rueda de pie, se elevan de 800,000 á 1,000,000 de pies-libras (de 110,602 á 138,252 kilográm). De estos cuatro los tres primeros pierden efecto útil por derramamiento, filtración ó por la necesidad de elevar el agua á un nivel más alto que aquel en el cual se bota.

Cuando cualquiera de las máquinas anteriores las mueven hombres por medio de tornos, el resultado es como la mitad menos que con la rueda de pie. Todas son frecuentemente movidas al vapor, agua, ó fuerza de un caballo.

**Caminando hacia adelante y hacia atrás sobre una palanca que oscile sobre su centro**, un hombre puede, según la *Filosofía Mecánica de Robinson*, ejecutar un trabajo mucho mayor que por medio de cualquiera de los métodos precedentes. Él dice que un joven con peso de 135 libras (61.23 kg), cargado con 30 litros (13.60 kg), trabajó de este modo 10 horas al día sin fatigarse y elevó 9¼ pies cúbicos (261 litros) de agua á 3.5 m de altura por minuto.

---

* En el día de trabajo deben comprenderse los descansos necesarios, y además los intervalos que exija la naturaleza del trabajo; pero no el tiempo perdido en las comidas. *Un día de trabajo* de 10 horas no puede tener por tanto sino 8, 7 ó 6, etc., horas de *trabajo efectivo*. Así debe entenderse cuando en lo sucesivo hablemos de un día de trabajo, ó simplemente de un día.

** Los cálculos de *Desaguliers* respecto al trabajo diario de hombres y caballos exceden á los anteriores; son muy exagerados.

*** El tambor gira sobre un eje horizontal; y es una especie de rueda grande, cuyos rayos ó brazos son cajuelas que terminan en sus extremos exteriores en paletas que se hunden en el agua. A proporción que el agua se eleva gradualmente, se desliza á lo largo de los brazos de la rueda hasta sus ejes donde se descarga. La rueda de paleta es una modificación de ellas. Es una máquina admirable para elevar grandes cantidades de agua á una altura moderada. No podemos entrar en detalles respecto á esta y otras máquinas hidráulicas.

§ Una especie de rueda grande con cubos ó cajones en los extremos de sus radios. Gira sobre un eje horizontal; se descarga por encima. Los cubos están sujetos separadamente, de modo que cuelguen verticalmente, evitando así derramamientos hasta que llegan á su propio punto donde se ponen en contacto con una pieza adecuada para vaciarlos. La noria es parecida, excepto que los cubos están firmemente colocados en su lugar y derraman mucha agua. Es por tanto inferior á la rueda Persa.

‖ Una interminable cadena vertical giratoria de cajones. D'Aubuisson y algunos otros la llaman erróneamente *noria*. Es una máquina muy eficaz.

Esto es igual á 3,984,000 pies-libras (3,984,000 × .138253 = 550,792 kilográmts) por día de 10 horas ó 6,640 pies-libras (917.99 kilográmetros) por minuto, ó cerca de $^1/_{10}$ del trabajo diario, neto, de un caballo en una grúa.

**Un trabajador, de pie,** apenas puede sostener por algunos minutos una carga de 100 libras (45.36 kg) por medio de una cuerda que pasa por sus hombros y horizontalmente por una polea. Y más difícil aún de sostenerla si con las manos extendidas hacia adelante sujeta el extremo de una cuerda horizontal (frente á frente á la carga y la polea). No puede empujar horizontalmente con las manos á la altura de sus hombres más de 30 libras (13.60 kg).

Weisbach hace constar por su propia observación que cuatro hombres prácticos estuvieron suspendiendo un pisón de madera, con cuatro barras redondas horizontales y peso de 120 libras (54.43 kg) á 4 pies (1.20 m) de altura, á razón de 34 veces por minuto, por intervalos de 4½ minutos alternando con otros 4½ minutos de descanso, y así sucesivamente durante 10 horas del día de trabajo.

Por tanto, 5 de estas horas se perdieron en descansos, y el trabajo ejecutado por cada hombre durante las otras 5 horas ó 300 minutos, fué

$$\frac{120 \times 4 \times 34 \times 300}{4} = 1{,}224{,}000 \text{ pies-libras, ó sean}$$

$$\frac{54.43 \times 1.22 \times 34 \times 300}{4} = 169{,}331 \text{ kilográmetros.}$$

**Efectuando el tiro por medio de caballos.** (Véase Tracción.) Si se trabaja todo el día, digamos diez horas, el término medio de la velocidad con que camina un caballo yendo con el carro lleno y regresando con él vacío, es como de 2 á 2¼ millas (3,218 á 3,620 m) por hora; pero teniendo en cuenta las paradas y descanso, etc., es más aproximado calcularlo solamente como 1.8 millas (2,896 m) por hora es decir 48.3 por minuto.

El tiempo perdido en cada viaje, cargando y descargando, se puede generalmente calcular como en 15 minutos. Por tanto, para encontrar el número de cargas que pueden ser llevadas á cualquier distancia dada en un día, búsquese primero el tiempo que se necesita en minutos para llevar una carga y regresar vacío. Así: divídase el doble de la distancia á la cual debe ser llevada la carga, ó, en otras palabras, divídase la longitud del viaje redondo por 48.3 m. El cociente es el número de minutos que el caballo está en movimiento durante cada viaje redondo. A este cociente, agréguesele 15 minutos perdidos en cada viaje, mientras se carga y se descarga; la suma es el tiempo total en minutos empleado en cada viaje redondo. Divídase el número de minutos de un día de trabajo (600 minutos en un día de 10 horas de trabajo) por el número de minutos que se requiere para cada viaje; el cociente será el número de viajes ó de cargas tiradas por día.

Ejemplo. ¿Cuántas cargas conducirá un caballo en un día de 10 horas de trabajo, ó 600 minutos, á una distancia de 292.60 m? En este caso tendremos: $292.60 \times 2 = 585.2$ m. Y $\frac{585.2}{48.76} = 12$ m, y agregando 15 tendremos 27. Finalmente, $\frac{600}{27} = \frac{\text{minutos en 10 horas}}{\text{minutos por viaje}} = 22.2$, ó digamos 22 viajes ó cargas tiradas por día.

**Tabla del número de cargas tiradas por día de 10 horas de trabajo.** La primera columna es la distancia á la cual la carga es llevada efectivamente, ó la mitad de la extensión del viaje redondo. El costo por carga llevada se supone ser para un carro de caballo, cargando y descargando el carretero, calculando el gasto del caballo, el carro y el carretero á $2 por día.

| Distancia en metros. | Número de cargas. | Costo por carga en dólares. | Distancia en metros. | Número de cargas. | Costo por carga en dólares. | Distancia en metros. | Número de cargas. | Costo por carga en dólares. |
|---|---|---|---|---|---|---|---|---|
| 15 | 38 | .053 | 450 | 18 | .11 | 1,610 | 7 | .29 |
| 30 | 37 | .054 | 600 | 15 | .13 | 2,000 | 6 | .33 |
| 60 | 34 | .059 | 760 | 13 | .15 | 2,400 | 5 | .40 |
| 90 | 32 | .062 | 900 | 11 | .18 | 3,200 | 4 | .50 |
| 120 | 30 | .067 | 1,060 | 10 | .20 | 4,830 | 3 | .67 |
| 180 | 27 | .074 | 1,220 | 9 | .22 | 6,450 | 2 | 1.00 |
| 300 | 22 | .091 | 1,525 | 7 | .29 | 14,500 | 1 | 2.00 |

Si la carga y descarga es tal que no pueda hacerse por el carretero solo, sino que necesita de la ayuda de máquinas, puede hacerse necesario un aumento de 10 á 50 cts (de dólar) por carga. El tiro se puede hacer generalmente más barato usando 2 ó 3 caballos y un carretero para un vehículo. La carga neta por caballo, en adición al vehículo, será generalmente de 500 á 1,000 kg, dependiendo de la condición é inclinación del camino. De .368 á .425 m cúb de piedra sólida, ó de 23 á 27 pies cúb (.651 á .793 m cúb) de piedra suelta, hacen 1 tonelada (1,000 kg). **Al calcular la carretada de piedra ordinaria de cantera para muros, alcantarillas, etc.**, recuérdese que cada metro cúbico de mampostería común requiere la tracción como de 1.2 m cúb de piedra tal como se acostumbra amontonarla para la venta en la cantera, ó como $^{9}/_{4}$ de metro cúbico de la roca original antes de banquearla. **Cuando se parte en pedazos un metro cúbico de piedra sólida, ocupa generalmente como 1.9 m cúb, si están sueltas, en desorden las fracciones,** ó como $1\frac{3}{4}$ si están amontonadas. Un carro fuerte para cargar piedra pesa como $\frac{2}{3}$ de tonelada y contiene piedra suficiente para 700 litros de mampostería de piedra bruta. El peso medio de un buen caballo de trabajo es como de 500 kilogramos *.

**Morín da los resultados siguientes** tomados de sus experimentos hechos cuidadosamente para el Gobierno de Francia. El tiro del mismo vehículo de rueda en un camino se considera que cambia en la práctica :

**1.° En caminos empedrados y pavimentos,** en proporción á las cargas; en sentido inverso á los diámetros de las ruedas, y casi independiente de las dimensiones de la llanta. Aumenta hasta cierto grado con las desigualdades del camino, la dureza (falta de resorte) del vehículo, y la velocidad, pero en proporción considerablemente menor que la raíz cuadrada de la última.

**2.° En caminos blandos el tiro es menor con llantas anchas que con angostas;** y para aplicaciones agrícolas se recomienda una anchura de 10 cm.

Con velocidades desde el paso hasta un trote ligero, el tiro no varía sensiblemente.

# ARMADURAS

## INTRODUCCIÓN

### Principios generales.

**1. El diseño de las armaduras es una especialidad.** El diseño, construcción y erección de las armaduras ha llegado á ser una especialidad, á la cual algunas personas se dedican más ó menos exclusivamente, obteniendo de esta manera cierto grado de conocimiento superior al del ingeniero no especializado en esta materia. Este último, sin embargo, debe poseer un conocimiento del asunto suficiente á lo menos para hacerlo capaz de formar una opinión bien fundada de los méritos generales de un diseño y evitar la adopción del que contenga imperfecciones serias *. En un libro como éste podemo discutir solamente los principios generales.

**2. El principio de las armaduras.** Teóricamente una armadura se compone de cierto número de barras rectas, unidas, cerca de sus extremos, por uniones perfectamente flexibles, cargadas solamente en estas uniones, y arregladas de tal manera que sus piezas sostengan todas las presiones internas, y que sólo las presiones verticales **, debidas á los pesos de la armadura y su carga, se transmitan á los extremos.

**3. Diferencia entre las vigas y las armaduras.** Cuando una viga sólida (§ 7, fig. 2, « Resistencia transversal ») se encorva bajo su propio peso ó el de su carga, todas las fibras que están encima del eje neutro se comprimen, y las que se encuentran debajo de él, se alargan; y el cambio que resulta en el largo de cada fibra, es proporcinal á la distancia de la fibra al eje neutro; pero, en una armadura, las cargas (incluyendo el peso de la armadura), se consideran teóricamente divididas en partes que se encuentran en las uniones de las barras (nudos) y que obran por el centro de gravedad de sus secciones transversales. Colocadas así, las presiones por ellas ejercidas no podrían obrar transversalmente respecto á los miembros, como en una viga, produciendo lo que se llama presiones secundarias, pues tienen que obrar longitudinalmente por el eje de las barras y deben distribuirse uniformemente sobre las áreas enteras de sus secciones transversales. Este es el carácter distintivo de todas las armaduras.

**4.** En las armaduras se debe usar el material con mucha economía, y las presiones en cada pieza y en cada parte de dicha pieza pueden determinarse con prontitud y exactitud.

**5.** En una armadura de techo ó puente bien trazada, se llena esta condición ideal, usando como miembros principales, piezas rectas y más bien delgadas, y distribuyendo la carga exterior de tal manera que obre solamente en las uniones (nudos) de las barras, y disponiendo las fuerzas de modo que obren principalmente en sus extremos y á lo largo de las piezas de la armadura.

En las armaduras unidas con pasadores (véase § 175) en las uniones son prácticamente flexibles.

La mayor parte de las armaduras en uso común se componen de dos vigas largas, frecuentemente horizontales (pero véase § 49), llamadas **cordones**, que abarcan toda la luz del puente ó techo, y unidas por piezas ó barras, que están algunas veces todas inclinadas, y otras alternativamente verticales é inclinadas. Las piezas inclinadas se llaman diagonales.

---

* Las Compañías de ferrocarriles y las Corporaciones municipales, casi siempre redactan las condiciones que deben satisfacer sus puentes; pero las proporciones generales, el número de tramos, etc., se dejan comúnmente á la elección de los constructores.

** Suponemos aquí que la armadura se va á cargar verticalmente. Si la carga obra de otra manera, como sucede con la presión del viento en una armadura reforzada horizontalmente, la presión en los apoyos puede ser horizontal, ó en cualquiera otra dirección, pero todas las fuerzas internas estarán aún soportadas por los miembros de la armadura.

**6. Tirantes y puntales.** El miembro sometido á tensión se llama tirante ó cuerda. El que sostiene presión se llama puntal ó poste. El que sostiene ambas se llama cuerda-puntal ó puntal-cuerda.

**7.** Las dimensiones de las armaduras se miden comúnmente en las líneas centrales de sus miembros; y en las armaduras unidas por pasadores, éstos se colocan en las intersecciones de estas líneas. De aquí que las medidas se hagan ordinariamente de « centro á centro de los pasadores ».

**8. En una viga llena** consideramos que las tablas ó alas ejercen la función de cordones de la armadura, y el alma de la viga representa la trabazón de la armadura.

## Cargas.

**9. Cargas muerta y viva.** En los puentes, hacemos distinción entre las cargas « muerta » y « viva »; la carga muerta comprende el peso permanente de la estructura; es decir, del mismo puente, con su pavimento, etc.; la carga viva comprende todas las cargas exteriores temporales, tales como máquinas, carros, caballos, vehículos, caminantes, etc., que trafiquen por el puente.

**10.** La carga muerta se distribuye siempre uniformemente á lo largo de la abertura; pero el cordón cargado (el que soporta la vía de tráfico) recibe, por supuesto, una parte mayor que el no cargado. La carga viva sólo obra sobre el cordón cargado. Para determinar los esfuerzos, se considera que el peso de la carga viva y del pavimento están sobre el cordon cargado, y el resto de la carga muerta dividido por igual entre los dos cordones. Algunas veces sucede, sin embargo, que ambos cordones, el superior y el inferior, soportan vías de tráfico. Es claro que se les debe considerar entonces como « cargados », aunque no por igual, porque quizás uno soporte un ferrocarril, y el otro una vía ordinaria solamente.

## Carga no simétrica. Contradiagonales.

**11. La carga no simétrica.** En las figs. 2 á 10, se supone que las cargas están colocadas simétricamente.

**12.** Si este fuese el caso en la práctica, no se someterían nunca las barras de compresión á resistir tensión, ni las de tensión á resistir compresión; y las armaduras de las figs. 2 á 10 serían suficientes (suponiendo que cada barra tenga la necesaria resistencia), aunque las barras de compresión no fueran capaces de resistir tensión y viceversa. Así pues, los tirantes ó barras de tensión podrían ser cadenas flexibles, y los de compresión, postes, solamente obrando contra los apoyos en sus extremos.

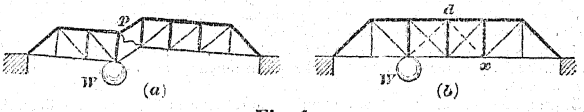

**Fig. 1.**

**13.** Pero en una armadura, fig. 1 (*a*) con un tirante flexible en el tramo, *p*, como está indicado, la carga W, colocada no simétricamente, causaría el efecto que indica el dibujo.

**14. Contradiagonales.** Para impedir esto, las barras que, bajo cargas movibles, puedan someterse alternativamente á tensiones y compresiones, pueden construirse de manera que resistan ambas especies de fuerzas. Es decir, las piezas de tensión pueden ser tan rígidas que puedan obrar como postes, y los extremos de las barras de compresión unidos de tal manera á las cuerdas que puedan obrar también como cuerdas. Este es el recurso que se emplea con frecuencia en las armaduras que no tienen barras verticales.

**15.** (*Obs. del T.* — Es oportuno hacer la siguiente explicación para lo que va á seguir. Marvá en su magnífica obra *Mecánica aplicada á las construcciones*, 4.ª edición, págs. 249 y 250, llama *brazos*, las barras inclinadas cuando trabajan por compresión, y *tirantes*, si están sometidas á extensión. Luego dice : « Para evitar que una barra sufra alternativamente esfuerzos de compresión y de extensión por la posición variable de las cargas móviles, se agrega en algunos sistemas otro grupo de barras inclinadas en sentido contrario, cuyo objeto es impedir el cambio de signo de las fuerzas en las barras primitivas, ó, lo que es lo mismo, hacer que cada barra trabaje

siempre por compresión ó por extensión, ó no sufra esfuerzo alguno. A este efecto, cuando una barra del primer sistema que está trabajando por compresión, por ejemplo, va á sufrir una extensión, hay una barra adicional del segundo sistema, que entrando á funcionar en aquel momento lo impide, sufriendo entonces una compresión y haciendo que la primera barra no experimente esfuerzo alguno. »

Llama *contradiagonales* á las del segundo sistema, ya sufran compresión ó extensión. *Contrabrazos* á las barras inclinadas en sentido contrario de las que trabajan por compresión, y *contratirantes* á las situadas en sentido contrario de las que trabajan por extensión.)

Así pues, la deformación, fig. (*a*), causada por una carga no simétrica, se evita introduciendo otros miembros que se llaman como hemos dicho, para distinguirlos de los miembros principales, cuya función es resistir las fuerzas normales debidas á cargas uniformes ó simétricamente distribuídas. Así, en la fig. 1 (*b*), la carga no simétrica W, tiende á convertir el rectángulo *p*, en un paralelogramo alargando su diagonal W*d*, lo cual puede evitarse introduciendo un miembro oblicuo de tensión en dicha diagonal, como lo indica la línea de puntos. Por la misma razón, se colocará otro igual en el tramo correspondiente, *xd*.

**16. Triángulos.** Se observará que la introducción de las contradiagonales hace que la armadura esté compuesta solamente de *triángulos*.

**17.** A primera vista aparecerá que las diversas partes de la armadura de un puente reciben la mayor presión cuando el máximum de la carga se extiende de extremo á extremo; pero esto es cierto solamente respecto al cordón y las principales partes, diagonales y verticales, próximas á los *extremos* de la armadura. Las otras barras podrán sufrir mayor esfuerzo de una parte de la carga, colocada no simétricamente en la armadura; de manera que, aunque de proporciones adecuadas para una carga total uniforme, puedan resultar débiles para una carga parcial. Si se construyen todas tan fuertes como la de los extremos, quedarán ciertamente seguras para una carga pasajera; pero esto requeriría un gasto de material, excusable sólo en casos en que la luz del puente sea moderada, y particularmente en los de madera, en que la construcción de algunos miembros usando pedazos de diferentes tamaños haría una economía en el material que quedaría más que anulada con la molestia de conseguir y unir adecuadamente piezas de tan diversas dimensiones.

**18.** En los puentes grandes en los que la carga viva es pequeña con relación á la muerta, se necesitan pocas contradiagonales, y solamente en el centro y cerca de él, mientras que en un puente muy ligero, las contradiagonales deben extenderse desde el centro, donde reciben más presión, hasta los extremos, donde la presión es la menor.

## Riostras.

**19. Ligazón entre las armaduras.** Se aprovecha la proximidad de dos ó más formas ó armaduras en un puente, uniéndolas con *riostras*, dando de esta manera á la estructura entera mayor estabilidad lateral que la que se obtiene en las armaduras sencillas.

**20.** De esta manera, las riostras de un lado al otro, fig. 39, forman verdaderas armaduras horizontales colocadas entre los dos cordones superiores de las armaduras principales, ó entre los dos inferiores, ó á la vez entre ambos; obrando los cordones de las armaduras principales como cordones de las armaduras horizontales laterales. Las **riostras laterales** impiden la desviación lateral de los cordones.

**21.** Las situadas como en la fig. 64 (*c*) (llamadas también laterales, de vibración contra el viento) se componen de armaduras cortas (ordinariamente verticales) que cruzan el puente transversalmente, uniendo de esta manera las dos armaduras mayores. Estas tienen su cordón propio, pero usan las partes de los postes de la armadura principal como sus postes extremos.

**22. Barras de portales**, fig. 54 (*a*), son los que (á veces en un plano inclinado) unen las partes superiores de los extremos de los postes, en las armaduras de altura suficiente para permitir su uso. Esta armadura de unión, con sus postes finales, forma un portal por el cual los trenes, etc., entran en el puente.

## Tipos de vigas armadas.

**23. La forma más simple de vigas armadas**, se compone de un triángulo simple, figs. 2 (*a*) y (*b*). En la fig. (*a*) la carga produce compresión en los pares

tensión en el cordón y compresión * (=tensión en el cordón) entre las cabezas de los pares; en la fig. (*b*), viceversa.

**24.** La viga representada en la fig. 2 (*a*) es de uso común para los techos de poca luz, en casas de habitación. En la práctica se carga, por supuesto, á lo largo de las vigas, y no solamente en el vértice como en la fig. (*a*); pero, calculando los esfuerzos de las barras de las armaduras, ordinariamente se supone que las cargas están concentradas en las intersecciones de las barras. El efecto de su distribución *á lo largo* de las barras se determina separadamente, considerando las piezas como vigas.

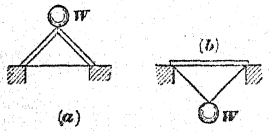

Fig. 2.

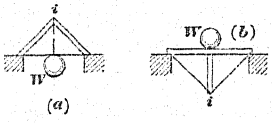

Fig. 3.

**25.** En la fig. 3 (*a*) la cuerda vertical llamada *pendolón* y en la fig. 3 (*b*) el poste vertical llamado mangueta, traen simplemente el peso de la carga al vértice, *i*, donde produce el mismo efecto que en las figs 2 (*a*) y (*b*).

**26.** De aquí que, despreciando los pesos de la cuerda vertical y de otras piezas, las presiones ejercidas por una carga dada, W, en las diagonales, y en la cuerda horizontal, fig. 3 (*a*), son las mismas (no solamente en su acción, sino en intensidad) que las producidas por una carga igual W, en la de la fig. 2 (*a*). Igualmente, las de la fig. 3 (*b*) corresponden á las de la fig. 2 (*b*).

**27.** Las figs. 4, 5 y 6, que indican modificaciones de las formas simples, dadas en las figs 2 y 3, muestran en principio, la mayor parte de las vigas armadas en uso común en los puentes, cuya luz es de 90, 120 y aun 150 m. Véanse las figs. 7 á 10, §§ 35, etc.

**28.** En las figs 4, 5, 6, hay un cordón superior en compresión y un cordón inferior en tensión: el cordón más corto sostiene la compresión entre los pares, figs. 2 (*a*) y 3 (*a*), ó la tensión horizontal entre los pies de las piezas diagonales, figs. 2 (*b*) y 3 (*b*). Las figs. 4 (*a*) y 5 (*a*) son modificaciones de las figs. 2 (*a*) y 3 (*a*); figs. 4 (*b*) y 5 (*b*) lo son de las figs. 2 (*b*) y 3 (*b*); la fig. 6 (*a*) de la fig. 2 (*a*), y la fig. 6 (*b*) de la fig. 2 (*b*).

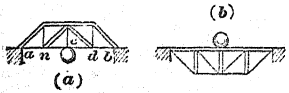

Fig. 4.

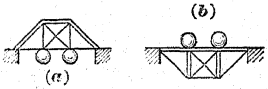

Fig. 5.

**29.** Las figs. 4 (*a*) y 4 (*b*) pueden considerarse como ilustraciones de las figs. 3 (*a*) y 3 (*b*) respectivamente, con la mangueta, así como la carga dividida en dos, y las dos partes separadas por un cordón horizontal. Si las cargas están colocadas simétricamente, de manera que las compresiones horizontales, fig. 4 (*a*), ó tensiones, fig. 4 (*b*), en los dos extremos del cordón más corto, sean iguales, las barras diagonales en el centro son innecesarias.

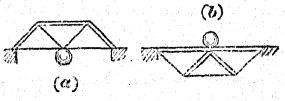

Fig. 6.

**30. Sistemas Howe y Pratt.** En la fig. 5 (*a*) las barras verticales de la viga están en tensión, y las diagonales en compresión, según el principio de « Howe », que se usa en los puentes de maderos, diagonales; mientras que, en la fig. 5 (*b*), las

* En las figs. 2 á 12, y 14 á 17, las líneas dobles ó gruesas indican postes ó puntal (sometidos á compresión), y las líneas delgadas indican cuerdas (sometidas á tensión

verticales sufren compresión, y las diagonales tensión, según el principio de «Pratt», usado en los puentes de diagonales metálicas. En tales puentes son objetables las barras sometidas á compresiones.

**31. Viga de armadura triangular ó de Warren.** En la fig. 6, que muestra la viga «triangular» ó de «Warren», las barras del tejido son todas diagonales y están alternativamente en tensión y en compresión. Dividen la armadura en triángulos *isóceles*.

**32. Armaduras de tablero superior, inferior, y armaduras pequeñas** (Pony). Las figs. 4 (*a*), 5 (*a*) y 6 (*a*), con la vía de tráfico entre los cordones inferiores, se llaman de «tablero inferior», y las figs. 4 (*b*), 5 (*b*) y 6 (*b*), con la vía de tráfico entre los cordones superiores, se llaman de «tablero superior». Éstas permiten el uso de barras diagonales en plano vertical contra la oscilación horizontal (véase § 21) entre, y por toda la altura de las dos ó más armaduras que forman el puente; la de tablero inferior, por supuesto que no lo permite. Pero el uso del tablero inferior es necesario á menudo, para dar amplia sección de paso (*head-room*) á los botes, las crecientes, los trenes en los caminos que se cruzan, etc., por debajo del puente. Una armadura, cargada en los cordones inferiores, pero demasiado baja para ligarla con barras laterales (véase § 20) entre los dos cordones superiores, se llama armadura (*pony*). (*N. del. T.* — No tiene que sepamos equivalente en español; la única palabra que puede aplicarse, es la muy familiar *rechoncha.*)

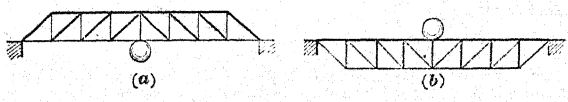
**33. Tramos.** Los puntos en que las barras verticales del tejido se encuentran con las cuerdas, en las figs. 4 y 5, se llaman puntos de división de los tramos, y los espacios rectangulares, *an*, *nc*, *cd*, etc., fig. 5 (*a*), entre las verticales, se llaman tramos.

**34. La viga Warren,** fig. 6, no tiene barras verticales, como partes esenciales de ella. Véanse los §§ 45 y 46 Sus subdivisiones se llaman triángulos simples, y un tramo es una longitud de la armadura igual al ancho de un triángulo. Una panela en cualquiera cuerda, es, sin embargo, la parte de ella comprendida entre dos puntos de división de los tramos.

**35.** Las modificaciones posteriores de estos diseños, con mayor número de tramos, se ven en las figs. 7 á 10. Las figs. 7 (*a*) y 8 (*a*), con barras verticales en tensión, representan la viga Howe de las figs. 4 (*a*) y 5 (*a*), mientras que las figs. 7 (*b*), 8 (*b*), 9 (*a*) y 9 (*b*), con las diagonales en tensión, representan la viga Pratt, de las figs. 4 (*b*) y 5 (*b*). Las figs. 10 representan la viga Warren de la fig. 6.

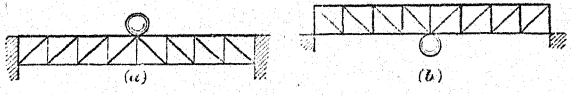
**36.** La fig. 8 (*a*) representa simplemente la fig. 7 (*a*), que ha descendido para convertirse en un puente de tablero superior en lugar de un puente de tablero inferior; y la fig. 8 (*b*) representa la fig. 7 (*b*) convertida de tablero superior en inferior, descansando en los extremos de postes verticales.

**37.** En las figs 8, los extremos de los postes verticales, y la pieza horizontal á cada extremo del cordón cargado, no forman parte de la armadura en sí. Estas últimas obran simplemente como vigas, soportando la carga durante su paso del estribo á la armadura y viceversa. El extremo del poste en la fig. (*a*) soporta solamente un extremo de esta viga, mientras que el de la fig. (*b*) soporta la mitad.



**Viga Howe, de tablero inferior.** **Viga Pratt, de tablero superior**

**Fig. 7.**



**Viga Howe, de tablero superior.** **Viga Pratt, de tablero inferior.**

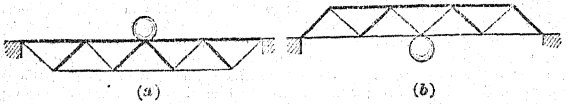
**Fig. 8.**

**38.** En las figs. 8 la vertical del medio no soporta ninguna parte de la carga. Teóricamente sirve sólo para impedir la flexión por su propio peso, de los dos tramos no cargados del medio del cordón.. Pero en la práctica tales miembros se

colocan con el objeto de obtener conexiones convenientes para las piezas laterales, tales como las vigas del piso.

**Viga Pratt, de tablero superior.** **Viga Pratt, de tablero inferior.**

**Fig. 9.**



**Viga Warren, de tablero superior.** **Viga Warren, de tablero inferior.**

**Fig. 10.**

**39.** En las figs. 9 (modificaciones de la fig. 7 *b*), y en la fig. 10, se muestran, en principio, las formas más comunes de las vigas de puentes metálicos, que se usan con tablero superior é inferior respectivamente.

**40.** En la fig. 9 (*a*) como en la fig. 8, los postes verticales de los extremos y las piezas horizontales á los extremos del cordón cargado no forman parte de la viga, y en la fig. 9 (*b*) como en la fig. 8, la vertical del medio soporta solamente los centros no cargados del cordón de los tramos.

**41. Intersecciones.** En las vigas altas se combinan algunas veces dos ó más cuerpos de trabazón en una sola viga, con un solo par de cordones. De esta manera las dos vigas simples de Pratt, de las figs. 11 (*a*) y (*b*), se combinan para formar la armadura de « Whipple », ó de « doble intersección de Pratt », fig. 11 (*c*), que está últimamente muy en uso.

(*Obs. del T.* — Estas son las vigas *compuestas* que se obtienen por la yuxtaposición de dos vigas simples del mismo sistema. Muévase paralelamente la fig. 11 (*a*) sobre a (*b*) hasta la completa coincidencia y resultará la viga, *c*.)

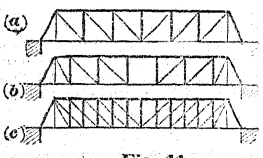


**Fig. 11.**

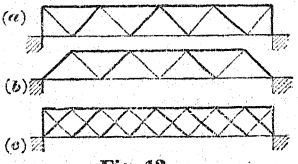

**Fig. 12.**

**42.** De igual manera las dos vigas simples de Warren, en las figs. 12 (*a*) y (*b*), se yuxtaponen para formar la de doble intersección (compuesta) de Warren de la fig. 12 (*c*).

**43.** La combinación de cuatro sistemas se llama viga de cuádruple intersección. Véase fig. 59 (*t*).

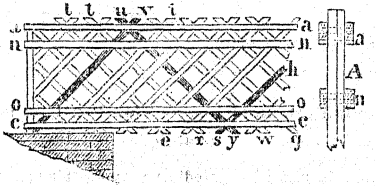

**Fig. 13.**

**44. La vieja viga de « celosía » «Towne »**, fig. 13, se compone de planchas que se entrecruzan (ordinariamente en ángulos rectos), y espigadas ó atornilladas en sus intersecciones, pueden considerarse como una combinación de varias vigas Warren.

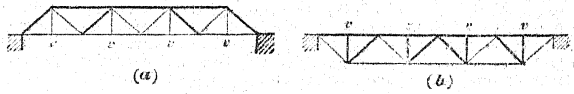

Fig. 14.

**45. Subverticales.** En las vigas altas, en que la extensión horizontal de los tramos es considerable, las subverticales, *v*, figs. 14 y 15, se usan á menudo, con especialidad en las armaduras Warren, para sostener los segmentos del cordón cargado. Véanse también las figs. 59 (*i*), (*r*), y (*s*).

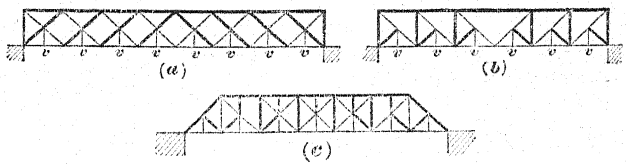

Fig. 15.

En la viga « **Baltimore** », fig. 15 (*b*), cada diagonal está apuntalada por un brazo diagonal corto inclinado en la dirección opuesta, y hay una subvertical suspendida en su unión. En los tramos muy largos, las subverticales algunas veces se usan también para los tramos del cordón no cargado. Véase fig. 15 (*c*).

**46. Puntales de colisión**, S, figs. 59 (*k*), (*m*), (*o*), y (*t*), y (73) *a*, se usan para apoyar largos postes extremos diagonales, contra el golpe de un tren descarrilado.

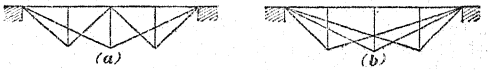

Fig. 16.

**47. Vigas Fink y Bollman.** Las figs. 16 muestran dos modificaciones anticuadas de la fig. 3 (*b*); es decir, la Fink, fig. 16 (*a*) y la Bollman, fig. 16 (*b*). El gran puente sobre el río Ohio en Louisville, Ky, terminado en 1870, es del tipo Fink. La Bollman se usó mucho en el ferrocarril de Baltimore y Ohio, hace años.

**48.** En las vigas Fink y Bollman había sólo un cordón como lo indicamos. A nivel de este cordón pasaba la vía ordinariamente. Cuando la vía se colocaba más baja, la viga parecía tener dos cordones. Bajo cargas distribuídas uniformemente, en la Fink, y en todas las circunstancias en la Bollman, la presión sobre este cordón era uniforme en todo él. En la Bollman (véase la fig.) los esfuerzos longitudinales en la viga se aplicaban todos en sus extremos. Cada tipo puede considerarse como una combinación de varias vigas de suspensión semejantes á la fig. 3 (*b*). En la Bollman, las vigas simples son todas de la misma luz y profundidad, y todas las manguetas, excepto la del centro, dividen desigualmente á las vigas simples. El sistema Fink se usa todavía mucho en las armaduras de metal para techos. Véanse las figs. 26.

Fig. 17.

**49. Vigas arqueadas.** Las vigas con cordones arqueados ó « quebrados », fig. 17, se usan ordinariamente en las grandes luces. Las barras colocadas entre los puntos de separación de los tramos son siempre rectas. En las armaduras de arco y cuerda (*bowstring*), fig. 17, los puntos de división de los tramos del cordón supe-

rior se encuentran en una línea curva, convexa hacia arriba. En la armadura de **media luna** (*crescent*), el cordón inferior es también convexo hacia arriba. La armadura de arco y cuerda tiene la ventaja, sobre las de cordón superior horizontal, de hacer que todos los esfuerzos en los cordones y barras sean más próximamente iguales, simplificando de esta manera la construcción y disminuyendo su peso. Tiene la desventaja de que no permite riostras transversales cerca de los extremos de la luz. Si la curva del cordón superior se hace parabólica, la presión de la carga muerta es uniforme en todo el cordón inferior, y en todas las barras verticales (ahora en tensión), el esfuerzo es igual á la carga muerta sobre la viga inferior. Las diagonales no trabajan con la carga muerta, sino con las cargas excéntricas.

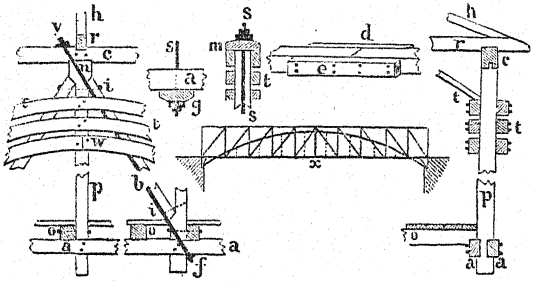

**Fig. 18.**

**50. La viga «Burr»**, fig. 18, en un tiempo muy usada en los puentes de madera, era una combinación de una armadura Howe y un arco.

### Ligera curvatura de los cordones.

**51.** En la práctica, los extremos de las barras del cordón superior é inferior no se colocan perfectamente en línea recta, sino de manera que los cordones se arqueen ligeramente, con la convexidad hacia arriba. Su objeto es impedir que la armadura descienda debajo de la horizontal, al estar cargada fuertemente. Cuando las vigas están combadas (véase *ys* y *cd*, fig. 19), se convierten aproximadamente en arcos

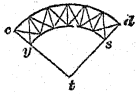

**Fig. 19.**

concéntricos de dos círculos de gran radio, cuyo centro está en *t;* el superior, por supuesto, más largo que el inferior. Las barras verticales, en lugar de permanecer verdaderamente verticales, se convierten en partes del radio de los arcos mencionados, y aunque sus largos permanezcan invariables, las partes superiores están, sin embargo, más separadas que los pies; haciendo necesario alargar las diagonales. Véanse §§ 211-214.

### Vigas consolas (*Cantilevers*).

**52. El principio de los cantilevers** se muestra en la fig. 20, en que A y B

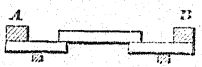

**Fig. 20.**

representan contrapesos. La fig. 21 hace ver el puente de (cantilevers) contrapesos del Niágara. Se compone de dos armaduras en cantilever, *ab*, *a'b'*, unidas por una

armadura ordinaria, que está suspendida por un eslabón, vertical en cada punta, de los extremos de las consolas. El peso de la armadura está contrabalanceado por anclajes A y B, ó por pesos, ó por ambos. La ventaja principal del cantilever, es que se puede construir hacia afuera de los estribos á través del canal; facilitando, de esta manera, grandemente, su erección en los casos en que no pueda usarse una construcción provisional.

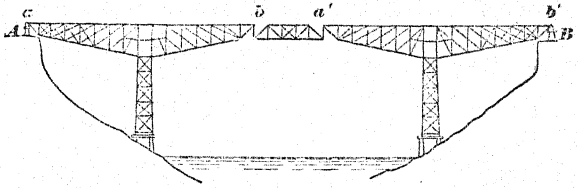

Fig. 21.

## Puentes movibles.

**53. Los puentes movibles**, incluyendo los levadizos, giratorios, y de alzamiento, son de tres clases generales, una en que la parte movible se desliza horizontalmente, otra en que gira horizontalmente, y otra en que gira verticalmente.

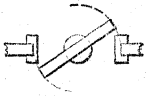

Fig. 22.

De ordinario la sección movible tiene su eje cerca del medio, y gira horizontalmente en el estribo central donde está el eje ó *pivote*, como en la fig. 22. Estos puentes se montan ordinariamente sobre un gran eje central, ó sobre un juego de cilindros, ó sobre ruedas que corren en una vía circular. Los puentes de esta clase deben construirse de manera que estando abiertos, ó sin haberse ajustado en los extremos al cerrarse, sostengan no solamente su propio peso, sino cualquiera otra carga que esté sobre ellos. Además, cada mitad debe resistir como un puente sostenido en ambos extremos, con todas las cargas vivas posibles, pues si no, al llegar una carga viva á cualquier extremo, dicho extremo no ajustaría. Los puentes bien construídos se disponen de manera que se puedan alzar los extremos de la parte movible, al cerrarse, haciéndolos ajustar firmemente, y quedando el pavimento á nivel con el del estribo fijo adyacente. Este alzamiento se hace ordinariamente lo suficiente para aliviar la pila del medio de una parte de la carga solamente. El puente obra entonces como una viga « continua » (véase Resistencia transversal, §§ 78, etc.), sostenido en tres ó cuatro puntos, que dependen de la disposición de la carga en la pila donde está el eje.

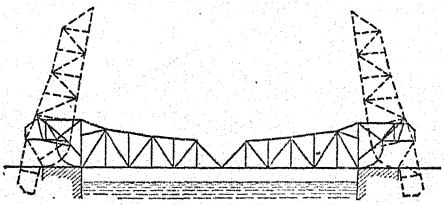

Fig. 23.

**54.** Los puentes levadizos en que la parte movible oscila verticalmente (teniendo el brazo corto un contrapeso), pueden girar en un *pivote* ó eje, ó rodar como en el

puente levadizo rodante Scherzer, fig. 23. En el puente Scherzer el centro de gravedad de cada uno de los dos brazos ó palancas movibles permanece á una elevación constante, de manera que no suba ni baje con ninguno de ellos, y el trabajo que se hace consiste sólo en vencer la fricción de rotación de la parte curva del brazo sobre su soporte.

**55. Los puentes oblicuos** se usan donde hay que cruzar un canal, un camino, etc., oblicuamente, y donde no es conveniente hacer los estribos perpendiculares á las vigas. Para la simplicidad al hacer las conexiones del pavimento, etc., la armadura se construye ordinariamente de manera que las divisiones de los tramos queden enfrente unas de otras, como en las figs. 24 y 25. Cuando la oblicuidad es ligera, se necesita una diferencia en la inclinación entre los dos postes de los

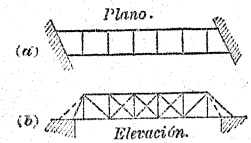

Fig. 24.

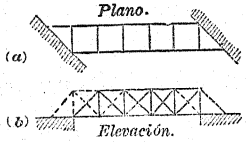

Fig. 25.

extremos, como en la fig. 24, complicando las conexiones de los cruceros en la entrada del puente. Pero cuando la oblicuidad es mayor, es posible hacerla justamente igual á uno ó más tramos completos, arreglando el largo de los tramos para que se correspondan, quedando las vigas simétricas, como en la fig. 25. En cada figura, la viga *más distante* (la superior en el plano) está indicada por líneas de puntos.

## Armaduras de techo.

**56. Las armaduras de techo** se construyen en una gran variedad de formas. Las que se ven en las figs. 26 son comunes. En la fig. 26 (*a*), parte de la carga, en *d*, comprime el par *ia* de *d* hasta *a*, mientras que el resto comprime el puntal, *dh*, y prensa la cuerda *hi* y la parte *ha* del tirante. Igualmente, una parte del peso de *e* pasa por *ca* hacia *a*, y el resto por *ckdhi* al vértice *i*. De esta manera cada carga es llevada por las piezas, parte al vértice y parte á lo largo de un par hasta un estribo. Se verá que los esfuerzos mayores en los pares y en los tirantes ocurren cerca de los extremos *. Algunas veces las piezas verticales de la fig. (*a*) se

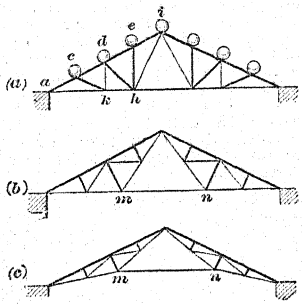

Fig. 26.

hacen inclinadas, ó el tirante se « quiebra » con la convexidad hacia arriba. Las armaduras de techo se componen, con frecuencia, como en las figs. (*b*) y (*c*), de dos vigas Fink, inclinadas, y apoyándose una contra la otra, ligadas las bases por una cuerda, *mn*, y formando los pares los cordones superiores de las armaduras Fink.

* Si las diagonales fueran paralelas, sus esfuerzos y los de las verticales serían mayores en el centro de la luz, y menores en los estribos.

## ESFUERZOS EN LAS PIEZAS DE LAS ARMADURAS

### Principios generales.

**57. Condiciones de equilibrio.** En las armaduras, como en las vigas, es necesario y suficiente, para el equilibrio, que los esfuerzos internos y sus momentos equilibren las fuerzas externas y sus momentos. Las fuerzas externas (por ej., las cargas y las reacciones en los extremos), los momentos resultantes y los esfuerzos cortantes, se estudian en Estática, § 285, etc. Aquí discutiremos la determinación de los esfuerzos internos. Para la distinción fundamental entre vigas y armaduras, véase Armaduras, § 3.

**58.** En general, los esfuerzos en las piezas se encuentran por la teoría de los momentos (Estática, §§ 301, etc.), y de los esfuerzos cortantes (Estática, §§ 325, etc.), usando el paralelogramo ó triángulo de las fuerzas (Estática, §§ 35, etc., y §§ 46, etc.) por el polígono de las fuerzas (Estática, §§ 72, etc., 86, etc.), y por el diagrama de influencia (Estática, §§ 339, etc.).

**59.** Un método muy conveniente y en uso común, se describe más ampliamente en los §§ 67, etc., más adelante, donde se consideran las armaduras en su sección transversal. Trataremos entonces de precisar qué fuerzas se requieren en las piezas así cortadas para mantener el equilibrio.

**60.** Antes de poder calcular los esfuerzos, y proporcionar la armadura á ellos, se debe conocer su peso, porque éste constituye una carga, y por consiguiente influye en los esfuerzos. Pero no podemos conocer su peso hasta que no conozcamos el tamaño de las diferentes piezas. En este dilema debemos atribuirle un peso aproximado, basados en el de algunas armaduras ya fabricadas. Éste es de la mayor influencia á proporción que la armadura aumenta de tamaño, de manera que su propio peso aumenta en mayor proporción que la carga.

**61. Para hacer distinción entre las cuerdas y los postes** del punto, en que está aplicada la fuerza, figs. 27, trácese *oc* representando la fuerza aplicada, en la dirección en que esa fuerza tiende á mover el punto *o*, y sobre *oc*, como diagonal, constrúyase el paralelogramo *ab* de las fuerzas. Por el punto *o* trácese *ii* paralela á la diagonal *ab*. Entonces, la pieza que se encuentre en el mismo lado de *ii* con *oc*, será un poste (sufriendo compresión), y si se encuentra en el lado opuesto, será una cuerda (sufriendo tensión).

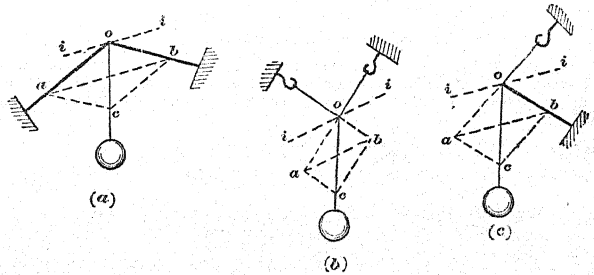

**Fig. 27.**

**62.** Las cuerdas y postes pueden distinguirse (como en la fig. 27) prontamente á la vista, imaginando que la pieza sea flexible, como un cabestro ó cadena. Si se juzga que resiste la fuerza que obra sobre ella, esa pieza es una cuerda, si no, es un poste. O bien, supongamos que la pieza no esté asegurada en sus extremos. Si vemos entonces que resiste la fuerza que obra sobre ella, esa pieza es un puntal, si no, será una cuerda.

**63.** O podemos proceder como sigue: En la fig. 28 (*a*), representando *a* un nudo, empezamos con la reacción vertical conocida R *; y encontramos las presiones

* Como cada una de las mitades de los tramos extremos descansa directamente en un apoyo y no agrega, de esta manera, nada á las fuerzas en las piezas, debemos, al determinarlas, usar solamente la **reacción neta** = *reacción — la mitad de la carga del tramo*.

desconocidas en la cuerda y en el extremo del poste por medio del triángulo de las fuerzas, haciendo que sus saetas sigan la dirección conocida de R. Transfiriendo estas saetas á las respectivas piezas de la armadura, fig: (*d*), encontramos que el cordón inferior tira de *a*, y es por consiguiente una cuerda; mientras que el extremo del poste empuja hacia *a*, y es por consiguiente un poste.

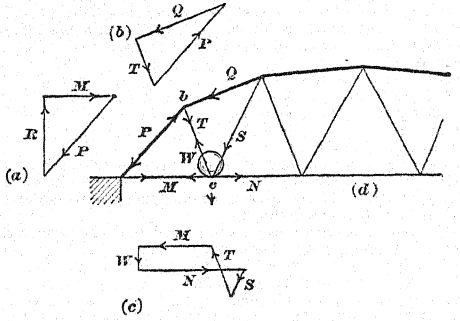

**Fig. 28.**

**64.** En la fig. (*b*), que representa un nudo (*b*), trazamos P hacia arriba para representar la presión del poste extremo hacia *b*, y los otros dos lados del triángulo de las fuerzas dan la presión en la pieza Q del cordón y la tensión en la cuerda T.

**65.** En la fig. (*c*), que representa un nudo *c*, conocemos á T, M, y la carga W, y obtenemos la tensión, N, y la presión, S, en las piezas correspondientes.

**66.** Las fuerzas *de tensión* (porque tienden á *alargar* la pieza), se consideran convencionalmente como *positivas*, y se designan por +; las compresivas se consideran como *negativas*, y se designan por —.

## Método por secciones.

**67.** Si la fig. 29 (*a*) representa una armadura de techo, con tres cargas iguales, W' de 2 toneladas cada una, aplicadas en *a*, *c* y *b* respectivamente, y si se desea encontrar las presiones producidas, por esas cargas solamente, en las piezas *ac* y *ad*;

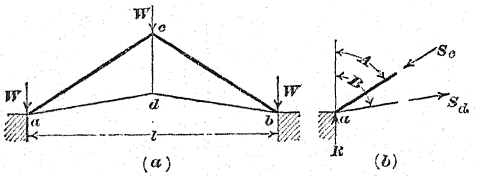

**Fig. 29.**

supongamos que la parte representada por la fig. 29 (*b*) sea separada del resto de la armadura, como se indica por un corte en las piezas *ac* y *ad*. Las partes inferiores de esas piezas, indicadas en (*b*), se supone, sin embargo, que están mantenidas en sus posiciones originales por los esfuerzos $S_c$ y $S_d$, ejercidos en dichas piezas. Tomando los momentos respecto al apoyo derecho, *b*, fig. 29 (*a*), tenemos, para la reacción hacia arriba del estribo izquierdo, *a*,

$$R = \frac{3W}{2}.$$

**68.** Tenemos, entonces, en *a*, fig. 29 (*b*), cuatro fuerzas, así: dos fuerzas conocidas, á saber: W, verticalmente hacia abajo, = 2 toneladas, y R, verticalmente hacia

arriba, $= \frac{3W}{2}$; y dos fuerzas desconocidas, $S_c$ y $S_d$. Ahora bien, $S_c$ y $S_d$ forman ángulos conocidos, A y B, con la vertical. Las fuerzas verticales, W y R, no tienen, por supuesto, componentes horizontales (véase Estática, §§ 54, etc.); y sus componentes verticales son las fuerzas mismas.

**69.** Las componentes horizontales de las fuerzas inclinadas $S_c$ y $S_d$ son, respectivamente : $S_c$ sen A y $S_d$ sen B, y las componentes verticales son : $S_c$ cos A y $S_d$ cos B.

**70.** Vemos por la simple inspección que la fuerza $S_c$ en el par *ac*, es una compresión, y en la viga inferior, $S_d$ es una tensión; pero por conveniencia podemos desde un principio suponer de antemano que todas las fuerzas cuya acción se desconoce son tensiones ó +. Entonces las que aparezcan al fin como + se sabe que son tensiones, y viceversa. Sus resultantes horizontales, en este caso, están ambas, por consiguiente, consideradas como si fueran de la derecha, ó positivas, y sus componentes verticales hacia arriba como positivas también. Se recordará (véase § 66) que consideramos las tensiones como positivas, y las compresiones como negativas.

**71.** Ahora bien, para que las cuatro fuerzas en *a*, á saber : W = 2 tons, hacia abajo; $R = \frac{3W}{2}$ hacia arriba, $S_c$ y $S_d$, puedan estar en equilibrio, es necesario :

(1) que la suma de sus componentes horizontales sea cero, ó que $S_c$ sen A + $S_d$ sen B = 0;

(2) que la suma de las componentes verticales sea cero, ó $R - W + S_c \cos A + S_d \cos B = 0$.

Así pues, sea A = 45°, sen A = .707; cos A = .707.
B = 75°, sen B = .966; cos B = .259.

Entonces $.707\, S_c + .966\, S_d = 0$;

$$R - W + .707\, S_c - .259\, S_d = 0;$$

$$S_c = \frac{-.966\, S_d}{.707} = \frac{-.259\, S_d - R + W}{.707}$$

$$.966\, S_d - .259\, S_d = .707\, S_d = R - W.$$

**72.** También, en la fig. 30, con la sección *u v*, el esfuerzo en $ed = W_1 - R = 6 - 15 = -9$. Con la sección *vy*, el esfuerzo en $ef = \frac{W_1 - R}{\cos \theta} = \frac{-9}{\cos \theta}$. Con la sección *ux*, el esfuerzo en $gd = \frac{W_1 + W_2 - R}{\cos \theta} = \frac{-3}{\cos \theta}$. Se verá que estas fuerzas, obrando todas *hacia abajo* en la parte de la armadura á la izquierda de la sección, dan tensión en *ed*, y *compresión* en *ef* y *gd*.

Con la sección *uz* cortamos dos miembros de la armadura *gd* y *gc*; pero la presión en *gd* ha sido encontrada ya $= \frac{3}{\cos \theta}$, cuya componente vertical es = 3. Por consiguiente, la presión en $gc = W_1 + W_2 + W_3 + 3 - R = 6$.

**73.** Es evidente, sin embargo, por una simple inspección que la vertical media soporta solamente la carga media $W_3 = 6$, porque, cortando la armadura por una sección curva, como en *c*, y examinando la parte pequeña separada de esta manera, veremos que sólo existen dos fuerzas verticales, á saber : la carga central, $W_3$ y la fuerza en la pieza vertical; y, para que haya equilibrio, estas dos deben ser iguales.

## Esfuerzos en los cordones. Momentos.

**74.** Para las tensiones en las cuerdas, fig. 30, sea P = largo del tramo = 10 pies *. Entonces el momento de flexión en el extremo, *d*, del tramo es

$$M = 2\, RP - W_1 P$$
$$= 15 \times 20 - 6 \times 10$$
$$= 300 - 60 = 240.$$

* *N. del T.* — Donde, como aquí, la unidad elegida puede ser cualquiera, sin que deje de comprenderse la teoría ó principio, dejamos las unidades inglesas.

Cortando la armadura por la sección *uv*, encontramos que, de las tres piezas cortadas, solamente el cordón, *eg*, tiene momento respecto al punto *d*. Llamemos su esfuerzo S. Su brazo de palanca es la altura, D, de la armadura = 12, y para que haya equilibrio, SD = M. Por consiguiente, $S = \frac{M}{D} = \frac{240}{12} = 20$.

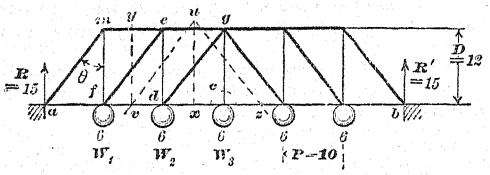

**Fig. 30.**

**75**. De igual manera, tomando momentos respecto al punto *e*, encontramos que el esfuerzo en el cordón inferior, *fd*, cortado por la sección *uv*, es $\frac{240}{12} = 20$, el mismo que el esfuerzo en la parte del cordón superior cortado por la misma sección. La sola inspección mostrará lo correcto de este resultado; porque el poste diagonal *ef* comunica evidentemente á la parte *eg* del cordón una compresión (véase § 77) igual á la tensión que le comunica á la parte *fd* del cordón inferior.

**76**. Si los cordones de la viga están inclinados, sus brazos de palanca deben, por supuesto, medirse *perpendicularmente á ellos*, y no podremos usar ya la altura vertical de la armadura como el brazo de palanca.

**77**. Cada diagonal comunica una compresión al cordón superior, y, en las armaduras de cordones paralelos, una tensión igual al cordón inferior. Encuéntrese el esfuerzo cortante, ó componente vertical, $V_1 V_2$, etc., de las fuerzas en cada diagonal, empezando por el poste del extremo. Entonces las tensiones ó compresiones $h_1, h_2$, etc. en las porciones de ellas, *af* y *me*, *fd* y *eg*, etc., debidas á las varias diagonales separadamente, son:

$$h_1 = V_1 \tan \theta$$
$$h_2 = V_2 \tan \theta$$
$$h_3 = V_3 \tan \theta$$

y para el esfuerzo total en cada cordón de la viga, tenemos: $H_1 = h_1$, $H_2 = h_1 + h_2$, $H_3 = h_1 + h_2 + h_3$, y así en adelante.

## Esfuerzo cortante.

**78**. Cualquier parte del diagrama de un esfuerzo cortante se aplica á todas las piezas atravesadas por él hasta llegar al extremo del tramo donde el esfuerzo cortante cambia. Así, en la fig. 31, el diagrama del esfuerzo cortante en la derecha de la figura incluye la vertical, *tu;* el de la izquierda incluye la diagonal *mo;* y el que está entre las cargas incluye la diagonal *tn*, y la vertical *mn*.

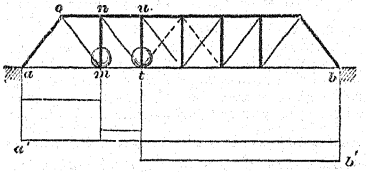

**Fig. 31.**

**79. Diagrama de influencia del esfuerzo cortante.** Véase Estática, §§ 325, etc. En una armadura, fig. 32, las ordenadas *c'g*, etc., á la línea *a"b'* (construída como en la fig. 156, Estática, § 349), dan las *reacciones* del extremo izquierdo, y las *c'h*, etc., hasta la línea *a'b"*, las *reacciones* del extremo de la derecha, para *cualquiera posición de la carga* y los esfuerzos cortantes resultantes de una carga W

(no indicada), *en cualquier división de tramo; pero los esfuerzos cortantes en un tramo, cd*, para una carga W *entre los extremos de los tramos*, se modifican por la acción de las vigas al distribuir la carga entre dichos extremos de tramo adyacentes, como lo indican las líneas de influencia, *qh*, etc., para los diversos tramos. Así, con W en *c* y en *d*, respectivamente, el esfuerzo cortante en el tramo *cd*, está representado, respectivamente, por *c'h* (negativa) y *d'q* (positiva), y al pasar la carga de *c* á *d*, el esfuerzo cortante en el tramo cambia de *c'h* á *d'q*.

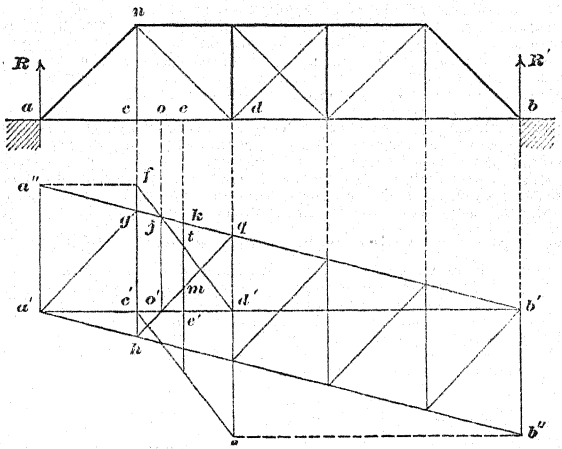

**Fig. 32.**

Pero cuando W se coloca en cualquier punto *e* entre *c* y *d*, su carga se distribuye entre *c* y *d*, por el cordón que obra como una viga.

**30.** De esta manera, trazando para esta viga *cd* (como para la viga entera en Estática, fig. 156), las líneas de influencia *jd'* y *c's* del *tramo*, vemos que, cuando W se mueve de *d* dentro del tramo *cd*, con respecto á *e*, la reacción de la armadura en *a* se aumenta ligeramente por esta razón de *d'q* hasta *e'k*; pero al mismo tiempo la parte de W, representada por *e't*, es transportada por el cordón á *c*, donde disminuye el esfuerzo cortante *e'k* (debido á la reacción de la armadura en *a*), dejando á *tk* como valor del esfuerzo cortante en el tramo. Al colocar el peso W en puntos, sucesivamente, más distantes de *d*, acercándose al punto *o*, la carga transportada por el cordón al punto *c*, y representada por las ordenadas de *c'd'* hasta *jd'*, continúa aumentando más rápidamente que la reacción R en el extremo izquierdo de la armadura, representada por las ordenadas de *a'b'* hacia *a''b'*, y los esfuerzos cortantes resultantes en el tramo están representados por las ordenadas entre *jd'* y *jq*. En *o*, la carga parcial, *o'j*, transportada al punto *c*, es=la reacción izquierda de la armadura, y el esfuerzo cortante en el tramo es cero. Con la carga entre *o* y *c*, las cargas parciales, transportadas á *c*, y representadas por las ordenadas de *o'c'* á *jf*, son *mayores* que las correspondientes reacciones del extremo izquierdo de la armadura, y el resultado es un esfuerzo cortante *negativo* en el tramo, indicado por las ordenadas de *jg* á *jf*. Se observará que los esfuerzos cortantes resultantes en todas partes, los positivos y los negativos, están indicados, por las ordenadas de *c'd'* hacia *hq* *.

Invirtiendo el proceso, se puede aplicar un argumento semejante á la línea de influencia del tramo *c's*, empezando con la carga en *c*, con esfuerzo cortante negativo en el tramo=*c'h*, y suponiendo que se mueve por el tramo hasta *d*, donde el esfuerzo cortante positivo en el tramo se hace=*d'q*.

**31.** En el caso de una **carga uniforme**, que se extienda por la luz desde

* Puesto que *fh*, *jo'* y *ke'* son paralelas, *me'* = *kt*, y *c'h* = *gf*.

el apoyo derecho, *b*, el punto *o* es la posición de la punta de la carga para el máximo esfuerzo cortante en el tramo *cd*, porque en el caso de una carga uniforme el esfuerzo cortante, con la cabeza de la carga en *e*, está representado por el *área* (suma de todas las ordenadas) *e'mqb'e'*, y evidentemente, esta área aumenta á proporción que la punta de la carga se acerca el punto *o;* pero, cuando llega al punto *o* el área sobre *a'b'*, no puede aumentar más, y cuando *pasa* de *o*, los esfuerzos cortantes *negativos*, representados por las ordenadas de *o'c'* á *o'h*, empiezan á *reducir* el esfuerzo cortante positivo que resulta.

**82.** Habiendo encontrado, por cualquier método, el esfuerzo cortante máximo, *d'q*, debido á una carga concentrada en *d*, para la diagonal *dn*, fig. 32, y el esfuerzo cortante máximo inverso, *c'h*, debido á la misma carga en *c*, podemos trazar una línea de influencia *hq*, que da como antes, el punto *o*, de la posición de la cabeza de la carga uniforme para el esfuerzo máximo en la diagonal, *dn*, por la cual (como anteriormente) encontramos la posición correspondiente de los extremos de una serie de cargas concentradas.

En la práctica, la línea de influencia del esfuerzo cortante es de importancia principalmente para encontrar la posición de la carga que produce esfuerzo máx, y los esfuerzos resultantes en las armaduras de cordones en curva como en la fig. 17. En tales armaduras, debido á la inclinación de las partes del cordón superior, estas partes reciben algo de los esfuerzos cortantes en sus respectivos tramos, y el esfuerzo en la diagonal es, por consiguiente, menor que el esfuerzo cortante en el tramo.

## Determinación gráfica de los esfuerzos de la carga muerta.

**83.** Constrúyase en primer lugar un diagrama de la armadura, como en la fig. 33 (*a*), poniendo letras en los espacios entre los miembros, y á los que están entre las saetas que representan las cargas muertas. Llámese el poste del extremo 1-3, entre A y B, « AB » el esfuerzo en él « *ab* », la carga en 2, « *cd* », etc., usando letras mayúsculas para los tramos y los miembros de la armadura, y letras minúsculas para las cargas y esfuerzos. Adóptese una escala de fuerzas adecuada, y constrúyase el diagrama, fig. 33 (*b*), como sigue :

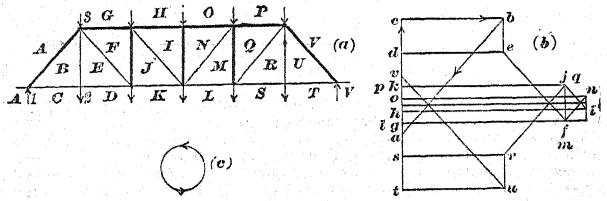

**Fig. 33.**

**84.** Consideremos en primer lugar el punto 1, fig. 33 (*a*). Aquí hay tres fuerzas en equilibrio, á saber : *ac*, *ab* y *bc*. Encuéntrese la reacción del extremo R = *ac*, trazándola hacia arriba (puesto que obra hacia arriba en 1), de un punto conveniente, *a*, hasta *c*, fig. 33 (*b*). Desde *a* trácese una línea indefinida *ab* paralela á AB, y desde *c* trácese *cb* paralela á BC, obteniendo el triángulo de fuerzas *acb* del punto 1. Las longitudes de *cb* y *ba* dan entonces los esfuerzos por la escala.

**85.** En la fig. 33 (*b*), la flecha en *ac* indica la dirección hacia arriba de esa fuerza. Siguiendo alrededor del triángulo, colocamos flechas (en la misma dirección), en *cb* y *ba*. Suponiendo que estas saetas se transfieran ahora á los miembros correspondientes en la fig. 33 (*a*), veremos que *bc* tira del punto 1, mostrando que *bc* es tensión ó +, y que *ba* empuja hacia 1, mostrando que *ba* es compresiva, ó —.

**86.** La naturaleza de las fuerzas puede encontrarse más rápidamente como sigue : trácese un círculo, fig. 33 (*c*), y pónganse saetas alrededor de él indicando la dirección (contraria á la del minutero en este caso) (véase *N. del T.* al pie, pág. 463) que se ha seguido alrededor de la armadura al construir la línea de la carga. Véase § 92, más abajo. Entonces consideremos un nudo cualquiera, fig. 33 (*a*), y sigamos las letras en los espacios alrededor de él en la dirección de las flechas del círculo. Obsérvese el orden de las letras y síguese el polígono de equilibrio, fig. 33 (*b*), en la misma dirección. Éste dará las direcciones según las cuales las fuerzas obran respectivamente en ese nudo.

**87.** Así, consideremos el nudo 2. Siguiendo alrededor de 2, en la dirección del círculo, leemos, B, C, D, E. Pasando ahora á la fig. 33 (*b*), y leyendo, *b*, *c*, *d*, *e*, encontramos que en *bc* vamos de derecha á izquierda (opuesto á la dirección indicada por la flecha trazada en el punto 1), por consiguiente *bc* obra hacia la izquierda en 2; BC está por consiguiente en tensión, y su fuerza *bc* es +.

**88.** Dada ya la fuerza *bc*, en BC, constrúyase sobre *bc* el polígono de fuerza *bcde*, de las cuatro fuerzas que obran en el punto 2. Desde *c*, trácese *cd*, hacia abajo, representando la carga muerta en el cordón inferior en 2. Puesto que *bc* obra como tensión hacia la izquierda en 2, y como las fuerzas deben seguirse una á otra alrededor del polígono, *cd* se deberá trazar evidentemente hacia abajo, desde *c*, y no desde *b*. Desde *d* trácese una línea indefinida paralela á la DE, y desde *b*, otra, paralela á BE. Éstas se interceptarán en algún punto, como *e*, y *eb* y *de* representarán entonces los esfuerzos en BE y DE.

**89.** Una inspección mostraría que $be = cd$, puesto que *cd* es la única fuerza que obra en 2, con una componente vertical, y que $bc = de$; pero la construcción del polígono de fuerzas *bcde* es necesaria para completar el diagrama.

**90.** Habiendo encontrado ya los esfuerzos en DE, BE y AB, y conociendo la carga del tramo ($= ga$) en el punto 3, constrúyase el polígono *gabefg*. Éste dará *ef* y *fg*, y desde éstas se podrá continuar el procedimiento y completar el diagrama.

**91.** Se observará que, en algunos casos, á un mismo punto del diagrama, fig. 33 (*b*), se le pone más de una letra. Ordinariamente, esto es una simple coincidencia, causada por la superposición de los polígonos de fuerza. En algunos casos, sin embargo, la coincidencia de las letras muestra que el esfuerzo en la pieza respectiva es cero.

**92.** En la práctica, se acostumbra construir primero la línea de carga entera de la manera siguiente: Trácese primero la reacción neta, *ac* hacia arriba, después siguiendo alrededor de la armadura, contra el movimiento del minutero (véase *N. del T.* al pie, pág. 463), trácense todas las otras fuerzas exteriores (carga muerta) en su orden respectivo, así: *cd*, *dk*, *kl*, *ls*, *st*, *tv*, *vp*, *po*, *oh*, *hg*, *ga*. El diagrama de los esfuerzos podrá entonces construirse como antes.

## Cargas vivas.

**93.** Podía suponerse, en primer lugar, que cada pieza de la armadura recibe el esfuerzo máximo cuando el tren cubre completamente el puente, pero esto es cierto solamente respecto á los cordones. En la armadura que muestra la fig. 33 (*a*) cada pieza entre cordones recibe el máximo de fuerza cuando el mayor esfuerzo cortante posible ocurre en una sección que corte esa pieza.

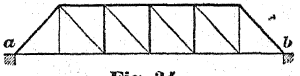

**Fig. 34.**

**94.** La fig. 34 indica las *principales* diagonales á la izquierda y las contradiagonales á la derecha del centro. Una cualquiera de estas piezas recibe el máximo de presión de una carga uniformemente distribuída cuando la carga se extiende desde él, hasta el soporte *derecho b*, con la cabeza de la carga en un punto, *o*, fig. 32 (*a*), que se encontrará como en el § 81; y viceversa para las diagonales inclinadas en dirección *opuesta*. Cada vertical recibe el máximo del esfuerzo cuando la carga se extiende desde el apoyo más distante hasta un punto *o* (véase § 81), en el tramo más allá de la vertical. Esta regla debe modificarse ligeramente cuando consideramos las cargas concentradas sobre ruedas. Véanse §§ 97, etc.

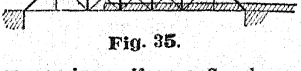

**Fig. 35.**

**95. Se supone la carga viva uniforme.** Con alguna aproximación la locomotora y el tren se consideran como una carga uniforme que cruza el puente, fig. 35; pero este método, donde no se toma en cuenta la gran concentración de peso en las locomotoras modernas, puede resultar, ó inseguro, ó produciendo desperdicio de material. Esta suposición es correcta al tratar de la presión del viento sobre el tren. Véase § 121.

**96. Exceso de cargas concentradas.** También para compensar las cargas de la locomotora se emplean algunas veces una ó más cargas de exceso concentradas. Los esfuerzos debidos á estas cargas pueden computarse separadamente, y agregarse á las presiones producidas por las cargas vivas uniformes. Para que produzcan el máximo de los esfuerzos en los cordones, las cargas de exceso deben estar en el

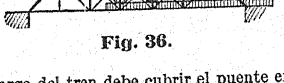

**Fig. 36.**

centro de la luz, y la carga del tren debe cubrir el puente entero. Este método es bastante aproximado, pero los ingenieros difieren respecto á si debe usarse este método ó el del peso real sobre las ruedas de la locomotora « típica » como se indica luego.

**97. Cargas sobre la rueda.** En el método de las cargas « típicas » sobre la rueda, se consideran los esfuerzos reales producidos por las máquinas más pesadas que puedan cruzar el puente. Aun en máquinas de casi el mismo peso, las cargas pueden estar diversamente separadas, y á intervalos de fracciones de centims, que hacen muy laborioso el cálculo. Por esta razón, y en previsón del uso de máquinas más pesadas en lo futuro, se acostumbra considerar una máquina imaginaria ó « típica », con cargas y espacios dados en números redondos, cuyas presiones sean por lo menos iguales á las que produzcan las máquinas más pesadas que puedan usarse en dicho puente. Las cargas vivas se consideran ordinariamente como compuestas de dos locomotoras normales con sus ténderes, seguidas de un tren de peso uniforme. Véase el Resumen de las especificaciones.

**98.** El siguiente, es un ejemplo del cálculo de las presiones de la carga viva por el método de las cargas sobre ruedas de locomotora. La fig. 37 (*b*) representa las cargas en un riel que corresponden al modelo de Cooper, clase normal E 40, que se compone de dos locomotoras de consolidación acopladas *, seguidas de un tren que se considera equivalente á una carga uniforme de 4,000 libras por pie lineal (5,960 kg por metro). En el diagrama, fig. 37 (*a*), todas las cargas están en miles de libra, los momentos en millones de pieslibras y las distancias en pies **.

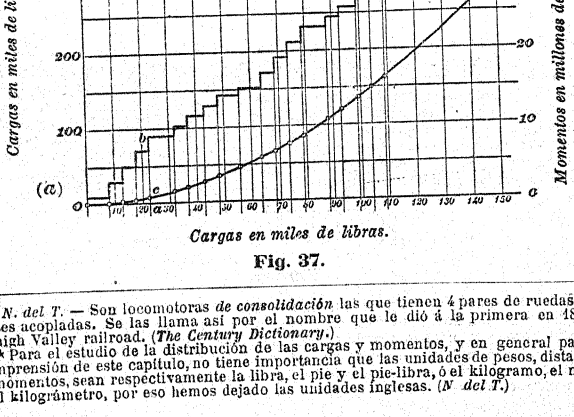

**Fig. 37.**

* *N. del T.* — Son locomotoras *de consolidación* las que tienen 4 pares de ruedas motrices acopladas. Se las llama así por el nombre que le dió á la primera en 1866 el Lehigh Valley railroad. (*The Century Dictionary.*)

** Para el estudio de la distribución de las cargas y momentos, y en general para la comprensión de este capítulo, no tiene importancia que las unidades de pesos, distancias y momentos, sean respectivamente la libra, el pie y el pie-libra, ó el kilogramo, el metro y el kilográmetro, por eso hemos dejado las unidades inglesas. (*N. del T.*)

**99. Esfuerzos producidos por la carga viva** sobre las piezas del tejido de la armadura. El máximo de estos esfuerzos ocurre en las barras ó piezas de cualquier tramo, figs. 34 ó 38, cuando la carga viva produce el máximo esfuerzo cortante en el tramo.

Puede demostrarse que esto ocurrirá cuando $P = \frac{W}{n}$, en que P=á la carga viva en el tramo cortado por la sección; W=la carga viva total en la armadura, y $n$=el número de tramos de la armadura. Esta ecuación se tiene como norma del esfuerzo cortante máximo.

**100.** La tabla siguiente se basa en esta relación. La segunda columna se obtiene agregando á P, las sucesivas cargas por rueda. En este caso W=6P, puesto que nuestra armadura tiene 6 tramos. Supongamos que una rueda esté en el punto de división de un tramo. Entonces, moviendo la rueda un poco á la izquierda ó á la derecha, estará incluída ó excluída de P. De aquí que P y W tengan cada uno un valor mínimo y máximo para cada rueda situada en un punto de división de un tramo.

| N.° de la rueda en cualquier punto de división de un tramo. | Valor, P, de la carga en el tramo á la izquierda del punto dado. | Valor correspondiente de W para el máximo del esfuerzo cortante en el tramo. |
|---|---|---|
| 1 | 0 á 10,000 | 0 á 60,000 |
| 2 | 10,000 á 30,000 | 60,000 á 180,000 |
| 3 | 30,000 á 50,000 | 180,000 á 300,000 |
| 4 | 50,000 á 70,000 | 300,000 á 420,000 |
| 5 | 70,000 á 90,000 | 420,000 á 540,000 |

**101.** La posición de la carga viva, para el esfuerzo cortante máximo, en cualquier tramo, se encuentra por ensayos sucesivos. Al encontrar la posición, se calcula el momento respecto al apoyo derecho, y de éste se obtendrá el esfuerzo cortante. Para ejemplos, véase más abajo.

**102.** Estas operaciones pueden ejecutarse por el cálculo con ó sin la ayuda de los métodos gráficos. Como el cálculo es un poco fastidioso, particularmente cuando la forma de la armadura es complicada por tener los cordones arqueados ó llevar subtramos, y como el método gráfico es bastante exacto para todos los usos prácticos, y tiene la ventaja de que habla á la vista directamente, damos este último solamente.

**103. El « diagrama de ruedas »**, fig. 37 (*a*) *, da (1) una « línea de carga » de escalones ó « diagrama del esfuerzo cortante », y (2) un diagrama en curva de los momentos ó « polígono de equilibrio ». Véase Estática, §§ 359, etc.

**104.** La línea de carga viva total á la izquierda de un punto cualquiera, incluyéndolo.

**105.** La línea de los momentos da, en cualquier punto, el momento de las cargas vivas (á la izquierda), con respecto á ese punto é incluyéndolo. Así, á la izquierda de la rueda n.° 5 é incluyéndola, tenemos :

| Ruedas. | Carga. | Distancia de la rueda 5. | Momento respecto á 5 en pies-lbs. |
|---|---|---|---|
| 1 | 10,000 | 23 | 230,000 |
| 2 | 20,000 | 15 | 300,000 |
| 3 | 20,000 | 10 | 200,000 |
| 4 | 20,000 | 5 | 100,000 |
| 5 | 20,000 | 0 | 0 |
| Total... | 90,000 | | 830,000 |

y las ordenadas, *ab*, á la curva de carga, y *ac*, á la curva de momentos, debajo de la rueda 5, miden 90.0 y .830 respectivamente.

**106.** La fig. 38 representa la armadura, en la misma escala que la fig. 37. Podemos llamar éste un « diagrama de armadura ».

*Método publicado por Ward Baldwin, « Engineering News », vol. XXII, sept. 28, 1889, pág. 295. Véase también « Eng. News », dic. 28, 1889, pag. 645.

**107.** Ejemplo. Para computar el esfuerzo cortante máximo en el tramo *bc*, fig. 38, encuéntrese primero aquella posición de la carga que producirá ese esfuerzo cortante máximo. Como tanteo, colóquese el diagrama de armadura, fig. 38 **, con el

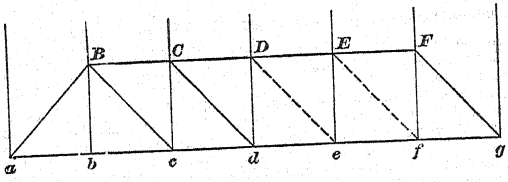

**Fig. 38.**

punto *c* debajo de la rueda 2, fig. 37. Examinando el diagrama de carga, en el extremo derecho, *g*, de la luz, vemos que ahora tenemos una carga total, W, de 284,000 libras en la luz, y que el diagrama de carga sobre la rueda 2 (colocada en el punto *c*) muestra (véase también la tabla § 100) que la carga P, en el tramo *bc*, está ahora entre 10,000 y 30,000 libras; pero para el esfuerzo cortante máximo en el tramo, *bc*, la carga, P, en ese tramo debe ser (véanse §§ 99 y 100° = W ÷ *n* = 284,000 ÷ 6 > 30,000 libras. De aquí que P deba aumentarse moviendo el diagrama de tren, fig. 37, hacia la izquierda (ó, lo que es lo mismo, moviendo el diagrama de armadura, fig. 38, hacia la derecha) hasta que la rueda 3 esté sobre *c*.

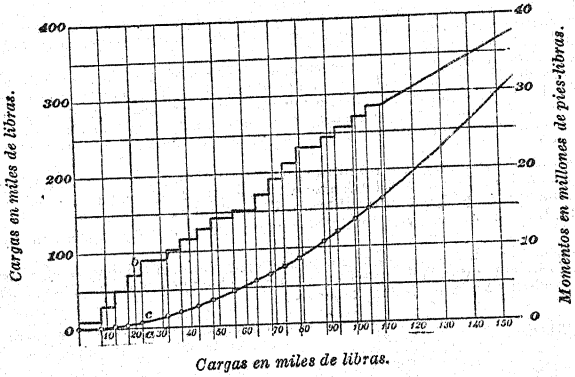

**Fig. 37 (repetida).**

Tenemos ahora, W = 292,000 libras, P = entre 30,000 y 50,000 y el valor requerido de P, para el esfuerzo cortante máximo = W ÷ *n* = 292,000 ÷ 6 = 48,667 libs. De aquí que las condiciones estén satisfechas, y el tramo *bc* reciba su esfuerzo cortante máximo cuando la rueda 3 está en *c*. El diagrama de los momentos indica verticalmente sobre *g* el momento de la carga viva, respecto al apoyo derecho = = 17,516,000 pieslibras, y el momento en *c* = 223,000 pieslibras.

** Para la discusión siguiente se encontrará cómodo hacer una copia de la fig. 38, ó simplemente del cordón inferior, en un pedazo de papel separado, que pueda aplicarse, en posiciones diferentes, á la fig. 37.

**108.** Sea M=el momento de la carga viva (de la izquierda) en el estribo de la derecha, debido á todas las cargas en la luz del puente.
L=la luz del puente.
$m$=el momento de la carga viva de la izquierda en la punta del tramo á la derecha del tramo en cuestión.
$l$=el largo del tramo.
V=el esfuerzo cortante en el tramo.

$$\text{Entonces } V = \frac{M}{L} - \frac{m}{l} = \frac{17{,}516{,}000}{150} - \frac{230{,}000}{25} = 107{,}600 \text{ lbs *.}$$

**109.** Los esfuerzos cortantes máximos de las cargas vivas en los otros tramos, computados de igual manera, son como sigue, estando la carga, en cada caso, colocada de manera que dé dicho esfuerzo cortante máximo.

| Tramo, n.º y posición de la rueda. | Mom M en el extremo derecho de la armadura. Pies-lbs. | Mom $m$ en el extremo derecho del tramo. Pies-lbs. | Esfuerzo cortante *. Libras. $V = \frac{M}{L} - \frac{m}{l}$ | Piezas ó barras. | Esfuerzo. Libras $S = \frac{V}{\cos \theta}$ **. |
|---|---|---|---|---|---|
| *ab* 4 á *b* | 27,176,000 | 480,000 | 162,000 | *a*B | — 217,200 |
| *bc* 3 á *c* | 17,516,000 | 230,000 | 107,600 | B*c* | + 144,200 |
| *cd* 3 á *d* | 10,816,000 | 230,000 | 63,000 | C*c* | — 63,000 |
| | | | | C*d* | + 84,500 |
| *de* 2 á *e* | 4,936,000 | 80,000 | 29,700 | D*d* | — 29,700 |
| | | | | D*e* | + 39,800 |
| *ef* 2 á *f* | 1,743,000 | 80,000 | 8,400 | E*f* | + 11,250 |

**110. El esfuerzo de la carga viva en el montante,** B*b*, es debida enteramente á las cargas sobre las dos porciones del cordón inferior, *ab* y *bc*. Así, pues, con la rueda cuatro en *b*, largo del tramo=*ab*=*bc*=25 pies, tenemos:

Sobre *ab*

| Rueda. | Carga, W. | Dist *d*, de *a* | Esfuerzo en B*d*= *wd* ÷ 25. |
|---|---|---|---|
| 1 | 10,000 | 7 | 2,800 |
| 2 | 20,000 | 15 | 12,000 |
| 3 | 20,000 | 20 | 16,000 |
| Total, | 50,000 | | 30,800 |

Sobre *bc*

| Rueda. | Carga, W. | Dist *d*, de *c*. | Esfuerzo en B*b*= *wd*÷25. |
|---|---|---|---|
| 5 | 20,000 | 20 | 16,000 |
| 6 | 13,000 | 11 | 5,720 |
| 7 | 13,000 | 6 | 3,120 |
| Total, | 46,000 | | 24,840 |

Carga total sobre *ab*= 50,000
— — — *bc*= 46,000
Rueda 4 = 20,000
Carga total sobre *ac*=116,000

Esfuerzo en B*b* de *ab* =30,800
— en B*b* de *bc* =24,840
— en B*b* de rueda 4=20,000
Esfuerzo en B*b*. Total, 75,640

**111.** Para cualquiera disposición de cargas sobre *ac*, el esfuerzo máximo tiene lugar cuando la carga sobre *ac* está igualmente dividida entre *ab* y *bc;* lo cual ocurre ordinariamente mientras alguna de las ruedas (encontrado por tanteo), esté pasando por *b*. Así pues, con la rueda 4 justamente á la derecha de *b*, tenemos, sobre *ab*, las ruedas 1, 2 y 3=50,000 lbs ; y, en *bc*, las ruedas 4, 5, 6 y 7 = 66,000 lbs ; pero con la rueda 4 justamente á la *izquierda* de *b* se tiene en *ab*, ruedas 1, 2, 3 y 4 = 70,000; y, sobre *bc* (despreciando la rueda 8 que entra ahora en *bc*), las ruedas 5, 6, 7=46,000 lbs. Por consiguiente, cuando a rueda 4 esté pasando por *b*, hay un instante en que las cargas sobre *ab* y sobre *bc* son iguales, y en ese momento la presión en B*b* llega á su máximo (75,640 lbs, véase § 110), para la serie de cargas dada.

**112. Esfuerzos de la carga viva en el cordón.** El criterio que guía para la posición de la carga, en el máximo momento flexor en una sección cualquiera, y

* A causa de ser $\frac{M}{L}$ = la reacción del soporte izquierdo, *a*, y $\frac{m}{l}$ = la porción de la carga del tramo que va al extremo izquierdo del tramo.
** $\theta$ = ángulo entre diagonal y vertical.

por consiguiente para el esfuerzo máximo en esa sección, es $\frac{W}{w} = \frac{L}{l}$ ó $l = L\frac{w}{W}$, en que W = la carga total en la armadura, $w$ = la carga á la izquierda de la sección, L = la luz del puente, y $l$ = el largo del segmento á la izquierda de la sección.

**113.** Para encontrar la posición de la carga para el momento máximo en cualquier tramo, por medio del diagrama de los momentos, fig. 37, colóquese una rueda, digamos la rueda 2, en el punto de división del tramo á la derecha del tramo dado. Desde la intersección de la línea de carga (que ordinariamente coincide con el eje de las $x$) verticalmente sobre el soporte izquierdo, colóquese una regla, ó extiéndase un hilo hasta la intersección de la línea de carga con una vertical sobre el soporte derecho. Si la línea construída de esta manera vuelve á cruzar la línea de carga en un punto situado sobre la sección en cuestión, la posición es correcta; si no, es incorrecta. Para facilitar este trabajo, es bueno usar un diagrama de armadura, fig. 38, dibujado en una hoja de papel de trazar, con las verticales prolongadas cuidadosamente desde los puntos de división de los tramos hacia arriba hasta donde las líneas de cargas ó de momentos puedan llegar.

**114.** Se encontrará con frecuencia que más de una posición satisface y que alguna de ellas puede dar momentos mayores que las otras. De aquí que sea conveniente buscar todas las posiciones posibles. Al encontrarlas, determinemos los momentos, como sigue: En la curva de momentos búsquense dos puntos que coincidan (verticalmente) con los apoyos izquierdo y derecho respectivamente, y únanse estos puntos con una línea recta. Cuando la cabeza del tren no ha llegado al apoyo izquierdo, el punto que corresponde á este apoyo, está en el eje de las $x$, prolongado.

**115.** El momento requerido se mide por la distancia vertical de la ordenada á lo largo de la sección, entre la curva de momentos y la línea recta que se acaba de trazar.

El esfuerzo en las partes del cordón es igual al momento dividido por la altura de la armadura. Empleando estos métodos se obtienen los siguientes resultados:

| Sección. | Rueda. | Momento en pies-lbs. | Presión lbs. | Piezas. |
|---|---|---|---|---|
| B$b$ | 4 | 4,049,333 | 144,600 | $ab = bc$ |
| C$c$ | 7 | 6,211,667 | 221,800 | $cd =$ — BC |
| C$c$ | 8 | 6,207,667 | No máx. | |
| D$d$ | 11 | 7,044,000 | No máx. | |
| D$d$ | 12 | 7,056,500 | 252,000 | — CD = — DE |

## Cargas debidas al viento.

**116.** Un puente está sujeto no solamente á las cargas *verticales*, debidas á la carga muerta, á la carga viva, y á los choques causados por desigualdades entre la vía y en el material rodante, sino también á las cargas horizontales. Estas cargas horizontales se deben á la acción transversal del viento, á las fuerzas centrífugas producidas

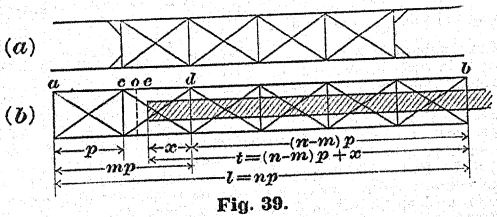

**Fig. 39.**

por el tren al pasar por una curva en el puente, á la tracción longitudinal ó «arrastre» causada por la parada de un tren en movimiento ó salida de un tren en reposo en el puente. Por consiguiente, es necesario construir barras horizontales que, con los dos cordones superiores ó los dos inferiores de las dos armaduras verticales, formen armaduras horizontales, como sistemas laterales superior é inferior, figs. 39 (*a*) y 39 (*b*), y también barras laterales, contra la vibración y el viento. Véanse §§ 21 y 22.

**117.** El viento se considera que sopla en ángulo recto con el puente.

**118.** El viento produce varios efectos y éstos deben considerarse separadamente, para determinar después sus efectos en conjunto. Entre estos efectos están:

(1) Los esfuerzos directos en ambos sistemas laterales, el superior y el inferior, causando presiones directas sobre los cordones, obrando horizontalmente sobre ellos como una carga uniformemente distribuída.

(2) Los esfuerzos directos adicionales en el sistema lateral del cordón cargado cuando un tren está en el puente, debidos á las presiones del viento contra el tren.

(3) Un momento de volcamiento sobre el puente como un todo, aumentando de esta manera las presiones de la carga viva y muerta en la armadura á sotavento y disminuyendo las de la armadura á barlovento.

(4) Una tendencia análoga á volcamiento sobre el tren y las ruedas, que modifica de igual manera sus presiones sobre las vigas del piso, y así, las presiones en las armaduras principales.

**119.** Supondremos que la carga que deriva del efecto del viento, obrando directamente, está igualmente dividida entre los cordones superior é inferior y entre la armadura á sotavento y la de barlovento.

**120.** (1) Las presiones directas del viento en las barras laterales, debidas á la presión del viento en la armadura, se encuentran como las presiones en las armaduras principales, debidas á la carga muerta; los puntales transversales horizontales de los tirantes laterales corresponden á los verticales de las armaduras principales.

**121.** (2) Presiones directas en el sistema lateral de cordones cargados, fig. 39 (*b*), debidas al viento contra el tren.

Examinando cualquier tramo, como *cd*, sea **

$w$ = la presión del viento, en lbs por pie lineal de tren.

$p$ = largo del tramo en pies.

$wp$ = presión del viento, en lbs, por tramo, todo ocupado por el tren.

$n$ = número de tramos en la luz (= 6 en este caso).

$l = np$ = la luz del puente en pies.

$m$ = número de tramos desde el apoyo izquierdo, $a$, hasta el tramo, $cd$, que consideramos é incluímos en el cálculo.

$mp$ = la distancia, $ad$, en pies.

$x$ = el largo, en pies, de la parte del tramo, $cd$, que está ocupado por el tren.

$t = (n - m)\,p + x$ = á la parte de la luz del puente que está ocupado por el tren.

= la presión del viento contra el tren para una presión de 1 lb por pie lineal.

R = reacción en $a$ (debida á la acción del viento en la armadura $= wt^2 \div 2l$*.

$r$ = reacción en $c$ debida á la acción del viento sobre el tramo *, $= wx^2 \div 2p$.

S = Esfuerzo cortante del viento * en el tramo, $cd$, $= \mathrm{R} - r = wt^2 \div 2l - wx^2 \div 2p$.

La reacción horizontal * de la *armadura*, en $a$, debida á la presión horizontal concentrada = 1, obrando á cualquiera distancia, $y$ (no indicada), de $d$, es $= \dfrac{(n-m)\,p+y}{np}$; y la reacción horizontal del tramo, en $c$, debida á la misma presión, es $= \dfrac{y}{p}$. El esfuerzo cortante máximo *, en el tramo $cd$, debido al viento contra el tren, ocurre (véanse §§ 79 á 81) cuando la cabeza del tren llega al punto, $o$, en el que, si las cargas concentradas estuvieran colocadas, estas dos reacciones serían iguales, es decir, $\dfrac{y}{p} = \dfrac{(n-m)\,p+y}{np}$. Con la cabeza del tren en $o$, tenemos $x = y = \dfrac{(n-m)\,p}{n-1}$.

Bajo cualesquiera condiciones, el esfuerzo cortante del viento *, S, en el tramo, es $= \mathrm{R} - r$, en que $\mathrm{R} = \dfrac{w\,|(n-m)\,p+x|^2}{2np}$ y, $r = \dfrac{x^2}{2p}$.

Sustituyendo aquí el valor de $x$ acabado de encontrar, para el esfuerzo cortante máximo, obtenemos, como valor máximo del esfuerzo cortante * del viento en el tramo,

$$\mathrm{S}_{max} = \frac{wp}{2\,(n-1)}\,(n-m)^2.$$

---

* Véase la nota ** al pie del § 2.

** *N. del T.* — Dejamos el pie y la libra, pues los ejemplos y la teoría son enteramente análogos usando el metro y el kilogramo.

**122.** (3) Esfuerzos en las piezas de las armaduras principales debidos a momento de volcamiento producido por el viento en la armadura: Momento de volcamiento = (carga debida al viento en el tramo en el cordón superior) × (número de puntos de división de tramos en la luz) × altura de la armadura.

$$\text{Reacción vertical en un apoyo} = \frac{1}{2}\,\frac{\text{momento de volcamiento}}{\text{ancho entre las armaduras}}.$$

Como el sistema lateral superior lleva todas las cargas debidas al viento á los extremos del puente, los postes de los extremos y los cordones (que reciben las componentes horizontales de los empujes del poste final) son las únicas piezas principales de la armadura, afectadas.

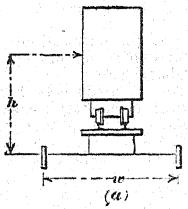

**Fig. 40.**

**123.** (4) Esfuerzos en los miembros principales de la armadura debidos al momento de volcamiento del viento contra el tren, fig. 40. Sea $h$ = altura del centro de gravedad del sistema lateral del cordón cargado, al centro de presión del viento contra el tren, $p$ = la presión del viento por pie lineal de tren, $w$ = la distancia entre los centros de gravedad de las armaduras, $m$ = momento de volcamiento por pie lineal de tren, $v$ = carga vertical añadida por pie lineal de la armadura de sotavento.

Entonces $m = hp$, y $v = \dfrac{m}{w}$.

## Percusión, choque, etc.

**124.** Los efectos del choque debidos á las desigualdades de la vía, los debidos á las paradas y salidas de los trenes, y los de la fuerza centrífuga de los trenes en las curvas, no son susceptibles de cálculo riguroso, y los ingenieros difieren en los medios de calcularlos y preverlos. Véase el Resumen de las especificaciones.

## Determinación de los esfuerzos máximos y mínimos.

**125.** Cuando las especificaciones permiten que la unidad de los esfuerzos dependa de la relación entre los máximos y mínimos esfuerzos en cualquier pieza, se deben calcular ambos.

Al calcular los esfuerzos máximos y mínimos en cualquier pieza, téngase presente que una condición que, por sí misma, tendría cierto efecto sobre un esfuerzo, puede traer consigo otras condiciones que produzcan un efecto mayor y contrario. Así, por ej.: aunque el efecto del viento en un tren reduce los esfuerzos en ciertas piezas, aquella acción puede tener lugar solamente con un tren en el puente, y la acción vertical de la carga del tren aumenta ordinariamente esos esfuerzos en más de lo que la acción del viento los disminuye.

Al calcular las presiones mínimas, aunque la carga viva se desprecia ordinariamente, no debemos despreciar la carga muerta que está siempre presente.

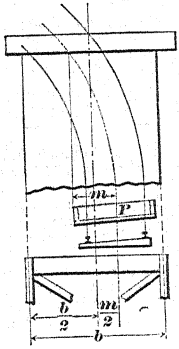
## Curvas en los puentes.

**126. Cuando la vía en un puente es curva,** se coloca ordinariamente de manera que la línea central del puente divida en dos la ordenada media, $m$, de la curva. Véase la fig. 40 (a). El centro de gravedad de una carga de tramo, P, en el centro de la luz del puente (suponiendo que esté en el centro de la vía), se proyecta en una distancia = ½ $m$ de la línea del centro del puente, ó una distancia = ½$b$ + ½$m$ de la armadura interior, en que $b$ = al ancho del puente entre los centros de las arma-

duras. Tomando los momentos respecto al centro de la armadura interior, tenemos por consiguiente, para la carga W, debida á P, en la armadura exterior,

$$W = P\,\frac{\frac{1}{2}b + \frac{1}{2}m}{b} = P\,\frac{b+m}{2b}.$$

Es costumbre (véase el Resumen de las especificaciones) proporcionar la armadura exterior suponiendo que su esfuerzo cortante debido á la carga viva, en cada punto de división del tramo, esté determinado por la fórmula que se acaba de dar, y trazando la armadura interior igual á la exterior.



Figs. 40 (a) y (b).

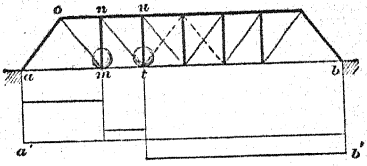


Fig. 31 (repetida).

## Contradiagonales.

**127.** En una armadura de forma ordinaria (como la de la fig. 31), bajo la acción de una carga viva ó muerta distribuída uniformemente ó de una carga viva distribuída simétricamente con respecto al centro de la luz, los esfuerzos cortantes en cada tramo á izquierda del centro de la luz son *positivos;* los de los tramos á la derecha son *negativos;* y los esfuerzos en toda la armadura son tales, que las cuerdas sufren tensión, y los postes compresión; siendo la tendencia en cada tramo *alargar* la diagonal ocupada por una *cuerda* y acortar la ocupada por un *poste.*

Pero, la tendencia de una carga *excéntrica,* igual á la que indica la fig. 31, es *invertir* los esfuerzos cortantes en los tramos entre ella y el centro, y si este esfuerzo, relativamente á las otras fuerzas, es de magnitud suficiente para invertir el esfuerzo cortante en cualquier tramo, la tendencia será acortar la diagonal *ocupada* por una *cuerda,* véase fig. 1 (*a*), y *alargar* cualquier diagonal ocupada por un *poste.*

Como se explica en los §§ 14 y 15, esta condición existe en la armadura triangular ó de Warren, haciendo que cada pieza ó barra pueda resistir ambas cosas: presión y compresión, y en las armaduras de barras verticales y diagonales por la adición de contradiagonales.

En un puente levadizo ó giratorio, no solamente los esfuerzos en las barras del entramado, sino también los de los cordones se invierten cuando la parte movediza se abre ó se cierra.

En previsión contra la posibilidad del aumento posterior en las cargas vivas, sobre las que se usan ahora, y cuando los esfuerzos de la carga viva y muerta sean contrarios, debe calcularse sólo el 70% de los esfuerzos de la carga muerta como cantidad efectiva para equilibrar los esfuerzos de la carga viva.

Para otros sistemas de calcular previsiones semejantes, véase Resumen de las especificaciones para puentes de acero, para ferrocarril.

## Armaduras de techo.

**128.** En las armaduras de techos, *la carga muerta,* es decir, el peso de la misma armadura, de sus accesorios, cubierta del techo, etc., y la carga de la nieve, se con-

sideran de ordinario distribuidas uniformemente. En muchos casos la suma de las cargas muertas y la de la nieve están divididas igualmente entre los dos apoyos. En otras palabras, las reacciones de los extremos son iguales.

**129. Los pesos de las armaduras de acero,** en kg por m cuadrado del espacio fabricado que cubren, puede tomarse, como apreciación preliminar, en (.80 á 1.28) × por la luz en m de acuerdo con el diseño y la carga. Los de las armaduras de madera, con tirantes de acero, hierro ó madera, pueden calcularse de un décimo á un quinto menos.

**130. El peso de los accesorios** de acero ó de madera puede calcularse en 9 á 15 kg por m cuadrado de espacio fabricado que cubra.

**131. El peso de la cubierta del techo** puede tomarse aproximadamente como sigue:

| | | | | | |
|---|---|---|---|---|---|
| Hierro corrugado..... | 9 á 15 kg por m cuadrado de superficie de techo. | | | | |
| Pizarra..... | 34 á 43 | — | — | — | — |
| Tejamaní sobre listoncillos. | 9 á 15 | — | — | — | — |
| Si están sobre tablas, agréguense..... | 13 | — | — | — | — |
| Si están con mezcla, agréguense..... | 29 | — | — | — | — |

**132. La carga debida á la nieve,** en los Estados al Norte de la latitud 35°, puede tomarse (variando principalmente con la latitud) de 48 á 146 kg por m cuadrado de proyección horizontal de superficie de techo.

**133.** Las piezas accesorias, las de refuerzo, etc., deben disponerse de manera de llevar el peso de la cubierta del techo y de la nieve directamente á los puntos de división de los tramos, evitando de este modo las presiones transversales en los cabios ó parecillos.

**134.** Cada armadura soporta, además de su propio peso, la mitad del peso del techo y de la nieve entre las dos armaduras (ó entre armadura y pared) adyacentes á ella, y cada punto de división de tramo soporta la mitad de la carga entre las dos duntas de tramo (ó punta de tramo y apoyo extremo) adyacentes á ella.

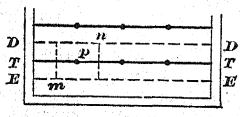

**Fig. 41.**

De esta manera, fig. 41, la armadura TT soporta un peso = al que está sobre la superficie entre las dos líneas de puntos, DD y EE, y el punto de división *p* del tramo R soporta un peso = al que se encuentra en el rectángulo *mn*.

**135.** El viento se considera que sopla horizontalmente sobre un lado del techo y que ejerce una presión normal distribuída uniformemente sobre ese lado. En la tabla siguiente de presiones normales supuestas, obrando contra las superficies inclinadas bajo una presión horizontal del viento de 195.2 kg por m cuadrado, los valores en la última columna están basados en los experimentos de Hutton. Aquí *a* es el ángulo entre la superficie inclinada del techo y el plano horizontal.

**Presión normal supuesta,** P, del viento, en kg por metro cuadrado. Presión horizontal = 195.2 kg por m cuad. *a* = ángulo entre la superficie del techo y un plano horizontal.

| | | P | | | | P | |
|---|---|---|---|---|---|---|---|
| *a.* | sen *a.* | 195.2 sen *a.* | Hutton. | *a.* | sen *a.* | 195.2 sen *a.* | Hutton. |
| 5° | .09 | 17.6 | 24.9 | 35° | .57 | 111.3 | 146.9 |
| 10° | .17 | 33.2 | 46.8 | 40° | .64 | 125.0 | 162.5 |
| 15° | .26 | 50.7 | 69.3 | 45° | .71 | 138.6 | 175.7 |
| 20° | .34 | 66.4 | 89.8 | 50° | .77 | 150.3 | 185.9 |
| 25° | .42 | 82.0 | 110.3 | 55° | .82 | 160.1 | 192.3 |
| 30° | .50 | 97.6 | 129.3 | 60° | .87 | 169.8 | 195.2 |

**136.** Las direcciones é intensidades de las reacciones de los extremos y de las presiones en las piezas, debidas al viento, dependen de que uno ó ambos apoyos estén

fijos. Si ambos están fijos, sus reacciones son paralelas á la presión normal del viento, es decir, están en ángulo recto con el lado del techo sobre el cual el viento está soplando; pero si uno de los extremos está libre para resbalar en el sentido de la armadura, su reacción se tomará como vertical y la del otro estará más cercana á la horizontal que la presión normal del viento. Cuando un extremo está libre, las presiones deben determinarse como si el viento soplara en el lado fijo (en cuyo caso tenderá á achatar el techo) y también como si el viento soplara en el lado libre, en cuyo caso su componente horizontal tiende á acortar el tirante y á levantar el vértice. Los esfuerzos sobre las piezas de las armaduras de techo se encuentran fácilmente por el método de secciones, §§ 67, etc., ó gráficamente como se indica más abajo.

**137.** La fig. 42 (*a*) ilustra el trazado gráfico de las presiones del viento en la fig. 42 (*b*), bajo las tres condiciones citadas, á saber: caso 1.°, con ambos extremos fijos; caso 2.°, con el viento soplando contra el lado fijo, y caso 3.°, con el viento soplando contra el lado libre *.

En la fig. 42 (*a*), los segmentos *ab*, *bc*, *cd* y *de* representan las presiones normales del viento en las puntas de los tramos AB, BC, CD y DE, respectivamente, y *de* por consiguiente representa la presión normal del viento total sobre el techo, estando todas ejercidas contra el lado izquierdo *.

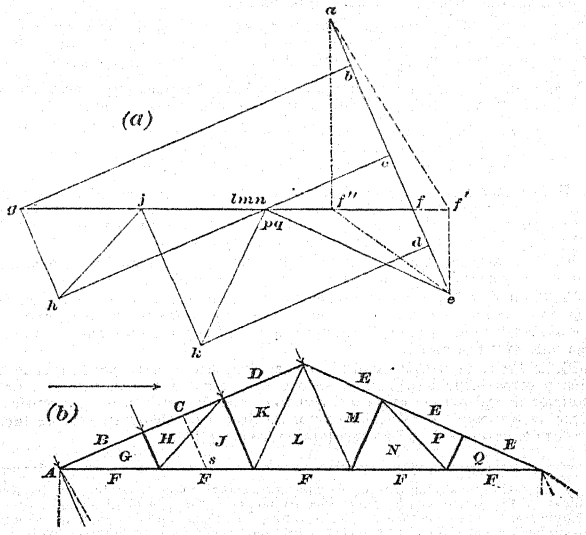

**Fig. 42.**

**138.** En el caso 1 (ambos extremos fijos) los segmentos *fa* y *ef* de la línea continua *ea*, representan las reacciones izquierdas y derechas respectivamente.

**139.** En el caso 2 (soplando contra el lado fijo) las reacciones están representadas por la línea de puntos *ef'a*, y en el caso 3 (soplando contra el lado libre) por la línea de puntos y rayas *ef''a*.

**140.** Los segmentos *f'f* y *ff''* representan respectivamente las componentes horizontales de las reacciones izquierda y derecha del viento en el caso 1, y *f'f''* la reacción del viento en el extremo fijo en el caso 2 ó 3, ó la de la reacción total del viento.

* Para evitar la necesidad de presentar dos figuras en esqueleto y dos diagramas,

**141.** Habiendo encontrado, por los momentos, las reacciones *ef* y *fa* de los extremos para el caso 1, en que, la fig. 42 (*b*),

$$ef = ae \frac{As}{\text{Luz de la armadura}};$$

las reacciones verticales, *ef'* y *af''*, para los casos 2 y 3 respectivamente, se encuentran bajando perpendiculares de *e* y de *a*, fig. 42 (*a*), sobre *gf* prolongada.

Las reacciones de los extremos fijos serán entonces dadas por la línea de unión *f'a*, en el caso 2, y por *ef''* en el caso 3.

**142.** Los esfuerzos en las barras del alma ó trabazón GH, MN, etc., fig. (*b*), y los de las varias partes de los pares BG, EM, etc., estarán dadas por las líneas correspondientes, *gh*, *mn*, *bg*, *em*, etc., en la fig. (*a*).

**143.** En el par á sotavento, el esfuerzo en los tres segmentos, ME, PE, QE, es uniforme en todas partes, y además es el mismo en cada uno de los tres casos, siendo $= me = pe = qe$.

En las cuatro piezas, LM, MN, NP, PQ, hacia sotavento, el esfuerzo en este caso es cero, representado como está por *lmnpq*, fig. (*a*).

**144.** Las presiones en las varias piezas, GF, JF, LF, NF y QF, del tirante horizontal, fig. (*b*), están representadas en la fig. (*a*).

en el caso 1 (ambos extremos fijos) por *gf*, *jf*, *lf*, *nf* y *qf*;
en el caso 2 (viento contra el lado fijo) por *gf'*, *jf'*, etc.;
en el caso 3 (viento contra el lado libre) por *gf''*, *jf''*, etc.

En cada uno de los tres casos hay una tensión uniforme en los tres segmentos de sotavento, LF, NF y QF, del tirante horizontal. Esta tensión uniforme es

en el caso 1 (ambos extremos fijos) $= lf = mf = nf$;
en el caso 2 (viento contra el lado fijo) $= lf' = mf' = nf'$;
en el caso 3 (viento contra el lado libre) $= lf'' = mf'' = nf''$.

**145.** Se verá así que, en nuestra figura, con tirante horizontal, la diferencia en el modo de fijar los extremos afecta sólo los esfuerzos horizontales en las partes de ese tirante, y, por medio, de ellas, la manera como la componente horizontal *f'f''* de la presión del viento se destribuye entre los dos apoyos.

**146.** Si la barra inferior ó tirante no fuera recta, los esfuerzos en las piezas interiores de la armadura y de los pares serían distintos en los tres casos.

**147.** El esfuerzo final ó resultante, en cualquier pieza, es la suma algebraica de las cargas muertas, de las debidas á la nieve y al viento en esa pieza. En algunos casos, la presión del viento puede disminuir y aun invertir los esfuerzos debidos á la carga muerta y á la nieve.

**148.** En las armaduras de madera de corta luz, figs. 43 á 47, para casas de habitación y otros edificios pequeños, se puede, con bastante exactitud, hacer una suposición liberal para la carga incluyendo la presión del viento. Al discutir estas figuras, investigaremos los esfuerzos por medio del paralelogramo de las fuerzas. Para las dimensiones de tales armaduras, véase el § 266.

---

hemos supuesto que el viento sopla siempre en una dirección (contra el lado izquierdo), suponiendo fijo primero un lado de la armadura y después el otro. En la práctica, por supuesto, sucede lo contrario, es decir, uno ú otro extremo de la armadura está fijo (sino ambos), y permanece así, y el viento puede soplar contra uno ú otro lado. Las figuras, sin embargo, servirán también para esta última condición. Así pues, si el viento sopla contra el lado izquierdo, como está indicado, y si, como en el caso 2, ese lado está fijo, entonces el diagrama, usando las líneas quebradas *ef'a*, darán los esfuerzos en las piezas en el orden de las letras. Pero ahora (permaneciendo el extremo izquierdo fijo) supongamos que el viento sople contra el lado libre, es decir, de la derecha. Podemos sin embargo suponer que el extremo derecho esté fijo y que el viento sople contra el lado izquierdo, como en la fig. (*b*), y encontremos los esfuerzos en las piezas de la fig. (*a*) como se encuentra, usando el diagrama de puntos *ef''a*; pero debemos recordar entonces, que las presiones encontradas de esta manera para BG, GF, etc., á la izquierda de la armadura, fig (*b*), realmente se aplican á los miembros correspondientes, QE QF, etc., á la derecha, y viceversa.

**149.** En las armaduras de techo de madera, fig. 43, uniformemente cargadas á lo largo de los pares, sea HI=el peso de un par y su carga. Entonces EI=á la presión horizontal en la cabeza y en el pie de ese par (siendo esta última la tensión en el tirante), y HE=la presión inclinada en su pie.

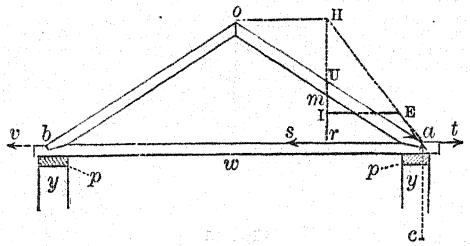

Fig. 43.

**150.** En la fig. 44, hágase GR=HI. Entonces GL será la presión transversal contra el par, como si fuera una viga, y LR será una presión longitudinal á lo largo del par, formando una *parte* de la presión longitudinal total.

**151.** Si GR estuviera concentrada en G, LR sería uniforme desde G hasta *a*, y no se ejercería por encima de G; pero como GR representa una carga distribuída uniformemente á lo largo del par desde el vértice hasta el pie, la presión representada por LR aumenta uniformemente, de cero, en el vértice, *o*, hasta ser LR, en el pie, *a*.

**152.** De la presión transversal, GL, una mitad=*op*, obra en el vértice, *o*, del par, y la otra mitad=*aq*, en el pie, *a*. En la parte superior, *op*, se descompone en una presión horizontal, *ob*=EI contra la cabeza del otro par, y en un empuje, *oz*, á lo largo de *oa*.

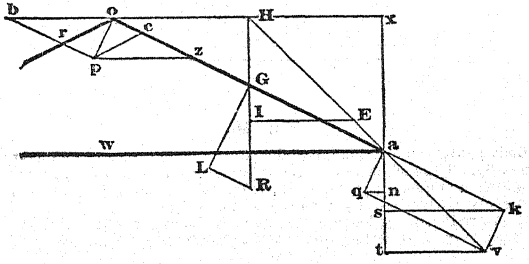

Fig. 44.

**153.** No importa que descompongamos á *op* directamente en *ob* y *oz* (como si la cabeza del par descansara contra una pared vertical en *o*), ó si la descomponemos primero entre los dos pares, en *oc* y *or*; porque en este último caso debemos añadir á *oc* un empuje (=*or*=*cz*) producido en *oa* por la presión transversal (semejante á *op*), de la cabeza del otro par, y la suma de estas dos (*oc* y *or*) es=*oz*.

**154.** El empuje longitudinal total en el par aumenta uniformemente de *oz*, en el vértice, á *oz* + LR=*ak*, en el pie, donde se combina con *aq* (=la mitad de la carga transversal) para formar á *av*=HE.

**155.** Tensión en el tirante=IE=*tv*=*sk* — *nq*. Presión vertical en el apoyo =HI=*at*=*as*+*an*=*as*+*st*.

**156.** En la fig. 45, habiendo encontrado, como en la fig. 43, los esfuerzos, etc., debidos á los pares y sus cargas, recordemos que el pendolón, *on*, soporta su propio peso más la parte *yy* del tirante = ½ del tirante. Haciendo *ot* = este peso combinado, tendremos *om* = *od* = una presión adicional uniforme en cada par, y *cm* = *cd* = una tensión adicional en el tirante.

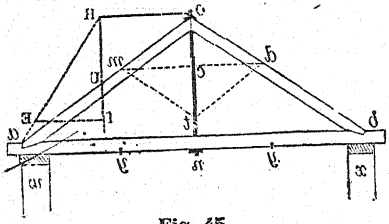

**Fig. 45.**

**157.** En la fig. 46, suponiendo para la seguridad, que el par *jb*, está dividido en su centro, U, hágase *eo* = el peso de *zr* y su carga (*zr* = la mitad del par).

**158.** Entonces *ei* = una presión adicional en U*b*, *ek* = presión en U*c*, *si* = *sk* = tensión adicional en la mitad del tirante, *cb* y *eo* = 2 *es* = carga de *zr* y en *zr*, = tensión adicional en el pendolón debida á ambos tornapuntas. Entonces hágase *ag* = *eo* + peso del pendolón + peso de los dos tornapuntas + peso de *yy* sobre *yy*, y procédase como en la fig. 45.

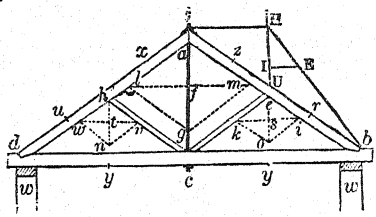

**Fig. 46.**

**159.** Cada puntal soportará la mitad del peso de *zr* y en *zr* ó *xu;* solamente cuando como en la fig. 46, la inclinación del puntal es la misma que la del par. Si el puntal está más inclinado que el par, soportará más de la mitad, si menos, menos de la mitad, y el resto lo soporta el par, en todo caso.

**160.** La introducción de los puntales convierte cada par, considerado como viga, en dos vigas de luz más corta y que soportan cargas menores.

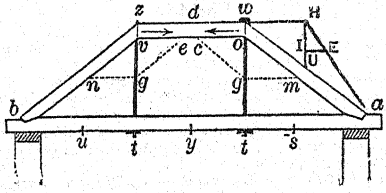

**Fig. 47.**

**161.** En la armadura de la forma, fig. 47, hágase *og* = la tensión total en la péndola + la mitad del peso de *zw*. La presión longitudinal sobre *zw* = la tensión en el tirante, *ba* = IE + *oc*.

## Deformaciones.

**162. La deformación total** de una armadura comprende (1) la deformación elástica ó temporal, debido al estiramiento * de sus varias piezas bajo la carga aplicada á la armadura, y (2) la deformación no elástica ó permanente, debida á la flojedad de sus uniones. En una buena construcción esta última es relativamente despreciable en las luces moderadas.

La deformación total elástica, D, de una armadura, en cualquier punto, *c*, se compone de las deformaciones elásticas parciales, *d*, *d*, etc., en *c*, cada una debida al alargamiento *k* *, en alguna pieza.

Supóngase que deseamos encontrar la deformación en un punto de división de tramo, *c* (ordinariamente, el centro de la luz ó el extremo del brazo de un puente levadizo ó el de un *cantilever*); y para cualquiera carga ó sistema de cargas, sea :

D = á la deformación total en *c*;
*d* = á la deformación elástica parcial en *c*; debida al alargamiento K * en cualquier pieza;
*p* = el esfuerzo en esa pieza por unidad de superficie;
P = el esfuerzo total en la pieza;
*l* = longitud de la pieza;
$k$ = alargamiento * de la pieza = $\frac{pl}{E}$;
W = la carga que, aplicada en *c*, produciría el esfuerzo P en la pieza;
$u = \frac{P}{W}$;
E = coeficiente de elasticidad del material = $p \div \frac{k}{l} = \frac{pl}{k}$.

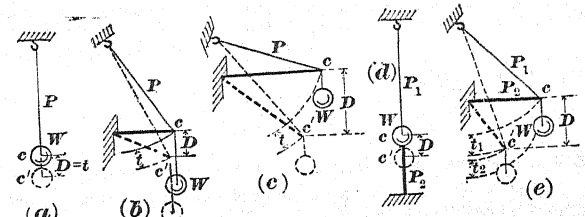

**Fig. 48.**

**163. Equivalencia de trabajo.** En la fig. 48, apliquese una carga, W, en cualquier punto, *c*, de una armadura ó barra. Entonces para una deformación pequeña ** como la que se permite en las armaduras, el trabajo exterior W*d* § de una deformación parcial, *d*, debida al estiramiento, *k*, en cualquier pieza, es prácticamente = al trabajo interno P*k*, en vencer la resistencia, P, en esa pieza, en la distancia *k*; ó bien

$$W d = P k.$$

Por consiguiente,

$$d = \frac{P}{W} \times k; \quad \text{ó bien} \quad \frac{k}{d} = \frac{W}{P}.$$

---

* Por brevedad usamos aquí la palabra alargamiento ó estiramiento para indicar cualquier cambio en la longitud refiriéndonos ya sea al acortamiento debido á la compresión, así como al alargamiento debido á la tensión.

** Para más claridad, los alargamientos y flexiones en nuestras figuras están exagerados mucho más allá del límite en que la razón $\frac{P}{W}$ permanece aproximadamente constante.

§ Estrictamente hablando, con una carga que aumente gradualmente de 0 á W, y con esfuerzos resultantes que aumenten gradualmente de 0 á P, deberíamos tomar la carga media = $^1/_2$ W, y la presión media = $^1/_2$ P, en cada pieza, pero se verá que esto no afecta las ecuaciones que se derivan.

Es decir: el estiramiento $k$, en cualquier pieza, está con la deformación parcial resultante, $d$, en $c$, en razon inversa del esfuerzo P, en esa pieza y del peso W, que aplicado en $c$, engendraría dicho esfuerzo P.

Así, en la fig. 48 $(a)$, en que $k$ está en la misma dirección que D*, P=W, y D=$k$.

En las figs. $(b)$ y $(c)$**, suponiendo el puntal incompresible; D se debe solamente al estiramiento de la cuerda, y $D = \frac{P}{W} \times k = uk$.

En la fig. $(c)$, $\frac{P}{W}$ es mayor, y (para un estiramiento dado, $k$, en la cuerda) D es por consiguiente mayor que en la fig. $(b)$.

**164. La deformación es independiente de la naturaleza de la fuerza.** Es evidente que la deformación $d$, en $c$, depende únicamente de la magnitud de $k$ en la pieza y es independiente de la naturaleza de la fuerza que produce el estiramiento. Es decir, cualquier cambio, $k$, en la longitud de la pieza, contribuye necesariamente con la cantidad fija, $d = \frac{P}{W} k$, á la deformación total, D en $c$. En otras palabras, puesto que $d$ y $k$ son meras distancias, y $u$ es simplemente un cociente, la relación entre $d$ y $k$ es puramente geométrica, y no está por consiguiente limitada á las deformaciones producidas por pesos, sino que es también aplicable á las producidas por cambios de temperatura, $o$, á los alargamientos y acortamientos intencionales de las piezas, ó á cualquiera otra causa.

Por consiguiente, si un miembro se alarga ó se acorta de cualquier modo, en una longitud $k$, ocurre un cambio correspondiente, $d, = \frac{P}{W} k = uk$, en la deformación en $c$.

Por ejemplo, si colocamos cualquier sistema de pesos sobre una armadura, y, por los principios de la estática, determinamos el esfuerzo total resultante, P, y la presión por unidad de superficie, $p$, en cualquier pieza, tendremos para la deformación parcial en $c$, debida al estiramiento, $k$, en esa pieza, bajo el sistema dado de cargas:

$$d = uk; \qquad \text{(Para } u\text{, véase § 165.}$$

y, puesto que $k = \frac{pl}{E}$,

$$d = \frac{pul}{E}.$$

**165. Para obtener la razón,** $u, = \frac{P}{W}$, para cada pieza, supondremos una carga concentrada aplicada en $c$, y por los principios de la estática, encontraremos los esfuerzos totales resultantes, P, P, etc., en los varios miembros. Si la carga que suponemos en $c$, se toma=la unidad, los esfuerzos, P, P, etc., así encontrados, serán los cocientes que deseábamos, $u$, $u$, etc.

**166. Suma de las deformaciones.** Siendo la deformación total D, en $c$, bajo el sistema dado de cargas=la suma de las deformaciones parciales, $d$, $d$, debidas (pero no necesariamente igual) respectivamente á los alargamientos $k$, $k$, en las varias piezas, tenemos

$$D = \Sigma d = \Sigma \frac{pul}{E}.$$

Así en las figs. $(d)$ y $(e)$ suponemos que la cuerda es extensible y el puntal compresible. En la fig. $(d)$, $W = P_1 + P_2$, y $WD = P_1 k + P_2 k = (P_1 + P_2)\, k$. Por consiguiente, $D = \Sigma uk = \frac{P_1}{W} \cdot k + \frac{P_2}{W} \cdot k = \frac{P_1 + P_2}{W} \cdot k = \frac{W}{W} \cdot k = k$. En la fig. $(e)$ $D = \Sigma uk = \frac{P_1}{W} \cdot k_1 + \frac{P_2}{W} \cdot k_2 = u_1 \cdot k_1 + u_2 \cdot k_2$.

**167. Alargamientos positivos y negativos.** En algunos casos puede suceder que el cambio de longitud de un miembro disminuya, en vez de aumentar, la deformación total en el punto $c$, en cuestión, y debe por consiguiente tomarse como

---

* Cuando, como en las figs. $(a)$, $(b)$ y $(c)$ se supone que sólo una pieza cambia de longitud D = $d$.

** Véase la nota ** en la página anterior.

negativa al sumar los valores de $u\acute{c} = \frac{pul}{E}$; pero cuando $c$ es el punto medio de una luz, ó el extremo de *cantilever*, todos los cambios en la longitud de las piezas contribuyen ordinariamente al alargamiento y deben por consiguiente tomarse como positivos.

Teóricamente, la fórmula $D = \Sigma \frac{pul}{E}$ se aplica también á las deformaciones de los arcos, represas y otras estructuras compuestas de bloques; pero debido á la inseguridad de los valores de E, es de muy poca utilidad práctica en estos casos.

**168. Piezas estáticamente indeterminadas.** Las armaduras contienen ordinariamente piezas cuyos esfuerzos no pueden encontrarse por los principios de la estática. Así, en la fig. 11 (*c*), las dos piezas diagonales de tensión que se encuentren en la parte superior de uno ú otro poste extremo se dice que son estáticamente indeterminadas, porque dichos principios no nos permiten determinar qué proporción de la carga total va á los apoyos por cada uno de los dos sistemas, figs. 11 (*a*) y (*b*), que componen la fig. 11 (*c*). Pero la fórmula que se acaba de dar nos permite determinar los esfuerzos en tales piezas, porque, por medio de ella podemos encontrar, separadamente, la deformación en cada uno de los dos sistemas, figs. 11 (*a*) y (*b*), y la parte de la carga, transmitida á los apoyos por cada uno de estos dos sistemas, inversamente proporcional á sus deformaciones.

## DETALLES Y CONSTRUCCIONES DE LOS PUENTES

### Principios generales.

**169.** En general, un *puente* de armaduras se compone esencialmente de dos ó más *armaduras* verticales, AB, CD, fig. 49, colocadas una al lado de la otra, y unidas por el sistema de pavimento, que, á su vez, soportan, colocando donde sea practicable, barras transversales (que forman un « *sistema lateral* ») entre los dos cordones opuestos, para sostener las armaduras paralelas.

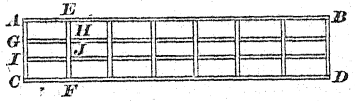

**Fig. 49.**

**170. El sistema de pavimento** se compone ordinariamente de *vigas de pavimento* y piezas de refuerzo. Las vigas del pavimento AC, EF, etc., fig. 49, se colocan transversalmente al puente, y están sujetas á las armaduras en los puntos opuestos de división de los tramos. Unidas á éstas y perpendiculares á ellas ó paralelas á las armaduras están las vigas longitudinales GH, IJ, etc. En los puentes para ferrocarriles hay ordinariamente dos ó más vigas longitudinales colocadas una al lado de la otra y paralelas á todo lo largo del puente, para sostener las traviesas. En los puentes de las vías de tráfico de las ciudades, estas vigas se colocan ordinariamente á pequeños intervalos y soportan placas unidas ú otra forma de apoyo sobre el cual se coloca el pavimento. En los puentes de los caminos reales en el campo, las vigas longitudinales son ordinariamente de madera, colocadas bastante juntas, y las planchas del piso se clavan directamente en ellas.

**Los pisos sólidos** (véase Pencoyd secciones de pisos) contribuyen á la rigidez y permanencia de un puente, y protegen mejor el tráfico debajo, contra la caída de cuerpos ó en caso de descarrilamiento. Su estructura plana es una ventaja, cuando se requiere espacio libre hacia arriba.

**171. Una carga** cualquiera es, pues, **transmitida** primero de los durmientes ó piso, etc., á las vigas longitudinales, después por éstas á las vigas del piso, y finalmente á los puntos de división de los tramos del puente, de donde se transmite por las armaduras á los apoyos.

**172. Los pedestales** ó placas de asiento, fig. 62, atornilladas á los estribos, soportan los extremos de las armaduras. Cuando el puente es de larga luz, de manera que la dilatación y contracción debidas el calor y al frío, sean considerables, deben colocarse placas ó rodillos, etc., **de expansión** en un extremo. Véanse §§ 205, etc. Para las riostras, barras laterales, etc., véanse §§ 19, etc.

## Naturaleza general del trazado.

**173. Piezas de tensión flexibles y rígidas. Ajustes. Contradiagonales.** Hasta hace poco, **las barras de ojo** se usaban como piezas de tensión de las armaduras. Éstas son barras largas chatas, que ceden bajo la compresión, y provistas en sus extremos con ojos ó aberturas, por los cuales entran los pasadores que las unen á las otras piezas del puente; pero hoy se usan como piezas de tensión, piezas rígidas, capaces de soportar alguna compresión, tan bien como la tensión. Las contradiagonales se hacían ordinariamente en dos largos y eran **ajustables**, uniendo las dos partes por tensores; pero éstos pueden causar esfuerzos indebidos y peligrosos en los tramos, y están reemplazados por contradiagonales hechas de una sola pieza.

**174. Las piezas de compresión** se hacen en piezas con ángulos y planchas, ó de canales y planchas, enrejadas, en forma hueca, que lleva la mayor parte del material tan lejos como sea posible del eje neutro de la sección transversal, aumentando así su momento de resistencia.

**175. Uniones de pasador y remachadas.** Las piezas del entramado se unen á los cordones por pasadores ó remaches. En el primer caso la armadura se llama de pasadores .y en el segundo, de remache. Hasta hace poco, las armaduras de pasadores han sido típicas en la práctica americana, pero ahora usan mucho las armaduras de remache con luces hasta de 45 á 50 m, mientras que los europeos usan en algunos casos pasadores. La ventaja principal que se les atribuye á los remaches, es que hacen el puente más rígido y no vibra, y que una armadura de remache comparada con la de pasadores, posee un margen adicional de seguridad á causa del aumento de rigidez. En los puentes de pasadores, por otro lado, se pueden determinar los esfuerzos con más exactitud, y las deformaciones pueden ocurrir sin producir esfuerzos de torsión ó de flexión en las mismas uniones.

**176. Tendencia á mayor rigidez.** Hay una tendencia creciente en usar barras más rígidas, por lo menos en todas las piezas cortas sometidas á compresión, y hacer aún las piezas más largas de tensión, de canales ó ángulos, formando una barra rígida. Las barras de ojos, unidas por pasadores, si no son de longitudes exactamente iguales, recibirán algunas, mayor esfuerzo del que les corresponde en el esfuerzo total.

**177. Uniones de las vigas del piso.** En los Estados Unidos, las conexiones de las vigas del piso se hacían antes suspendiendo las vigas de los pasadores por medio de soportes colgantes, pero ahora, donde es posible, sus extremos se remachan directamente á los lados interiores de los postes.

**178.** En las piezas de tensión, los remaches se arreglan de modo que reduzcan la sección neta efectiva lo menos posible.

**179.** Las piezas de compresión se disponen de manera que la mayor parte del material quede lo más lejos posible de sus ejes neutros, y son á veces reforzadas por cuerdas ó postes auxiliares que las apoyan en sus puntos medios, en los casos en que la economía de material hecha en la pieza sea considerablemente mayor que el que se gasta en el poste auxiliar.

**180.** Hasta donde sea posible, los miembros sometidos á compresión deben hacerse igualmente resistentes á la flexión en ambos ejes principales, AB y XY, fig. 52, de sus secciones transversales.

**181.** Cuando una pieza se repite muchas veces en un puente, y por consiguiente un exceso de material en su diseño causaría un gran desperdicio total, se repetirá el cálculo de la pieza hasta encontrar la sección más económica.

**182.** En las armaduras de metal, los miembros más cortos se hacen para resistir compresión, y los más largos, tensión, resultando así más economía de material. Por eso la armadura Pratt, con piezas de tensión diagonales, se usa en los puentes de acero, y la armadura Howe se fabrica ahora solamente con diagonales de madera.

## Piezas sometidas á tensión.

**183. En las barras de ojo, el área de la sección transversal** $= \frac{\text{tensión máxima}}{\text{unidad de tensión permitida}}$.

**184.** Las dimensiones de las cabezas de las barras de ojo las determinan ordinariamente los manufactureros, y las trazan dándoles un exceso de fuerza en los agujeros para los pasadores, de manera que, al someterlas á prueba, los dos tercios se quebrarán en el cuerpo de la barra; así se exige ordinariamente en las especificaciones. Es importante que las proporciones de las cabezas de las barras de ojo sean tales que tengan suficiente resistencia al recalcarlas.

**185.** La fig. 50 muestra, en dos escalas diferentes, el « acomodo » (arreglo de pasadores y barras de ojo) en la mitad izquierda del cordón inferior de un puente oblicuo, de 45 m de luz, fabricado por la « Phoenix Bridge Company », en 1900, para la Compañía del « Ferrocarril Philadelphia and Reading », cerca de Reynolds, Pa.

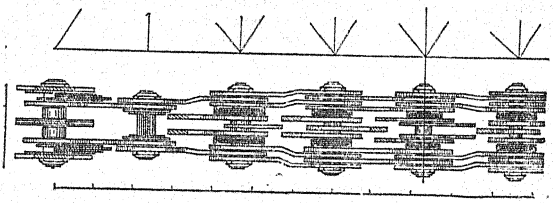

Fig. 50.

**186. Construcción de secciones.** Los montantes, las contradiagonales y sus partes principales se fabrican ordinariamente de acero laminado. Una sección de uso común es la de la fig. 51; se compone de cuatro ángulos unidos, á intervalos, por pequeñas barras chatas angostas remachadas á los ángulos en zigzag.

Cuando es sencillo como en la fig. 51, se llama « entrenzado » (*lacing*); cuando es doble como en la fig. 52 (*b*), « enrejado » (*latticing*). El área sombreada de los ángulos, fig. 51, menos la de los agujeros de los remaches, se toma como sección efectiva.

**187. Secciones mínimas.** Las especificaciones (véase Resumen) requieren á menudo el uso de alguna sección mínima. Así, en contradiagonales en que la presión es de 26,308 kg (58,000 libras), 22.57 cm cuad (3.5 pulgs cuad) de sección transversal serían suficientes; pero las especificaciones prohiben á menudo el uso en tales secciones, de un ángulo menor de $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{7}{16}$, que da 59.34 cm cuad (9.20 pulgs cuad) en bruto, ó, deduciendo un agujero de remache de cada ángulo, 49.5 cm cuad (7.68 pulgs cuad) de sección neta.

## Piezas sometidas á compresión.

**188. El cálculo** de una pieza sometida á compresión consiste en una serie de aproximaciones, porque la unidad de esfuerzo depende del radio de giro, del área de la sección y la disposición de material con respecto á los ejes, y ésta, á su vez, de la unidad de esfuerzo. Véase Pilares, en Resistencia de Materiales.

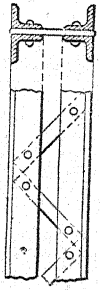

Fig. 51.

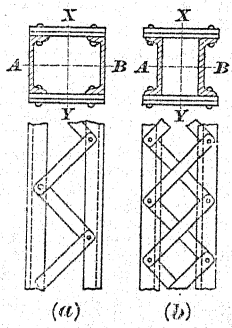

Fig. 52.

**189.** La fig. 52 (*a*), que se usa con frecuencia en los postes, compuesta de dos vigas en U, colocadas con la parte de atrás hacia fuera, ligadas entre sí con entrenzado (§ 186). En la fig. 52 (*b*) las vigas en U están colocadas con la parte posterior

hacia dentro. Por economía las vigas en U se deben separar de tal modo que el radio de giro sea el mismo respecto á uno ú otro eje, A-B ó X-Y. Este radio lo dan los manuales de los manufactureros de estas piezas de forma.

**190.** La sección del cordón superior se construye ordinariamente con dos vigas en U y una placa, ó en la forma que indica la fig. 53, que se compone de dos placas verticales ó almas, una placa horizontal superior ó « cubierta », cuatro « ángulos » y piezas chatas en cada lado de la parte inferior. El refuerzo de enrejado ó de entrenzado se coloca á lo largo de la parte inferior, excepto en los puntos de división de los tramos, donde se omite para que el poste y las cuerdas puedan entrar en la viga por debajo. En las armaduras de pasadores el eje del pasador se encuentra en la línea AB.

**191.** El ancho interior, *w*, depende principalmente del espacio que requieran el poste y las cuerdas que se encuentran en la división del tramo, y también de la altura de las cabezas de los remaches interiores. Ordinariamente, para comodidad en la construcción, el mayor ancho, *w*, que requieran se conserva constante hasta el cordón superior. La altura, H, depende principalmente del tamaño de la cabeza de la barra de ojo, y se conserva constante. El espesor de las placas del entramado ó alma, y algunas veces los de las barras y ángulos también, varían á lo largo del cordón, para tener, en cada punto, área suficiente para resistir los esfuerzos.

**192. El poste extremo** debe considerarse, no solamente como una columna, sino como una viga sujeta á esfuerzo constante, porque el viento sopla contra la parte superior del lado de la armadura. El trazado de esta construcción en piezas es muy parecido en principio al que se ha dado más arriba para los postes. Ciertas secciones se prueban, y después se cambian si es necesario.

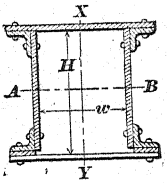

Fig. 53.

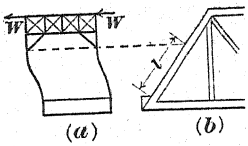

Fig. 54.

**193.** El poste extremo debe estar seguro, no solamente contra la flexión alrededor al eje AB, fig. 53, contra compresión, sino también contra flexión alrededor del otro eje X-Y, bajo el efecto combinado de la compresión y del momento de flexión, debido á que el viento sople contra la parte superior de la armadura. Véase fig. 54 (*a*).

**194.** Las riostras de la entrada ó portal del puente, arriba, y la viga del piso, abajo, se supone que impiden la flexión de la parte de los postes adyacentes á ellos, y podemos considerar cualquier mitad de uno ú otro poste ($=\frac{1}{2}l$) como un *cantilever* vertical, fijo en un extremo y cargado en otro extremo (que es el punto medio del poste) con una carga=la presión del viento en la mitad de la parte superior de una armadura.

**195.** Los máximos esfuerzos debidos á la compresión, obran, por supuesto, cerca del medio del poste, mientras que los debidos al viento obran cerca de los extremos. Por tanto sería irracional exigir que el poste resista ambos efectos simultáneamente en toda su longitud, y las especificaciones por consiguiente conceden que la unidad del esfuerzo debido á la carga muerta, viva, percusiones y fuerza del viento (combinadas), se aumente hasta 21,000 libras por pulg cuad (1,470 kg por cm cuad), debidamente reducida por la fórmula para compresión.

**196.** Para la resistencia de las piezas largas sometidas á compresión, véase más adelante Compresión en Resumen de especificaciones; § 19 en Columnas de hierro y acero; §§ 1 á 5 y 7 en Columnas de madera.

**197.** La fórmula para la presión extrema de las fibras debida á la compresión y flexión combinadas, es:

$$S = \frac{P}{A} + \frac{M_b T}{I - \frac{Pl^2}{Ec}}.$$

En que P=la fuerza compresiva longitudinal;
A=área de la sección;
$M_b$=momento de flexión debido á la carga transversal;
T=distancia del eje neutral á las fibras extremas;
I=momento de inercia;
$l$=largo de la viga;
E=módulo de elasticidad;
$c$=coeficiente. Véase Esfuerzo transversal, § 103.

## Uniones.

**198. Placas de pasadores.** Cuando un pasador pasa por una ó más partes de alguna pieza, sucede á menudo que las superficies combinadas de las piezas de la armadura, en contacto con el pasador, son insuficientes para transmitir todos los esfuerzos que deben transmitirse á esa pieza. Hay pues peligro de triturar el material que se comprime contra el pasador. Para evitar esto, otras partes, ordinariamente chatas y llamadas placas de pasadores ó placas de refuerzo, se remachan á la pieza, formando, suficiente superficie de apoyo para el pasador. Véase, fig. 55, en que las letras denotan:

AA, ángulos, W, alma, F, llenador,
C, cubierta, P, pasador, O, placa de pasador,
B, barra, J, telera, T, tabla.

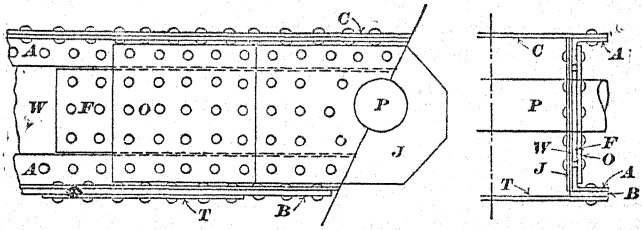

**Fig. 55.**

**199.** En la fig. 56, las dos vigas en U forman toda la pieza (excepto el enrejado que no puede incluirse para resistir compresión) y el pasador atraviesa por ambas vigas en U. En el caso de una sección del cordón ó de un poste extremo, fig. 53, las almas caladas forman solamente una parte de la sección, mientras que la cubierta, los ángulos y las piezas chatas no pueden recibir presión directamente del pasador, pero deben recibirla indirectamente del entramado del alma y de las placas de pasador, empatadas á él.

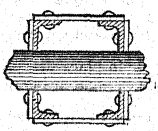

**Fig. 56.**

**200.** Cuando se coloca una placa de pasador en uno y otro lado del alma, la exterior debe, de acuerdo con la mayor parte de las especificaciones, cubrir los ángulos, y debe llevar además una placa de relleno entre ella y el alma.

**201.** Los ingenieros difieren respecto á la manera como se transmiten los esfuerzos por las diversas partes de una unión de pasador. Podemos suponer que los esfuerzos en las placas de pasadores se comunican casi directamente á las piezas. De este modo, la placa reforzadora exterior transmite probablemente la mayor parte ó todos sus esfuerzos á los ángulos, y poca ó ninguna al alma.

**202.** En cada ángulo, los remaches que pasan por la placa interior de pasadores,

deben transmitir, por medio de su apoyo contra el ángulo, la suma de los esfuerzos que reciben como esfuerzo cortante del interior y del exterior. En otras palabras, estos remaches están sometidos á doble esfuerzo cortante.

## Pasadores.

**203.** El pasador debe estar dispuesto de modo que resista los esfuerzos flexores de las piezas por las cuales pasa. Está también sujeto á esfuerzo cortante, pero esto es rara vez importante

**204.** El pasador que requiere la mayor sección transversal es ordinariamente el que está en el medio de la luz y en el cordón inferior, donde los esfuerzos del cordón son mayores, ó el que está en la unión del poste extremo y el cordón superior; pero como los pasadores son piezas pequeñas relativamente, todos los otros pasadores se hacen, por uniformidad, del mismo tamaño que él.

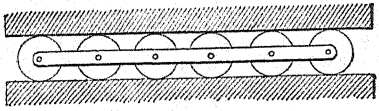

Fig. 57.

## Sistemas para la expansión en los apoyos.

**205. Las piezas de dilatación** se componen ordinariamente de un juego de cilindros cuidadosamente torneados que se colocan entre dos superficies planas, indicados en principio en la fig. 57.

**206. Los cilindros** son de acero, de 3 á 6 pulgs (7.5 á 15 cm) de diámetro, y de 1 á 4 pies (.30 á 1.22 m) de largo, con superficie lisa. De 4 á 8 de ellos ó más se unen por un marco, que se coloca debajo del extremo de una armadura por lo menos. Los cilindros descansan sobre una fuerte placa de hierro plana, fijada por debajo á la mampostería. Debajo del extremo de la armadura está una placa igual por la cual la armadura descansa sobre los cilindros. Como una armadura, aun de 60 m de luz, cambia apenas de longitud 7 cm por los extremos de temperatura, el juego de los cilindros es insignificante. Se les conserva en su lugar por medio de bordes alzados á su lado á lo largo de la placa. Los bordes deben también proyectarse de la placa superior hacia abajo para proteger los cilindros enteramente contra la lluvia, el polvo, etc.

**207.** El desplazamiento total en el extremo libre de una armadura se establece de antemano. (Véase Resumen de especificaciones.) Puede calcularse así, en metros:

$$D = 0.000011\ (T - t)\ \text{luz en m}$$

en que T y $t$ = las temperaturas máxima y mínima en grados C, respectivamente. La temperatura mínima que se puede esperar se obtendrá en los informes de la *Weather Bureau*, pero la máxima debe tomarse 10 ó 15° C más alta que la de la Oficina de Temperaturas, porque, con el sol fuerte, el puente se pone mucho más caliente que el aire.

**208.** Para disminuir el largo de la placa de apoyo, cuando el desplazamiento es moderado, se usan con frecuencia en lugar de los cilindros unas especies de balanceadores. Véase la fig. 62 *.

**209.** Para otros detalles respecto á la disposición de estas planchas y cilindros, véase el Resumen de las especificaciones, y las figs. 60 y 61.

## Cargas, etc.

**210. Cargas, sección libre, etc., para puentes de calzadas.** Véase también el Resumen de especificaciones para los puentes.

**Pesos de las multitudes.** En el puente Chelsea, Londres, los individuos agrupados y colocados sobre la plataforma de una romana, dieron una carga de

---

* *N. del T.* — Estos no son cilindros de sección circular como se ven en la fig. 57. En la fig. 62 no se percibe la forma. Su sección es cercana á la elipse y á veces como la de

84 lbs solamente por pie cuad (como 410 kg por m cuad). Y en el Palacio de Buckingham individuos acuñados y tan apretados unos contra otros como era posible en un espacio de 20 pies (6.1 m) de diámetro, dieron 120 lbs por pie cuadrado (586 kg por m cuad). Pero con los experimentos modernos se han obtenido fácilmente cargas de 680 á 720 kg por m cuad. Con individuos, con peso medio de 73 kg cada uno, agrupados todos con la cara á un mismo lado, cuidadosamente colocados, y contenidos en un espacio de 1.83 m en cuadro, el profesor L. J. Johnson obtuvo, en la Universidad de Harvard, un máximo de 884 kg por m cuad. Véanse también las páginas. 817, etc.

Cuando la cerca del espacio es tal, que algunas de las personas que están paradas contra ella se inclinan hacia fuera, aumenta por supuesto la carga por unidad de superficie, y en las pequeñas, este aumento puede ser relativamente importante.

## Flecha de curvatura.

**211.** Dando al puente una flecha igual á ($^1/_{600}$) un seiscientosavo de la luz, tendrá una curvatura suficiente. La curvatura que debe usarse está ordinariamente estipulada en las especificaciones. Véase Resumen. Un puente bien trazado y bien construído bajo su carga mayor, no debe presentar una flexión mayor de 1 en 1200. Y en verdad, la flexión es siempre mucho menor que esto.

**212.** El exceso de longitud del cordón superior sobre el inferior, dadas la luz, la altura de la armadura y la curvatura, será =

$$\frac{8 \times \text{altura} \times \text{curvatura}}{\text{luz}}.$$

Esta regla se aplica rigurosamente con una curvatura que no exceda de .02 de la uz.

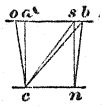

Fig. 58.

**213.** El largo de la diagonal, $cb$, fig. 58, $cb = \sqrt{ac^2 + ab^2}$ en que $ac$ = altura de la armadura y $ab = cn + \frac{ob - cn}{2}$.

**214.** Algunas veces, el alargamiento ó acortamiento, producido por la carga, se calcula para cada pieza y se cambia en proporción el largo de las piezas afectadas. Véanse §§ 162, etc.

## Ejemplos.

**215.** En las figs. 59 de ($a$) á ($u$) en una escala uniforme de 1 en 720 (una pulg por 60 pies), sirve para indicar la práctica corriente en la elección de los tipos de las diferentes luces, la relación, entre la luz, el largo del tramo y la altura, la disposición de los cordones y del entramado, el uso de las barras ó piezas rígidas y flexibles, las contradiagonales y tensores, en las armaduras, y, aproximadamente, las dimensiones de las piezas rígidas, escuadras ó placas de ángulos (*gusset plates*) y cubrejuntas, como se ven en la elevación.

**216.** En cada caso se muestra la mitad izquierda de la luz, estando la línea del centro de la luz indicada por una línea de puntos y rayas. Las armaduras de tablero inferior y superior se distinguen por la elevación de la vía, como se indica aproximadamente en el apoyo ó estribo izquierdo.

**217.** En las figs. de ($h$) á ($q$), que representan armaduras, las piezas rígidas están

---

un abanico ó sector, con un movimiento de *balance*, siempre sobre la curva inferior, cuando el puente se alarga ó recoge. El eje mayor en el caso de la forma elipsoidal, es el vertical, y en el segundo se apoyan en la curva más amplia. Estos los llaman los ingleses *rockers*. No creemos que tienen nombre especial en español. Adoptamos balanceadores.

indicadas por líneas dobles; las flexibles en las verticales y diagonales principales, por líneas sencillas, y las contradiagonales, por líneas de puntos. En las vigas de

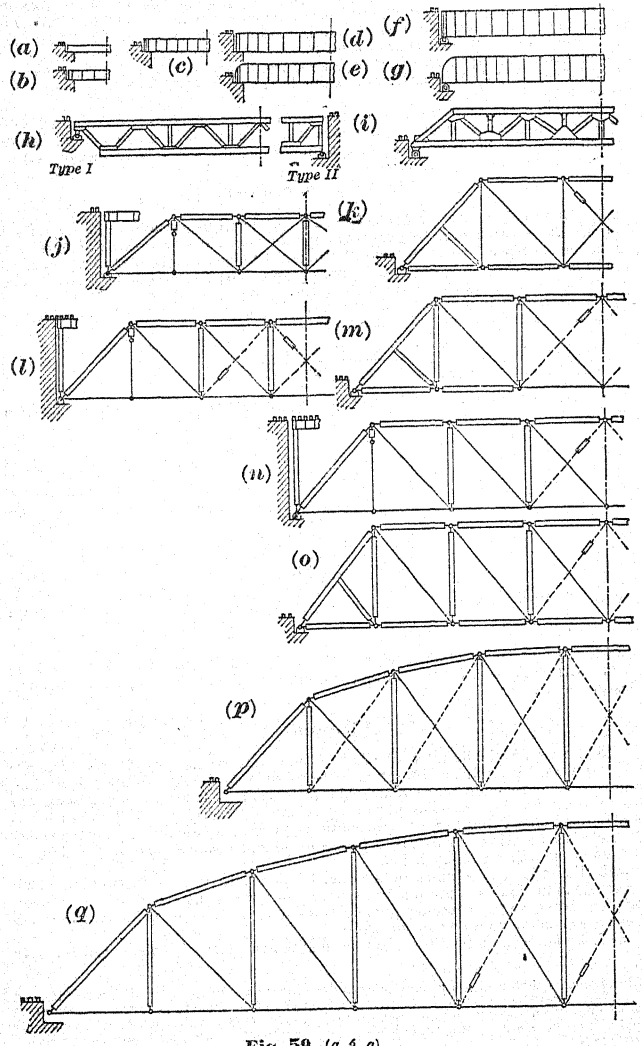

**Fig. 59.** (*a* á *q*).

pasadores, para evitar confusión, las piezas rígidas aparecen cortadas cerca de los pasadores.

**218.** Las figs. de (*a*) á (*o*) representan diseños modelos para luces de 7.5 á 61 m, por Mr. Ralph Modjeshy, I. C. de la Compañía de ferrocarril del Norte del Pacífico; la fig. (*p*), una luz de ferrocarril de 75 m trazada por la « Pencoyd Works » de la Compañía Americana de Puentes; la fig. (*q*), una luz de ferrocarril de 94 m por la Compañía de Puentes Phoenix; las figs. (*r*) á (*t*), diseños de armaduras roblonadas por la « Elmira Works of the American Bridge Co »; y la fig. (*u*), un puente de ferrocarril de 31.11 m de luz, trazado por la « Pencoyd Works ».

**219.** La fig. (*a*) representa una viga de remache; las figs. (*b*) á (*g*), vigas laminadas, y las figs. de (*h*) á (*g*), armaduras de remaches y de pasadores; las figs. (*h*) é (*i*) son de remaches; las figs. (*i*) á (*q*), de pasadores.

**220.** La fig. (*r*) representa una luz de 39 m para el Ferrocarril Central de Nueva York sobre el río Hudson, y las figs. (*s*) y (*t*), luces de 43.6 á 48.8 m respectivamente para el Ferrocarril Occidental de Delaware y Lackawanna. Las figs. (*r*) y (*s*) son modificaciones de la armadura Baltimore; la fig. 15 (*b*) y fig. (*t*) es una armadura

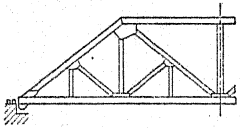

**Fig 59** (*r*).

*Vista del extremo.*

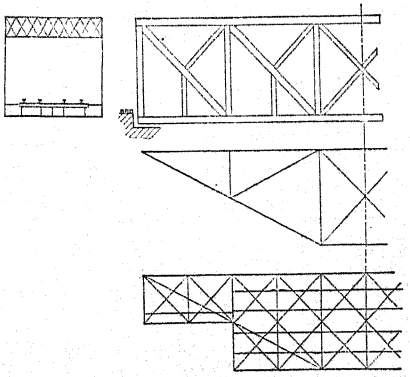

**Fig. 59** (*s*).

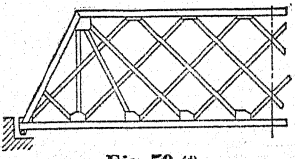

**Fig. 59** (*t*).

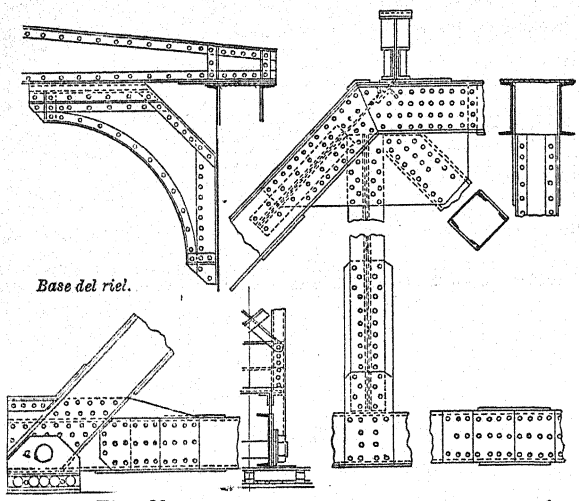
Warren cuádrupla. La fig. (*s*) es una luz de puente oblicuo. La fig. (*u*) es una luz (*pony*) *.

* *N. del T.* — « Pony » no puede, á nuestro juicio, traducirse por pequeño, pues indica algo más. Quizás sea para este caso : enana, chata, ó algo así el término conveniente en español y que no hemos podido encontrar.



*Base del riel.*

Fig. 60.

**221. Detalles.** En las figs. 60 á 65 se ven unos pocos detalles sobre las armaduras y las vigas remachadas.

**222.** Las figs. 60 y 61 indican las uniones del extremo izquierdo de dos armaduras de puentes de tablero inferior (con apoyos de cilindro para la dilatación) proyectadas por la « Pencoyd Works »; la fig. 61 representa una armadura de pasadores, de tablero inferior de 76 m de luz que corresponde á la fig. 59(*p*), y la fig. 60, una remachada, de tablero inferior de (124) 37.8 m, donde se ven las vigas del portal del puente.

(*N. del T.* — Para las figs. 60 y 61 la escala es $^1/_{40}$).

*Base del carril.*

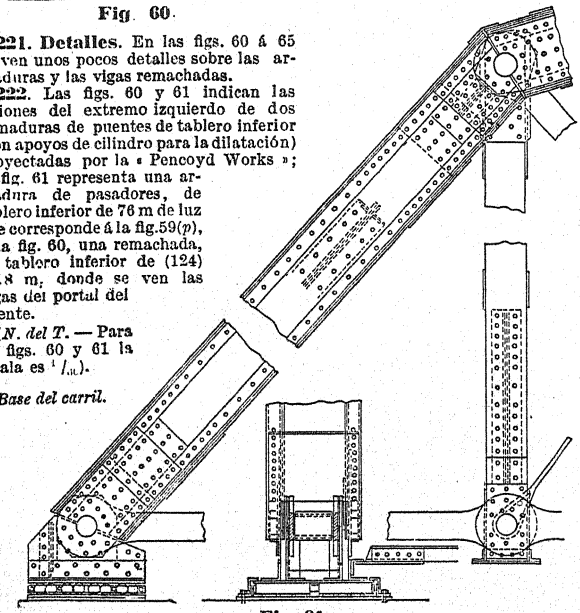


Fig. 61.

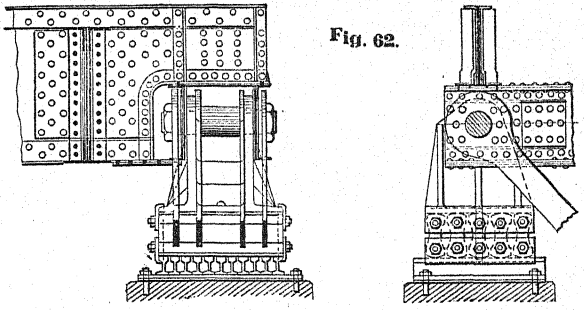

Fig. 62.

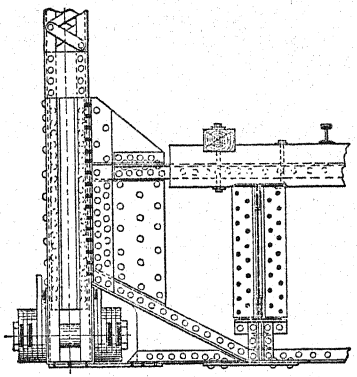

Fig. 63.

**223.** La fig. 62, muestra el apoyo del puente en el extremo izquierdo con balanceadores (véase *N. del T.* al § 208), y la unión de las vigas del piso de un puente de pasadores, de tablero superior de 61 m de luz, en el ferrocarril del Pacífico, fig. 59 (*n*); y la fig. 63 muestra la unión de las vigas del piso de un puente, de pasadores de tablero inferior de 48.8 m del mismo ferrocarril, fig. 59 (*m*).

(*N. del T.* — En las figs. 62, 63 y 64, la escala es $^1/_{50}$)

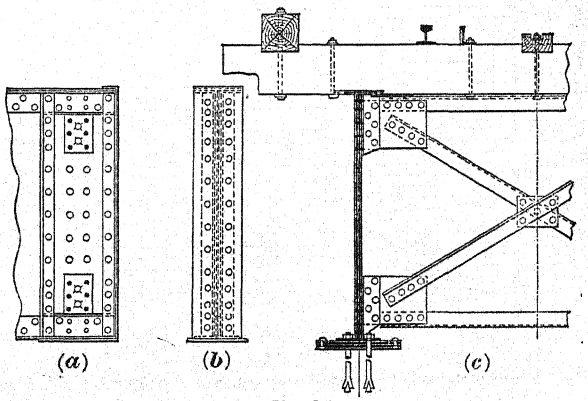

Fig. 64.

**224.** Las figs. 64 y 65 representan respectivamente una viga de 15 m, de tablero superior y otra de 25.9 m de tablero inferior del mismo ferrocarril.

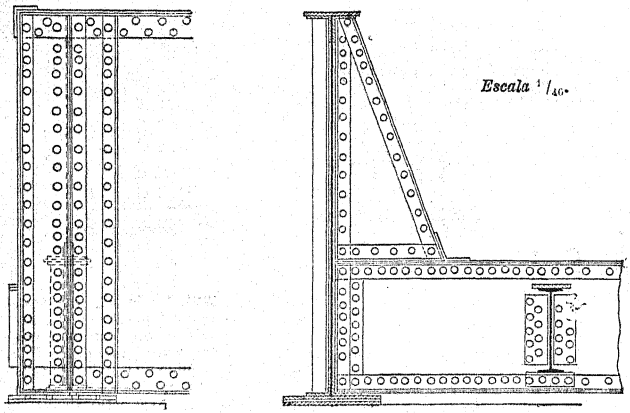

**Fig. 65.**

**225. Pesos de los puentes de acero para ferrocarril.** La fig. 66, fundada en la práctica del ferrocarril del « Northen Pacific Railway », 1902, muestra aproxi-

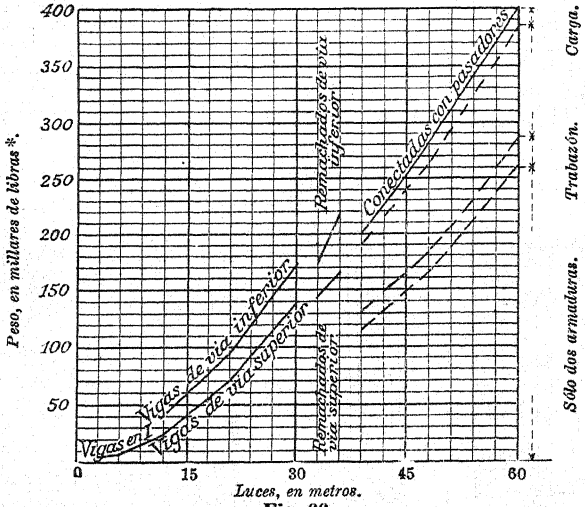

**Fig. 66.**

madamente los **pesos de los puentes de acero para ferrocarril,** proyec-

* *N. del T.* — 1,000 libras = 453.5 kg.

tados para dos locomotoras, de 146 toneladas cada una, y un tren cargado uniformemente con (4,000 libras por pie de vía) 5,960 kg por metro. Los pesos incluyen las dos vigas, las armaduras de una sola luz de una vía con sus riostras, refuerzos, sistema de piso metálico y apoyos extremos. Para los de sistema de piso de madera, agréguese 600 kg por m lineal. En los puentes de 40 á 60 m, unidos con pernos, los tres diagramas de rayas indican respectivamente los pesos de las dos armaduras solas, de las dos armaduras y trabazón, y de las dos armaduras, trabazón y piso de metal. La curva continua incluye los pesos de las piezas de apoyo extremo.

Para los pesos de los puentes mixtos (hierro y madera), de ferrocarril, véase § 249.

Los puentes para calzadas difieren tanto en la práctica y en los proyectos, que sería apenas posible dar aquí datos útiles sobre su peso.

### Lista de grandes puentes.

Todos los puentes que damos aquí creemos que son los más grandes de su tipo en el mundo.

| Tipo. | Luz sobre el | En | Luz, metros. | Edificado. |
|---|---|---|---|---|
| Armadura..... | Río Ohio | Louisville | 167.8 | 1893 |
| Levadizo..... | Río Missouri | Omaha | 158.6 | 1894 |
| De suspensión..... | Río del Este («Brooklyn») | Nueva York | 486.5 | 1882 |
| De suspensión..... | Río del Este («Nuevo») | Nueva York | 488.6 | |
| De arco (metal)..... | Río Niágara | Cataratas del Niágara | 256.2 | 1898* |
| De arco (piedra)..... | Petruff Valley | Luxembourg | 84.5 | |
| *Cantilever*..... | Firth of Forth | Queensferry | 518.5 | 1890* |

El viaducto más alto es el viaducto de Gokteik, en Birmania, con un alto máximo de 97.6 m y un largo total (compuesto de luces cortas) de 689.3 m, construído en 1901.

### Armaduras de madera.

**226.** La madera de construcción se ha puesto ahora tan costosa, excepto en las regiones no pobladas, y el trabajo de proyectos tan barato, que ya no se pone en práctica el uso de vigas innecesariamente pesadas, sólo con el objeto de asegurar la estabilidad y evitar cálculos. Por consiguiente, en los puentes importantes, cada parte de cada pieza que sufre un esfuerzo se calcula siempre. Además, la resistencia de las maderas es tan incierta que es mejor adoptar el cálculo que exige la mayor sección, debiéndose usar factores amplios de seguridad.

**227. Las piezas de compresión** se estudian como si fueran columnas (véase Pilares en Resistencia de Materiales), y si están sujetos á esfuerzos transversales también, deberán tomarse éstos cuidadosamente en cuenta. Todos los agujeros y otras reducciones de sección, deben por supuesto deducirse de la sección bruta.

**228.** En las piezas **sometidas á tensión**, también se deben considerar todas las reducciones de sección; pero ahora se usan generalmente barras de hierro ó de acero en lugar de madera, para dichas piezas.

**229.** Además, se debe tener cuidado de que las vigas de madera resistan cualquier esfuerzo transversal ó esfuerzo cortante que pueda presentarse ó estar obrando sobre ellas. Así pues, es necesario examinar los postes de los extremos para cerciorarse de que están asegurados contra cualquier esfuerzo transversal. Cuando un poste se encuentra con otra pieza bajo un ángulo y va á ser empotrada en él, es económico calcular la profundidad de la muesca que se requiere, pues mientras más honda es ésta, mayor será la sección requerida. Cuando los tornillos están sujetos á las vigas por tuercas, se deben poner siempre arandelas debajo de las tuercas, calculando el tamaño de las arandelas necesarias para impedir el hundimiento de la madera.

**230.** Cuando la madera está sometida á esfuerzo cortante, como con un tornillo que pasa por una viga, se transmite el esf por el apoyo contra el interior del taladro, ó cuando hay un escalón sobre el cual obre la presión de otra pieza, se debe siempre tener suficiente superficie á lo largo de la fibra de la madera, para que reciba el esfuerzo cortante, haciendo algún aumento por la posibilidad de que la

* En construcción, 1902.

fibra pueda deslizarse en la superficie ó hacia algún agujero antes de que todos los esfuerzos cortantes sean transmitidos.

**231. Sección transversal del cordón superior.** Como no sería conveniente, en la práctica, cambiar la sección de un cordón superior de madera en diferentes puntos, se le diseña todo para que resista el esfuerzo *máximo* que ocurra entre dos puntos de división de un tramo cualquiera. Supóngase el espesor del cordón. Encuéntrese á $r^2 = (\text{radio mínimo de giro})^2 = \frac{(espesor)^2}{12}$. Encuéntrese la unidad del esfuerzo permitido de acuerdo con la fórmula para columnas, dada en las especificaciones ó adoptada, usando la presión máxima dada. Encuéntrese el área que se requiere para esta unidad de esfuerzo. Encuéntrese la profundidad resultante, y, para una pieza horizontal ó inclinada, se prefiere un poco mayor que el ancho, teniendo en cuenta el momento de flexión debido á su propio peso. Si esto no da un buen tamaño comercial, revísese bien para obtener una sección mejor.

**232. Puntales.** Los puntales se hacen con preferencia del mismo ancho que la viga superior. Cada puntal debe diseñarse separadamente. Obténgase á $r^2$, la unidad de esfuerzo permitida, etc., como para el cordón superior. Por economía los puntales deben ser casi cuadrados por término medio, aunque fuera necesario alterar la sección del cordón superior para impedir que se separen mucho de la sección cuadrada.

**233. Los tirantes verticales** (de hierro) pueden estudiarse ahora. El área de la sección vertical $= \frac{\text{esfuerzo máximo}}{\text{unidad de presión permitida}}$. Pero véase Sección mínima, § 187. El tamaño de una tuerca se fija ordinariamente por el diámetro de la barra, pero las arandelas se usan de modo que no hundan la madera.

**234. Los apoyos ó cortes** que se requieren en el cordón superior é inferior para sostener las piezas inclinadas en su lugar, se calcularán ahora. Se calcula la componente (en el puntal) perpendicular á la cara ó caras que comprime, y se obtendrá la altura necesaria, suponiendo el ancho del cordón inferior igual al del superior y al de los puntales.

**235. La sección del cordón inferior** se podrá decidir ahora, puesto que la reducción de la sección, debida á las ensambladuras, se conoce.

$$\text{El área de la sección transversal} = \frac{\text{esfuerzo máximo}}{\text{unidad de esfuerzo permitido}}.$$

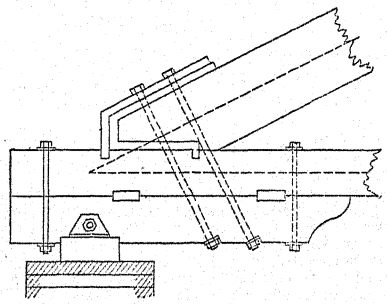

**Fig. 67.**

**236. Unión del extremo,** fig. 67. Muchos diseños diferentes se han hecho, propuesto y discutido para esta unión. Los extremos de las abrazaderas deben entrar en las muescas de la viga inferior, á tal profundidad que el esfuerzo total, recibido por el extremo de las fibras de los lados de las muescas, sea igual al esfuerzo que las abrazaderas de los extremos puedan resistir por flexión. Esta profundidad puede encontrarse por pruebas sucesivas, ó por medio de dos ecuaciones algebraicas en que la presión máxima permitida y la profundidad de la muesca son las dos cantidades desconocidas.

Determínese la superficie del esfuerzo cortante necesaria para transmitir este esfuerzo al cuerpo del cordón inferior. Esto determinará también el espacio entre las muescas y el extremo del cordón inferior.

Calcúlese el esfuerzo (si lo hay) que quede por transmitir, y trácense de acuerdo los tornillos largos inclinados y sus arandelas. Calcúlese también el área comprimida, y la profundidad de la cara vertical del extremo inferior del cordón superior que se necesita para transmitir la componente horizontal de su empuje. Véase también que el apoyo inferior presente bastante superficie para resistir la componente vertical. Los tacos entre la viga saliente del estribo ó pila y el cordón inferior deben soportar la componente horizontal del viento. Para más seguridad, la *fricción* entre las dos partes se desprecia.

**237.** La fig. 68 muestra las *uniones* ó ensambladuras que se usan más en las vigas de madera, etc. Necesitan muy poca explicación. La fig. (*a*) es un buen modo de ensamblar un poste, pero al hacerlo, la línea, *oo*, no debe quedar nunca inclinada, sino paralela al eje del poste, de otro modo, en caso de encogimiento, ó de gran presión, las partes en cada lado de ella tienden á resbalar una sobre otra, produciendo una gran presión sobre los tornillos.

Cuando se necesite mayor resistencia, se pueden usar abrazaderas de hierro, como en *b*, *h* y *j*, en lugar de tornillos. La fig. (*b*) muestra un poste de 4 piezas entablilladas, que pueden sujetarse por tornillos como en la parte superior, ó por aros como en la inferior. Los aros pueden apretarse por medio de rebordes y tornillos como en *s*, ó pueden introducirse cuñas delgadas de hierro entre ellas y la viga, si fuere necesario. La fig. C muestra un buen arreglo, fuerte, para unir una viga tirante *k*, ó un par, *l*, y una péndola *u*, haciendo que *k* y *l* empotren uno en otro dentro del pendolón ó péndola doble *tt*; *nn*, son dos bloques por los cuales pasan los tornillos. Un arreglo análogo es también bueno para unir un tirante *w* con el pie *v* de las péndolas, agregándoles una abrazadera como en la figura. La fig. (*e*) es un sistema de ensamblar una viga en otra en ángulo recto con ella. Por medio de una brida de hierro como en *f*, se logra el mismo objeto, y es más fuerte. Las figs. *g*, *h*, *i*, *j*, son vigas compuestas. Cuando se requiere una viga de gran espesor, si la construímos colocando simplemente una viga chata sobre otra, obtendremos sólo la resistencia que tendrían las vigas si estuvieran separadas. Pero si impedimos que una resbale sobre otra, insertando bloques transversales, como en *g*, ó ensamblando una entre otra, como en *i*, *j*, y luego atornillándolas ó con abrazaderas sujetándolas firmemente para crear la fricción, obtendremos próximamente la resistencia de una viga sólida de la altura total, resistencia que está como el *cuadrado* de la altura. Véase Esfuerzo cortante horizontal, § 51, en Resistencia Transversal.

**238.** La resistencia de una viga compuesta se aumenta, aumentando el espesor en su centro, donde trabaja más, como en los cordones superiores de un puente. Esto puede efectuarse agregando la pieza triangular, *yy*, entre las dos vigas.

**239.** Se puede colocar un pedazo de plancha de hierro en las uniones de las vigas de madera, cuando hay gran presión, para distribuir de esta manera el esfuerzo con más igualdad sobre todo el área de la unión.

**240.** Frecuentemente una simple abrazadera no basta cuando es necesario unir las dos vigas muy apretadas.

En tales casos un extremo de la abrazadera podrá, como en *x*, terminar en una especie de tornillo, y después de pasar por la barra transversal Z, se ajustará todo por medio de una tuerca en *x*. Puede emplearse el sistema que se indica en K. Algunas veces, como en A, se taladra primero el agujero para el tornillo, después se hace un agujero en un lado de la viga, que llegue hasta el agujero del tornillo, bastante grande para que la tuerca del tornillo pueda introducirse. Habiendo hecho esto, se rellenará el agujero con un tarugo de madera para sostener la tuerca en su lugar. Después se insertará el tornillo, de modo que entre en la tuerca. Haciendo girar el tornillo se ajustarán las vigas.

**241.** Cuando los extremos de la vigas, viguetas, etc., se introducen en la pared, como se usa, con sección cuadrada, hay peligro de que, en el caso de que se quemen y partan en dos, puedan, al caer, tumbar la pared. Esto se evita cortando los extremos en la forma que se indica en *m*.

**242.** Cuando una abrazadera, *o*, fig. R, tiene que soportar una presión tan grande que haya peligro de que se hunda en la viga, *p*, sobre la cual descansa, podrá usarse una pieza fundida, *v*, debajo de ella. La abrazadera pasará por la parte *r* de la pieza. Las pequeñas prolongaciones en la parte inferior impedirán que la pieza resbale bajo el esfuerzo oblicuo de la abrazadera. Esto mismo puede usarse con los tornillos oblicuos, y tanto sobre la viga como debajo de ella. Cuando se usa debajo, podrá ser necesario atornillar la pieza fundida en la parte baja de la viga. Cuando la tracción

en una abrazadera forma ángulo recto con la viga, si es muy fuerte aquélla, puede ponerse un pedazo de plancha de hierro, en lugar de la pieza dicha, entre la abra-

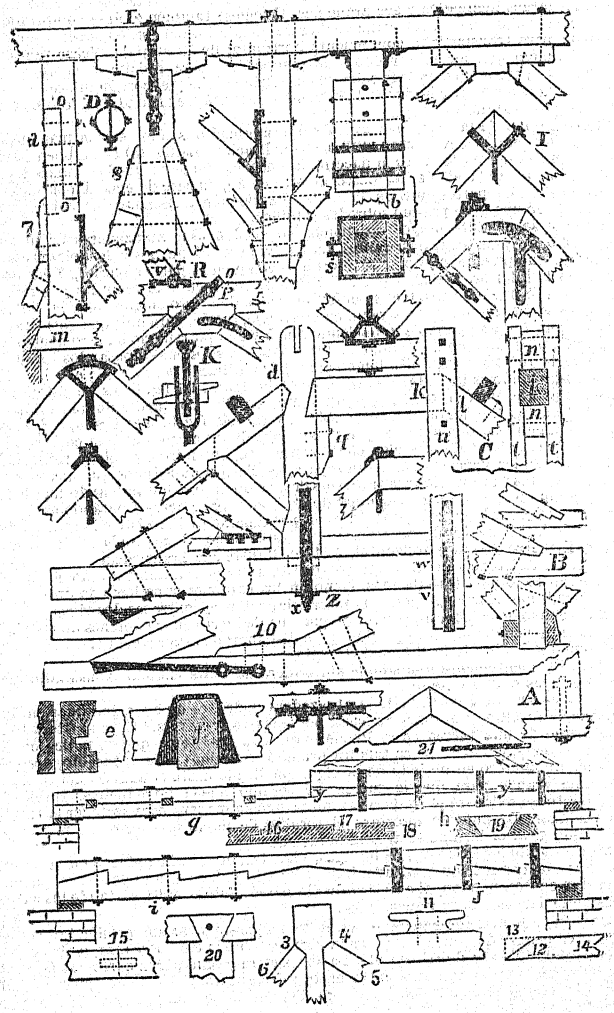

**Fig. 68.**

zadera y la viga, para impedir que esta última sea cortada en parte ó dañada; véase I é I.

**243. Ensambladura del cordón inferior.** Debido al largo del cordón inferior, puede ser necesario ensamblarlo (fig. 69). El número de planchas que se deben emplear es en gran parte un asunto de prueba. Si se ponen muchas, se necesitará mucho trabajo de carpintería, y como consecuencia incertidumbre en la distribución de las presiones, y si se ponen pocas, habrá que hacer muescas hondas, y esto puede reducir la sección en gran parte. Estas planchas deben trazarse para resistir empuje contra sus extremos y que no puedan ser arrancadas por el esfuerzo cortante. Se atravesarán con tornillos para impedir que se encorven hacia afuera, y las arandelas se dispondrán para que transmitan á la madera sin dañarla todas las presiones que obran en el tornillo.

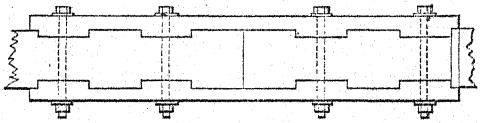

Fig. 69.

**244.** La fig. 70 muestra una forma de viga inferior usada en los puentes de armadura Howe combinada (madera y hierro), de los ferrocarriles de Chicago, Milwakee, y St. Paul. Véanse §§ 249-251, figs. 73. Cuatro de estas abrazaderas ó bridas se necesitan para cada unión, poniéndose un bloque en cada lado de cada trozo que se vaya á ensamblar. Los dos bloques opuestos que forman un par, se sostienen contra el trozo por medio de cuatro tornillos que lo atraviesan, y los tarugos cilíndricos fundidos (en el molde) en la superficie de cada bloque, entran en agujeros correspondientes taladrados en la cara del trozo. Los dos bloques de un mismo lado se sujetan por una barra de empalme y de gancho.

(*N. del T.* — Damos las equivalencias de las pulgs y pies del clisé en centímetros. 13 ½" = 34.3 cm; 15" = 38.1 cm; 8 ½" = 21.6 cm; 3" = 7.6 cm; 1" = 2.5 cm; 6 pies = 183 cm.)

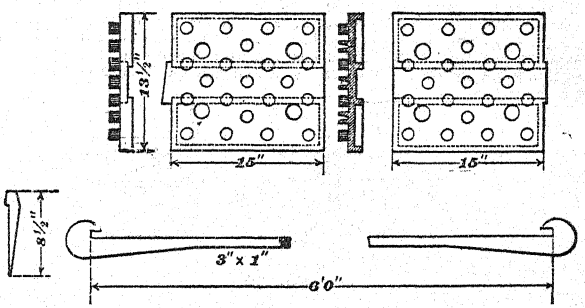

Fig. 70.

**245.** Las figs. 71 muestran un puente **pequeño de madera de armadura Howe.** Los cordones inferior y superior están formados de tres ó más maderos paralelos, *c, c, c,* colocados á poca distancia uno de otro para hacer que las barras verticales, *rr,* pasen entre ellos. Los brazos principales, *oo,* están en pares ó en tres. Las piezas que los componen se empotran en *bloques triangulares, s,* que si son de madera dura son sólidas, y si de hierro fundido son huecas, fig. (*d*) y reforzadas por bordes interiores. Estos bloques se extienden á través de tres ó más piezas del cordón. Contra su centro se apoyan también las contradiagonales *e.* Estas son piezas

sencillas en los puentes pequeños, ó dobles en los grandes. Los brazos de madera y las contradiagonales se sujetan en el punto donde se cruzan.

En la fig. (*d*) la línea de puntos muestra los bordes reforzadores, y el tarugo *x* retiene el bloque en su lugar. Las cuerdas verticales, *rr*, de hierro están en pares, en tres, ó en cuatro, etc., de acuerdo con el tamaño del puente, y con tornillo y tuerca en cada extremo. Las partes superiores é inferiores de los brazos y contradiagonales se apoyan con sección cuadrada contra los bloques de ángulo, y ordinariamente se fijan en su lugar, apretando simplemente los tornillos de las cuerdas verticales. Los postes *p* y *d* de los extremos, las cuerdas de los extremos, *ic* y *by*, y las porciones horizontales, *gi* y *wb*, del cordón superior, no forman propiamente parte de la armadura.

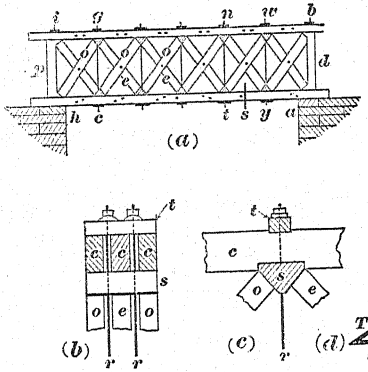

**Fig. 71.**

**246. En las luces grandes**, para impedir que la presión en los extremos de las diagonales aplasten los cordones, se funden los bloques de ángulo con bordes altos que se prolongan debajo de sus bases. Estos bordes al pasar entre las piezas que componen una viga, se prolongan hasta la cara opuesta de ella. Allí los bordes empujan sobre arandelas anchas en los extremos de los tirantes verticales.

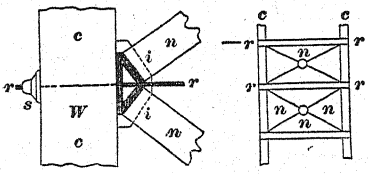

**Fig. 72.**

**247. Una forma común de refuerzo lateral** (riostras), fig. 72, se parece á la armadura Howe colocada á un costado. En ella las diagonales son puntales de madera y las piezas, *r*, *r*, barras redondas. Uno de los puntales está entero, á excepción de pequeñas escotaduras hechas para recibir la otra diagonal.

A los lados de los cordones, los extremos de las diagonales descansan sobre un saledizo (indicado por la línea de puntos *ii*), como de 4 cm de ancho en la parte inferior del bloque de ángulo de hierro fundido. La barra *rr*, pasando por los cordones de ambas armaduras, se aprieta por medio de la tuerca *s*, y sujeta las diagonales firmemente en su lugar; en caso de que se encojan mucho con el tiempo, podrán apretarse de nuevo del mismo modo.

El bloque de ángulo, de hierro fundido, es del mismo grueso que el brazo, su espesor no es necesario que pase de 13 mm en un puente grande. Tiene agujeros para el pase de la barra, *rr*.

**248. Dimensiones** para cada una de las dos armaduras de un **puente Howe**, de una sola vía para ferrocarril eléctrico en caminos urbanos ó rurales, con carros que pesen de 20 á 25 toneladas cada uno. La madera no debe forzarse más de 800 libras por pulgada cuadrada (56 kg por cm cuad), ni el hierro más de 5 toneladas por pulgada cuadrada (350 kg por cm cuad). Suponiendo que el hierro sea de calidad superior que requiera como 4,200 kg por cm cuad para quebrarlo. Las barras deben, cuando llevan tornillo, ser de rosca *recalcada*. A cada lado de cada uno de los cordones se supone que se ha añadido, uniéndola firmemente á ella en su centro, una pieza de un espesor igual por lo menos á la mitad del de una de las piezas que forman el cordón y de un largo igual al dé tres tramos.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| Peso en kilogramos §.. | 59.401 | 70.521 | 82.551 | 94.980 | 105.750 | 117.885 | 12..950 |

* El largo de los tramos es de 3.33 m. Cada luz es más larga, en un tramo, que la precedente. La altura, en todos los casos, es de 7.6 m libres entre cordones. Ancho, 4.32 m libres entre armaduras.

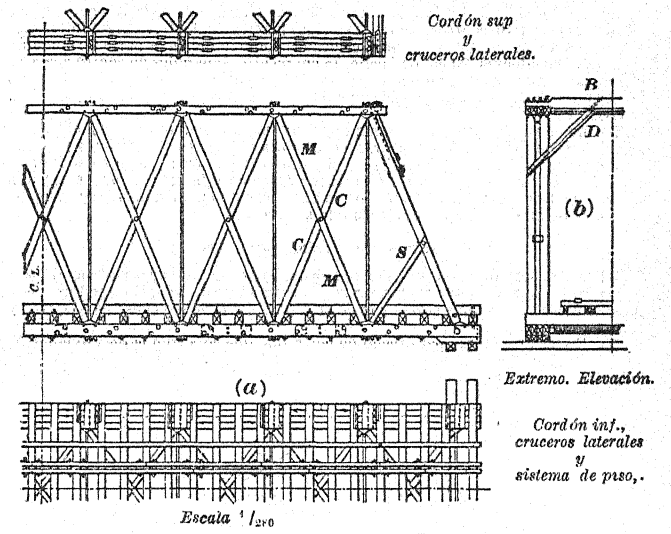
** Para las ensambladuras en el cordón inferior, véase fig. 70, § 244.

*** Debido á que las luces tienen alternativamente un número de tramos pares ó impares, hay alguna ambigüedad respecto á las dimensiones de las piezas del entramado en el centro de la luz.

§ El peso incluye las dos armaduras, riostras y pavimento para una vía. Del peso total del puente, las armaduras tienen como 53 0/0, los sistemas laterales 26, el sistema de pavimento 18, y las planchas sobre los muros 3 0/0.

(*N. del T.* — La tabla del autor la hemos convertido al sistema métrico. Desde la cuarta línea hasta la penúltima, la primera cifra separada de las demás indica el número de piezas elementales.)

**250.** Para todas las luces, traviesas laterales; 15 × 15 cm en el centro. 20 × 20 cm en los extremos de la luz; barras laterales, 28 mm en el centro, de 38 á 40 mm en los extremos; tornapuntas S (uno en cada extremo de cada armadura), 15 × 35 cm; tirante transversal, B, en el portal, entre los extremos de los cordones superiores



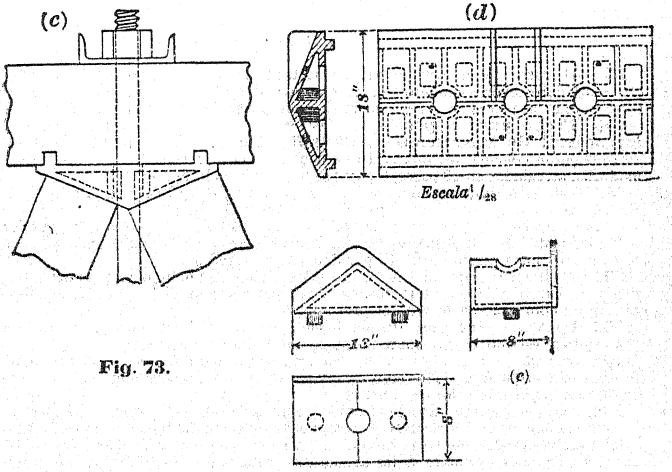


Fig. 73.

(*N. del T.* 18″=45 cm; 13″=33 cm; 8″=20.3 cm.)

(uno en cada extremo del puente), 25×30 cm; puntales angulares, D (dos en cada extremo del puente), 15×20 cm.

Las vigas del piso son de 25 × 40 cm, 6.1 m de largo, 4.27 m de luz neta, y con .76 de separación de centro á centro. Las vigas longitudinales ó refuerzos inferiores, 12½ cm de ancho por 30 cm de alto, colocadas como lo indica la parte terminal de la fig. (*b*). Durmientes, 20 cm de ancho, 15 cm de alto, separados de centro á centro 30 cm. Los guardarrieles, 20 cm de ancho, 12½ de alto. Debajo de cada extremo del cordón inferior hay dos planchas murales de madera, de 30×30 cm y 6.10 m de largo.

**251.** Las figs. 73 muestran una luz de 30.19 m. La fig. (*a*) es una elevación lateral de la mitad de la luz con tirantes laterales superiores é inferiores y el sistema de piso; la fig. (*b*) es la mitad del corte vertical normal al eje del puente; la fig. (*c*) una unión en los puntos de división de tramos (la misma para el cordón superior é inferior); la fig. (*d*) un bloque de hierro fundido para la misma; y la fig. (*e*) un bloque de hierro fundido para las traviesas laterales.

## Armaduras de metal para techos.

**252.** Entre los tipos que se usan ordinariamente en armaduras de metal para techos, está la armadura triangular, fig. 26, y la armadura de arco; la armadura triangular se usa para las luces cortas y la de arco para las *largas*. Véanse §§ 255, etc., y la fig. 75.

**253.** En las armaduras para techo de corta luz, que soportan cargas livianas, la sección mínima prescrita en las especificaciones de puentes, basta á menudo para todas las piezas. Las conexiones se hacen con remaches y planchas, más ó menos como se ve en las figs. 74.

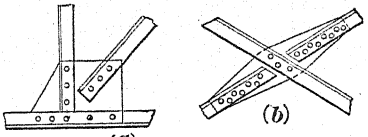

**Fig. 74.**

**254.** Al trazar dichas armaduras, no obstante lo pequeño que puedan ser los esfuerzos, debe tenerse cuidado de evitar las cargas excéntricas, que pueden presentarse cuando las piezas no se repiten simétricamente en ambos lados de las planchas.

**255. Techo para depósito de trenes. Estación de Broad Street, ferrocarril de Pensilvania, Filadelfia.** Figs. 75 de (*a*) á (*f*). Fabricado en 1893 por la Pencoyd Cº. Luz 91.64 m, flecha 33.14 m, largo 179.7 m. Veinte armaduras, arregladas en 10 pares, 3 pares se muestran en la fig. (*c*).

**256.** Cada armadura se compone de dos semiarcos, AB y BC, y un tirante horizontal, AC, con tres uniones de pasadores, A, B y C, fig. (*a*).

Cada semiarco está compuesto de dos cordones, 14 brazos ó montantes radiales y 26 diagonales. Por la buena apariencia, los cordones se prolongan á través de los tramos superiores, juntándose allí por una unión corrediza.

**257. El tirante horizontal** AC, fig. (*a*), se encuentra debajo del piso del depósito, y está suspendido, á intervalos, por vigas que soportan dicho piso, las que descansan en columnas de hierro del piso inferior.

**258. Apoyos extremos.** Un pie de cada armadura descansa sobre una pieza fija sujeta al estribo, el otro sobre un juego de 11 cilindros de acero.

**259.** En cada extremo del techo, una armadura horizontal contraviento WW, fig. (*a*), está suspendida de los cordones, y sus extremos descansan en barras remachadas en la parte inferior de aquéllos.

**260.** Entre estas armaduras horizontales contravientos y los semiarcos, y exactamente debajo de las vidrieras que cierran cada extremo del techo, están colocadas armaduras verticales, contravientos (no indicadas), con barras horizontales y diagonales en planos normales á las armaduras principales. Estas armaduras verticales están suspendidas de los puntos de división de tramos de los semiarcos, fig. (*a*). Ellas resisten la presión del viento en la vidriera, y la transmiten, por medio de las armaduras horizontales contravientos, á los cordones inferiores del arco.

**261.** Dos semiarcos AB y BC, fig. (*a*), de una armadura pesan juntos 69,916 kg. Un par de armaduras, 139,832. El techo completo 3,178,000 kg.

**262.** Las cargas extrañas supuestas en kg por metro cuadrado del área cubierta: pares, 46.4; correas, 37; ventilador y marco de la claraboya. 46.4; cubierta y claraboyas, 74; nieve, 83; viento, 171.

**263.** El andamio movible, figs. (*a*) y (*f*), era de madera y se diseñó así para usar el depósito viejo mientras se hacía el techo nuevo.

**264.** La sección superior del vértice á la junta 9, figs. (*a*) y (*c*), fué remachada

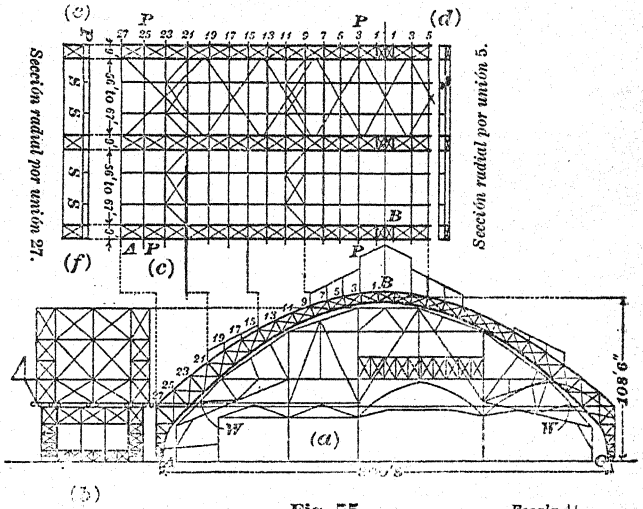

**Fig. 75.** *Escala* 1/150.

*(N. del T.).* — Para las cifras que trae la figura recuerdese que un pie (') = 30.5 cm y una pulgada (") = 2.5 cm.)

en la fábrica y colocada entera, como lo fué también la sección del pie desde la junta 27 hasta la parte superior del pie triangular. El resto fué remachado en el andamio ambulante. Para levantar una armadura con correas, viguetas, etc., uniéndola con las ya colocadas, se necesitaron cerca de 10 días. Para mudar el andamio ambulante á una distancia igual á su largo, para recibir el par de armaduras siguientes, se necesitaron como 3 minutos, y se hizo con las máquinas de suspender.

**265 Dimensiones de techos arqueados de luz grande.**
(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| | Arcos. | | Techos. | |
|---|---|---|---|---|
| | Luz. | Flecha. | Largo. | Área cubierta. |
| | metros. | metros. | metros. | metros cuad. |

## Armaduras de madera para techos.

**266. Dimensiones para armaduras de madera para techos pequeños.** Las figs. 43 á 47, §§ 148, etc., de pino blanco. Luz = 4 × flecha. Peso combinado de las armaduras, techo y carga, incluyendo nieve y una concesión para el viento, 195.2 kg por m cuadrado de superficie de techo. Armaduras separadas 3.66 m de centro á centro. Factor de seguridad = 3, $b$ = ancho, $d$ = la altura. En la fig. 46, los puntales de 11.4 × 11.4 cm, serían suficientes, pero por razones prácticas los puntales se hacen ordinariamente tan anchos como los cabios ó parecillos. En la fig. 47, el tirante compresor es de 30 × 30 cm. En las figs. 45, 46 y 47, se dan dos series de dimensiones, la primera para el tirante descargado, la segunda para la viga cargada con 488 kg por m cuadrado.

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| Fig. | Luz en metros. | Flecha en metros. | Pares centímetros. | | Tirante. Madera centímetros. | | Tirante. Hierro. Diámetro. | Pendolón y péndolas. Hierro. Diámetro. | Tirante. |
|---|---|---|---|---|---|---|---|---|---|
| | | | b. | d. | b. | d. | cm. | cm. | |

| | | | 30. | 35. | 30. | 30. | .... | 5.1 | cargado |

## TRANSPORTE Y ERECCIÓN

**267.** Las vigas deben **transportarse** en carros de plataforma, con el alma en posición vertical, y con apoyos en puntos situados á ¼ de su longitud, de los extremos hacia el centro. Si fuesen demasiado largas para dos carros, se colocan uno ó más carros sueltos, haciendo espacio, y se apuntalan los puntos de apoyo.

**268.** Las vigas se pueden **colocar en la obra** por medio de una cabria, malacate, grúa, etc., ó pueden ser sacadas de los carros rodándolas sobre rodillos y colocadas en sus puestos por medio de gatos y poleas. Las cabrias deben tener por o menos cuatro tirantes, para su maniobra y ajuste. La operación de levantarlas

se hace á menudo por medio de locomotoras moviéndolas sobre la parte de a vía ya construída. Las cuerdas se usan hasta un ¼ de su resistencia máxima.

**269. Los viaductos** se construyen generalmente desde sueparte superior, por medio de un andamio movible (torre movible). A veces por medio de una vía de cables, pero este método es más lento. En algunos casos la torre movible se coloca en el suelo y alcanza hasta la parte superior del viaducto. También se puede construir el viaducto por medio de andamios fijos ó de una estructura ya existente.

**270.** Los puentes de grandes luces se construyen generalmente en una plataforma de andamiaje sobre una hilera de caballetes, bien reforzados.

**271. Erección.** Primero se colocan los cordones inferiores sobre el andamio, tan á nivel como fuese posible. Luego se montan los cordones superiores sobre apoyos provisionales que descansan en los que sostienen el cordón inferior. Los cordones superiores se colocan primero á unas cuantas pulgadas más altos que su posición definitiva, á fin de que las piezas del entramado puedan entrar fácilmente en sus respectivos lugares. Cuando éstas se han colocado, se bajan gradualmente los cordones superiores hasta que todo descanse sobre los cordones inferiores. Luego se aprietan gradualmente los tornillos hasta llevar todas las superficies de las uniones á su posición de contacto, y por medio de esta operación (teniendo las piezas de los cordones superiores el necesario exceso de longitud) se forma la curvatura y se levantan los cordones superiores del andamio; las armaduras reposarán en sus apoyos permanentes.

**272. El andamiaje** se construye generalmente de pino ó pinabete, al costo de $20 por 1,000 pies (medida de tabla) = 2,360 metros cúbicos. Calcúlese un margen de unos $15 por 1,000 pies (medida de tabla) por armadura, etc. Se puede vender el material usado de $5 á $15 por los 1,000 pies (medida de tabla).

Las piezas principales son generalmente de 12 × 12 pulgadas (30 × 30 cm) y las diagonales 3 × 12 (7½ × 30 cm). Pernos, $^{7}/_{8}$ de pulgada (22 mm). Debido al carácter provisional de los andamios y al ahorro que se hace en su venta, si *no* está muy maltratado, se aconseja emplear bastante material de dimensiones corrientes, sobre todo en las piezas longitudinales, que se pueden colocar entre los pares alternados que forman las torres.

**273. En el caso de lechos de fondo blando**, el andamiaje puede descansar sobre pilotes á los cuales se fijan los maderos verticales del andamio por medios cortes y pernos, ó por ligaduras. No debe emplearse menos de cuatro pilotes por cada pata de caballete*. Se han empleado hasta 24. Los pilotes deben ir reforzados por debajo del nivel del agua. Los caballetes deben construirse en varios pisos, de 12 á 30 pies (3.66 á 9.1 m) cada uno. Deben conectarse por medio de piezas laterales ó placas de unión.

**274. En lechos de roca**, con fuerte corriente, sería conveniente sumergir cajones llenos de piedras, como cimiento del andamiaje.

**276. La renovación** de puentes se puede hacer por desalojamiento hacia adelante, rodando el nuevo tramo de luz á lo largo de la vía; por desalojamiento transversal por el cual los dos tramos de luz, el viejo y el nuevo, se colocan sobre vías que van en dirección normal al puente; por desalojamiento vertical : ya sea por levantamiento ó descenso; ó por desalojamiento por giración, haciendo girar el tramo de luz viejo sobre un eje y al nuevo sobre otro eje hasta colocarlo en su puesto.

**277. Precauciones.** Para la erección ó renovación, calcúlese el peso muerto del puente, los choques de la corriente del río, de los botes, del hielo, el arrastre de la corriente, etc., sobre todo cuando se pueden temer las crecientes, y el esfuerzo del aparejo. Para la rigidez debe emplearse un factor muy liberal de seguridad. Los arrastres de la corriente pueden amontonarse y formar una represa. Los caballetes*, en el agua aumentan la velocidad y fricción, pudiendo así producir socavaciones. El andamiaje se puede proteger con estacadas de defensa. Hay que preveer las excentricidades de la fuerza del viento. Numerosos accidentes han demostrado la necesidad de proteger las mismas armaduras (sin concluir) de los vientos fuertes. Todos los refuerzos y contravientos laterales deben estar colocados y asegurados antes de quitar el andamiaje y antes de que las armaduras descansen en sus apoyos definitivos.

Evítese la caída de la herramienta, etc. Aun las más pequeñas piezas, cayendo de una gran altura, son un peligro para las vidas y hasta para el mismo puente. Los garfios de los aparejos están expuestos á quebrarse ó estirarse. Los andamios deben estar bien sujetos por contravientos y asegurados por abrazaderas cuidadosamente arandeladas.

---

(*Obs. del T.* — Estas páginas del Resumen que va á continuación, son las que más dificultades nos han presentado para su traducción. Son muchos los detalles de las innumerables piezas y elementos, y muy considerable la variedad de nombres para dichas piezas y para las operaciones de fundición, fraguado, etc., no bien determinados en español.

A lo que se agrega, la forma exageradamente sintética y los giros y modismos de los norteamericanos, tratándose de estas industrias y de las construcciones con ellas relacionadas. Pero hay tan copiosa enseñanza en esta condensada síntesis,

y como además es este uno de los varios capítulos de esta obra que no se encuentran en los Manuales análogos en español, no hemos omitido esfuerzo ni consulta para tratar de interpretar lo mejor posible sus dictámenes y fórmulas de irreemplazable valor en la práctica, sobre todo para los que han construído poco.

Es la ocasión de llamar la atención del lector sobre la manera de indicar la usanza de las diversas Compañías é industriales, á veces en parcial ó completa contradicción, y la importancia de conocer con tanta brevedad el desiderátum sancionado por serios estudios y larga experiencia.

Damos las gracias al notable ingeniero de puentes Sr. C. R. Grimm, por la eficaz ayuda que nos ha prestado en esta parte del trabajo.)

# RESUMEN DE ESPECIFICACIONES PARA PUENTES Y EDIFICIOS

(1) Puentes de acero, para ferrocarriles, calzadas y ferrocarriles eléctricos.

(2) Puentes de hierro y madera (combinados) para ferrocarriles.

(3) Armaduras de acero para techos y edificios.

El siguiente Resumen de especificaciones para puentes y edificios tiene por objeto principal dar una idea general de los caracteres esenciales que presentan en la práctica aquellos materiales, y, á la vez, indicar el modo de construir de las diversas Compañías.

---

## (1) RESUMEN DE ESPECIFICACIONES PARA PUENTES DE ACERO EN FERROCARRILES Y CALZADAS

### Abreviaciones usadas.

**A,** American Bridge Company,
Especificaciones generales para puentes de acero en ferrocarriles, 1900.

**Aa,** American Bridge Company,
Especificaciones generales para puentes de acero en calzadas, 1901.

**B,** Baltimore and Ohio Railroad Company,
Especificaciones generales para puentes en ferrocarriles y calzadas, techos y edificios de acero, 1901.

**C,** Cooper, Theodore,
Especificaciones generales para puentes de acero en ferrocarriles y viaductos, 1901.

**Cc,** Cooper Theodore,
Especificaciones generales para puentes de acero en calzadas y ferrocarriles eléctricos y viaductos, 1901.

**D,** Delaware, Lackawanna and Western R. R. Company,
Especificaciones para puentes de acero en ferrocarriles, octubre 1899: revisadas hasta julio 1900.

**E,** Erie Railroad Company,
Especificaciones generales para puentes, 1900.

**G,** Práctica ordinaria.

**Oo,** Osborn Engineering Company,
Especificaciones generales para las superestructuras en puentes de calzadas 1901.

**P,** Pennsylvania Railroad Company,
Especificaciones modelos para puentes de acero, enero 1 de 1901.

**R,** Philadelphia and Reading Railway Company,
Especificaciones para puentes de acero, 1898, revisadas febrero 1901.

**Y,** New York Central and Hudson River R. R. Leased and Operated Lines,
Especificaciones generales para puentes de acero, 1900.

(*N. del T.* — Hemos creído conveniente, por tratarse de las prácticas de Compañías americanas, dejar las medidas inglesas junto á las métricas.)

**A, Aa,** Am B Co; **B,** B y O; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

## I. PROYECTO EN GENERAL

### Limitación de luces para diversos tipos.

| *Vigas.* | | **A** | **Aa** | **B** | **C** | **Cc** | **D** | **Y** |
|---|---|---|---|---|---|---|---|---|
| Vigas de acero laminado, pisos, etc. | pies. | hasta 20 | hasta 40 | hasta 20 | hasta 20 | hasta 40 | hasta 20 | hasta 25 |
| | metros. | (6.09) | (12.19) | ** | | | | (7.62) |
| Vigas de remache.. | pies. | 20 á 100 | 25 á 80 | 20 á 100 | 20 á 120 | 20 á 80 | 20 á 100 | 25 á 100 |
| | metros. | (6.09 á 30.48) | (7.62 á 24.38) | | (6.09 á 36.57) | (6.09 á 24.38) | | (7.62 á 30.48) |
| ***Armaduras.*** | | | | | | | | |
| Armaduras de remache..... | pies. | 100 á 140 | 40 y más | 100 á 120 | 75 á 150 | 40 y más | 90 á 160 | 100 á 200 |
| | metros. | (30.48 á 42.67) | (12.19) | (30.48 á 36.57) | (22.85 á 45.72) | | (27.43 á 48.77) | (30.48 á 60.96) |
| Armaduras de pasadores..... | pies. | más de 140 | más de 140 | más de 120 | más de 120 | más de 120 | más de 150 y más | más de 200 y más |
| | metros. | (42.67) | | (36.57) | | | (45.72) | (60.96) |

Armaduras de remache menos de 100 pies, armaduras de pasadores, más de 100 pies (30.48 m), **Oo.**

Altura de la armadura, mín, = un octavo de la luz, **Oo.**

### Clasificación para puentes en calzadas y ferrocarriles eléctricos.

**Aa Cc**

**A** A1* Puentes para ciudades con pisos de planchas cóncavas, pavimentados sobre base de concreto.

**A** A2* Puentes para ciudades con pisos de planchas de madera.

**B** B* Puentes suburbanos para tranvías eléctricos pesados.

**C** C Puentes urbanos y rurales para tranvías eléctricos livianos, ó grandes pesos.

**D** D Puentes rurales para tráfico común de calzadas.

**E1** E1 Puentes para tranvías eléctricos pesados ó automotores solamente.

**E2** E2 Puentes para los mismos, livianos.

### Curvatura.

Las secciones del cordón superior serán mayores que las del inferior : 1 en 960 **A, B, C, E, R, Y.**

En los puentes de calzadas tres dieciseisavos de pulg para cada 10 pies (=1 en 640), **Cc.**

Como $\frac{3}{4}$ de pulg (19 mm) en 100 pies (30.48 m) ó sea 1 en 1,600, **D.**

Lo suficiente para hacer que las uniones del cordón sometido á compresión trabajen en ángulo recto cuando la armadura tenga su carga completa. Cada pieza se construirá mayor ó menor en proporción al esfuerzo á que se someta con toda la carga muerta y viva, de manera que tengan su longitud normal, **Oo.**

### Sección transversal de puente.**

**Entrecarril,** usual. 4 pies 8½ pulgadas (1.43 m). **Distancia,** de centro á centro de las vías, 12 á 13 pies (3.67 á 3.96).

**Ancho entre las armaduras ó vigas con tablero superior.** Separación pasadores .05 de la luz. Armaduras ó vigas de remache (**D**), 10 pies (3.05 m). Vigas laminadas (**G**), 5 á 7 pies (1.52 á 2.13 m). Para luces no mayores de 60 pies (18.30 m), 7 pies (2.14 m); de 60 á 100 pies (18.3 á 30.48 m), 8 p (2.44 m); para más de 100 p (30.48 m). un duodécimo de la luz, **D.** Vigas laminadas (**Y**) de más de 60 pies (18.3 m), en proporción á la altura.

---

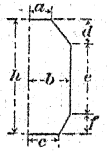
* Cc, las clases A y B se proyectan para llevar después doble vía de tranvía eléctrico

** *N. del T.*— Algunas veces suprimimos la conversión de algún número de pies, etc. en metros, porque ya se ha hecho esa misma no lejos de allí.

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

**Espacios varios á través de las luces, en tangentes, G.**

| | | | | |
|---|---|---|---|---|
| *a* | 3 á | 3½ | pies á | (.91 á 1.06 m) |
| *b* | | 7 | — | (2.14 m) |
| *c* | 5 á | 5½ | — | (1.52 á 1.67 m) |
| *d* | 4 á | 6 | — | (1.22 á 1.83 m) |
| *e* | 10 á | 14 | — | (3.05 á 4.27 m) |
| *f* | 1 á | 5 | — | (.30 á 1.52 m) |
| *h* | 20 á | 22 | — | (6.09 á 6.70 m) |



**El mínimo de espacios libres en las curvas.**

El mismo mínimo que en las tangentes, **A**. Lo mismo para vagón de 74 pies (22.56 m) de largo, 48 pies (14.63) de centro á centro de los bastidores de las ruedas de 10 pies (3.05 m) de ancho, **B**. Lo mismo para vagones de 75 pies (22.86 m) de largo, 54 pies (16.45 m) de centro á centro de bastidores. Espacio libre adicional = = 0.8 **d** pulgadas (una pulg = 25.4 mm) de cada lado; = 1.6 **d** pulgs entre las vías; en que **d** = al ángulo central subtendido por una cuerda de 100 pies (30.48 m), **C**; aumento lateral de espacio sobre el carro 2.5 pulg (63 mm) por cada pulg (cada 25.4 mm) de peraltación del riel exterior, **C**. El eje del puente es bisectriz de la ordenada media y paralela á la cuerda, **Y**.

**Puentes de calzada. Altura libre**, 14 pies (4.27 m), **Oo**. Para las clases **A**, **B**, **C** y **E**, mínimo = 15 pies (4.57 m), **Aa**, **Cc**; para ancho de 6 pies (1.83 m) sobre cada vía, **Aa**. Para clase **D**, 12.5 pies (3.81 m), **Aa**, **Cc**. **Espacio libre horizontal**. Mínimo 14 pulgadas (35.6 cm) más que el ancho entre los guardaruedas, **Aa**. Para tranvías eléctricos, 6.5 pies (1.98 m) del centro de la vía, **Aa**; 7 pies (2.13 m), **Cc**. En las curvas provéase espacio para vagones de 45 pies (13.71 m) de largo y 8 pies (2.44 m) de ancho en su máximo, 20 pies (6.09 m) entre los centros de los bastidores de las ruedas, **Aa**. Ancho entre los centros de las armaduras, mínimo = .05 de la luz, **G**.

## Piezas de tensión.

En general, los montantes así como uno ó dos tramos del cordón inferior, á cada extremo de la luz, deben ser de secciones rígidas para que soporten tanto la tensión como la compresión.

**Los ángulos**, empleados como piezas de tensión, deben asegurarse por ambas piernas, **C**, **D**; ó sólo se considera como efectiva la sección de una pierna, **C**.

**Tensores** (piezas de ajuste). Evítese el empleo de piezas de ajuste, **A**, **Aa**, **D**, (**P**, excepto en las contradiagonales). Evítense los tensores en las contradiagonales, **C**. Pueden ser ajustables las barras de las contradiagonales y tirantes en las armaduras de pasadores, **Y**; las puntas de las barras llevan roscas recalcadas, de mayor diámetro, **C**, **E**, **Y**; tornillos con rosca del patrón del Gobierno de los Estados Unidos, **C**, **Cc**, **D**, **E**; diámetro en la base de la rosca un dieciseisavo de pulgada (1.59 mm) mayor que el diámetro de la barra, **D**; un 10 por ciento, **Y**; 17 por ciento, **Oo**.

Las barras de cabeza remachada deben ser de hierro forjado, **Oo**. Los ganchos de unión deben desarrollar toda la fuerza de la barra, **Oo**.

## Piezas de compresión.

**Los postes extremos y los cordones superiores** tienen dos almas, una tabla de cubierta, una tabla inferior ó de tensión y aseguradas en el reborde inferior, **G**.

No más de una plancha, y ésta de no más de media pulgada (13 mm) de espesor

**A, Aa**, Am B Co; **B**, B y O; **C, Cc**, Cooper; **D**, D L y W; **E**, Erie;

(en puentes para calzadas de tres octavos de pulgada (9.5 mm), se empleará como lámina ó tabla de cubierta, **C, Cc**. Éstas no deben sobresalir más de 4 pulgadas (10 cm) fuera de la línea de remaches, **D**.

**Los empates entre las secciones** se empalman en todos sus lados con 2 hileras por lo menos de remaches, bien unidos á cada lado del empate, **C**. Colóquense de frente las superficies de los extremos **A** (**D, P** con excepción de los rebordes superiores de las vigas), **E, R, Y**. No se confíe en las superficies de los extremos, **E**.

**Barras de celosía.** Ancho de 1.5 á 2.5 pulgs (38 á 63 mm). Espesor de las celosías sencillas, un cuarentavo de la distancia entre los remaches; en las dobles, un dieciseisavo, **G**. Si son mayores de siete dieciseisavos de pulg (11 mm), empléense ángulos, **Oo**. El ángulo con el eje de la pieza, en celosías sencillas 60°; dobles 45°, **G**.

Distancia entre centros de remaches, ancho de la viga en U+9 pulgs (22.9 cm), **C, Cc**; 8×el menor ancho del segmento, **P, R**.

Las barras de celosías dobles remachadas en sus intersecciones, **C. D**.

Tablas inferiores de listón. (Planchas de tensión, planchas de sujeción.) Longitud mínima usual=.75 á 1.5×su propio ancho. Ancho mínimo, 9 pulgs (22.9 cm) ó .66×su propio largo, ó=al menor espesor de la pieza, **Oo**. Menor espesor=tres octavos de pulg (9.5 mm) ó de $^1/_{20}$ á $^1/_{40}$ de la distancia entre los centros de los remaches, **G**. Espacio entre los remaches (**D**), máximo 4 pulgs (10 cm) entre los centros.

## Uniones de pasadores.

**Barras de ojo.** Espesor mínimo, .625 pulgs (15.75 mm), o bien .2×el ancho de la barra, **Oo**. Cabezas recalcadas, laminadas ó á fragua **A, R**. No deben emplearse las soldaduras **A, D**, excepto (**R**) para formar argollas laterales, contradiagonales ó riostras, **R**. Recalcadas y moldeadas, **Y**. Las cabezas no deben tener más de $^1/_{16}$ de pulgada (1.5 mm) más gruesa que el cuerpo, **D, P**. Las barras templadas, **G**; antes de taladrar, **D**. No se debe hacer ningún trabajo de fragua después de taladrar, **R**. Las barras que han de colocarse unas al lado de otras deben ser taladradas á la misma temperatura, **A, Aa, Y**. Los pasadores deben penetrar sin esfuerzo. Las barras de ojo que trabajen juntas deben empalmarse y taladrarse en una misma operación, **Oo**.

La variación máxima de las distancias entre los taladros para los pasadores debe ser de un sesenticuatroavo á un trentidosavo de pulgada (.39 á .79 mm); ó un sesenticuatroavo de pulg (.39 mm) para distancia de 20 á 25 pies (6.10 á 7.60 m), **G**.

**Piezas de tensión compuestas.** Sección neta en el taladro del pasador=1.25 á 1.50×la sección neta á través del cuerpo de la pieza. Sección neta detrás del taladro=.75×la sección neta á través del taladro, ó=.80 á 1.00×la sección neta á través del cuerpo de la pieza, **G**; proporción para doble esfuerzo cortante en la sección situada detrás del pasador hasta el fin de la plancha, **Oo**; longitud de la plancha detrás del pasador, mínimo 2.5 pulgs (63 mm), **Oo**. Distancia detrás del ojo hasta el respaldo de la pieza, mayor que el radio del pasador, **Y**.

**Taladros para pasadores.** Espacio libre entre el pasador y el taladro, de un cincuentavo á un trentidosavo de pulgada, **G**.

**Planchas para pasadores ó de refuerzo.** Por lo menos una plancha á cada lado, que debe extenderse no menos de 6 pulgadas (15 cm) fuera de la lámina de tensión, **G**.

**Pasadores.** Hasta 7 pulgadas (17.8 cm) de diámetro, acero laminado, **P**; más de 7 pulgadas (17.8 cm) forjadas, **C**.

Diámetro mínimo de .66 á .85×la mayor dimensión de cualquiera de sus barras de ojo, **G**.

## Vigas de remache.

**Altura mínima :** de un noveno á un duodécimo de la luz, **G**.

**Proporción entre el alma y las alas ó tablas.** Los momentos flexores los resisten solamente las alas, y el esfuerzo cortante lo resisten enteramente las almas ó piezas del entramado, **C, Cc, R**; excepto cuando el alma está hecha de una sola pieza ó bien empalmada como para resistir á los esfuerzos de flexión, en cuyo caso $^1/_8$ del área de la sección transversal del alma puede considerarse como si fuese efectivamente área de las tablas, **Oo**.

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa, Cc, Oo**, Calzadas.

Un octavo del área del alma, se considera como de la tabla, **A, Aa, B**; si su largo fuese=90 pies (27.43 m) ó más, **E**; si su largo fuese menor de 50 pies (15.24 m), sólo la plancha de cubierta y las piernas horizontales de los ángulos de la tabla deben incluirse en el área de las tablas, **E**; ninguna parte del alma debe incluirse en la tabla, **C, Cc, D, P, R, Y.**

**Alma.** Espesor mínimo, tres octavos de pulgada (9.5 mm), **G**; en puentes de calzadas (**Cc, Oo**), cinco dieciseisavos de pulgada (8 mm).

Todo el esfuerzo cortante, obrando hacia el lado del estribo, se considera como trasladado á los ángulos de la tabla dentro de una distancia=á la altura de la viga, **A, Aa, B, E, Oo, P.**

**Empates del alma.** Una lámina á cada lado del alma, **G**; por lo menos de tres octavos de pulgada (9.5 mm) de espesor, **A, B**; por lo menos cinco dieciseisavos de pulgada (8 mm) ó ¾ del espesor del alma, y suficientemente ancha para contener 2 hileras de remaches á cada lado del empate, **Oo.**

**Piezas de refuerzo** (que aumentan la rigidez). Se requieren generalmente á los extremos y en los puntos de concentración de las cargas. Estas piezas intermediarias se necesitan generalmente cuando las distancias sin apoyo entre los ángulos de las tablas de las vigas exceden de 50 á 60 veces el espesor del alma; cuando el esfuerzo cortante excede de

$$10.000 - 75 \times \frac{\text{altura}}{\text{espesor}}\text{; ó } \left[\left(703 - 5.27\ \frac{\text{altura}}{\text{espesor}}\right) \text{(en kg por cm cuad)}\right]\text{, C;}$$

en puentes para calzadas cuando el esfuerzo cortante excede de

$$12{,}500 - 90 \times \frac{\text{altura}}{\text{espesor}}\text{; ó } \left[\left(880 - 6.32\ \frac{\text{altura}}{\text{espesor}}\right) \text{(en kg por cm cuad)}\right]\text{; Cc,}$$

Dimensiones corrientes de los ángulos, $3\frac{1}{2} \times 3 \times {}^{5}/_{16}$ á $5 \times 3\frac{1}{2} \times {}^{5}/_{8}$ (8.8 cm × 7.6 cm × .8 cm) á (12.7 cm × 8.8 cm × .9 cm).

**Alas.** Longitud sin asegurar de las alas (alas de compresión **C, P**) máximo =12 × ancho, **B, P, R, Y**; 16 × ancho, **A, C, Cc**; 20 × ancho, **D**; en puentes para calzadas=20 × ancho, **Aa**=25 × ancho, **Oo.**

Las alas de compresión tienen la misma área que las de tensión **A, Aa, B, C, Cc, Oo, P.**

Las planchas de cubierta no deben extenderse más de 5 pulgs (12.7 cm), ú 8 × el espesor de la primera plancha fuera de la línea de remaches, **A, Aa, C, Cc.** Si fuesen de espesores diversos, las planchas más gruesas estarán sobre los ángulos y las más delgadas hacia fuera, **A, Aa, B, C, Cc, Y.** Una debe extenderse á todo el largo de la viga, **B, E.** Otras deben ser suficientemente largas para soportar dos hileras de remaches adicionales en cada extremo, **C, P.**

**Refuerzos, remache, resistencias.** Véase más abajo Refuerzos, Uniones de remache y resistencias.

## Vigas durmientes.

Vigas en grupos de 2, 3 ó 4 para cada carril, separadas por vigas en U de 10 pulgs (25 cm), y más ó menos á cada 3 pies (.91 cm) remachadas á las almas, **B.**

## Refuerzos.

Compuestos de piezas rígidas, remachadas, **A, Aa, C, Cc, Y**; las piezas deben cruzarse entre sí y con las otras á que están conectadas, sobre líneas centrales comunes, pasando por todos los centros de gravedad. Los accesorios de las piezas remachados simétricamente en todas direcciones, **Y.**

**Para vigas de durmiente.** Puntales de vigas en U de 10 pulgs (25.4 cm) á cada extremo; con 2 ó 3 vigas colocadas en ángulo reforzando las remachadas; con 4 vigas postes en ángulo, como á 6 pies (1.83 m) de separación. Las uniones deben llevar por lo menos 3 remaches, **B.**

**A, Aa,** Am B Co; **B,** B y O; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

**Laterales.**

**B,** en armaduras de vía inferior. Refuerzos arriba; postes de portal (entradas de puente); puntales intermedios tan altos como los cordones; ángulos sencillos, $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{3}{8}$ (8.9×8.9×1 cm), cortándose en cada tramo para vía simple; ángulos dobles de celosía para vías dobles.

**B,** para puentes de vía inferior, refuerzos interiores; puntal final al fondo y ángulos intermedios, remachados entre sí y á los refuerzos en cada intersección. No menos de 4 remaches en cada intersección y en cada conexión final.

**B,** para puentes de vía superior, sistemas completos superior é inferior en cada tramo.

**Oo,** puntales finales al fondo en todas las armaduras, ya sean de vía superior ó inferior.

**Y,** refuerzos laterales arriba y abajo en todos los puentes, de vía superior é inferior, que tengan suficiente altura libre de entrada. Refuerzo inferior lateral en todos los puentes de vía inferior. En el sistema superior todos los refuerzos deben estar trabados entre sí y remachados á las vigas del piso cuando el largo de las traviesas es de más de 15 veces el ancho de sus tablas.

**Y,** en puentes de vía superior sin piso metálico, el refuerzo superior es de puntales cruzados á cada punta de tramo, compuestos de cuatro ángulos enrejillados, con la misma altura que el cordón superior; las diagonales rígidas se cruzan en cada tramo y están remachadas entre sí en sus intersecciones.

**Para vigas laminadas.** Vía superior. Entre las tablas superiores, ángulos con cuatro remaches por lo menos, en las conexiones. Vía inferior; refuerzo lateral inferior de ángulos cruzados en cada tramo, remachados entre sí y á las traviesas en sus intersecciones, **B.**

Los ángulos de las riostras laterales son generalmente iguales á los de las de refuerzo, **R.**

**Cc,** en puentes para calzadas puede considerarse el piso de planchas encorvadas como suficiente refuerzo lateral á nivel del piso.

**Riostras** (diagonales, cruzadas, para vibración ó para el viento) y de **Portal.**

Proporcionadas para resistir pesos desiguales de armaduras en puentes de doble vía, **E, R;** riostras extremas para transmitir todas las fuerzas horizontales á los estribos, **E;** para soportar la mitad del aumento del esfuerzo máximo debido al viento y á la fuerza centrífuga, **A, Aa, B, P.**

En puentes de vía superior, en cada punto de división de los tramos, **A, Aa, D, E, P, R, Y.**

Refuerzos superiores en puentes de tablero inferior cuya altura exceda de 25 pies (7.5 metros), **C, D, P, Y;** en puentes para calzadas, 20 pies (6.1 m), **Cc;** 25 pies (7.6 m), **Oo.**

En armaduras enanas (*pony*) (véase *N. del T.*, § 220) y en vigas de tablero inferior, en los extremos y en cada viga del piso ó de los postes cruzados, **A, Aa, R;** en cada punto de división de los tramos, **D.**

En las vigas laminadas de vía inferior ó intermedia, en cada viga del piso y en los extremos, ó, si el piso fuese enterizo, á no más de 8 pies (2.44 m) de separación, **Y.**

En las vigas laminadas de tablero superior, se emplean cruceros rígidos en los extremos con separación máxima de 20 pies, **Y;** riostras en marcos con 4 ángulos, por lo menos, en los extremos y puntos de división de los tramos de 12 ó 14 pies 3.66 á 4.37 m) de separación, **B.**

## Uniones de remache.

**Taladros para remaches.** En vigas I deben ser taladrados, **B.**

Pueden hacerce por punción; en acero de no más de $\frac{5}{8}$ á $\frac{3}{4}$ de pulgada (16 á 19 mm) de espesor, **G.**

Subpunzados un octavo de pulgada más pequeños y escariados hasta un dieziseisavo de pulgada más grande que el remache, en acero de más de $\frac{5}{8}$ hasta $\frac{3}{4}$ de pulgada (16 á 19 mm) de espesor; en las uniones de las vigas del piso y las vigas que las cruzan con las armaduras maestras ó vigas de remache, **E.**

No se debe permitir (*drifting*)*, **A, B, C, D, E, R.**

* *N. del T.* — Sucede, á veces, que en dos ó más planchas perforadas, al yuxtaponerlas no coinciden los huecos y algún borde sobresaliente impide la entrada del perno—entonces, algunos, á golpes de martillo, fuerzan el perno, venciendo el obstáculo. Esta operación, no permitida, es el *drifting*. No encontramos palabra adecuada que la exprese en español.

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

No se deben cambiar las piezas después de escariadas, **D**, **P**.

Los huecos para remaches deben ser un dieciseisavo de pulgada (1½ mm) mayores que los remaches, **G**.

El taladro debe ser mayor que la perforación en un máximo de un dieciseisavo de pulgada (1½ mm), **G**.

Distancia entre la orilla de la plancha al centro del remache. Mínima, 1.25 á 1:5 pulgadas (32 á 38 mm), ó 1.5 á 2 diámetros del remache. Máxima, 4 á 5 pulgadas (10 á 12.7 cm), ú 8× el espesor de la plancha, **G**.

Distancia entre remaches. Mín=3×diámetro del remache, generalmente; con preferencia 4×diámetro, **Oo**.

Máxima distancia entre remaches en líneas de mayor resistencia, 5 á 6 pulgadas (12.7 á 15.2 cm), ó 16× espesor de la plancha exterior más delgada que se conecte; normales á los esfuerzos, 30 á 50× espesor de la plancha exterior más delgada que se conecte. En los extremos de las piezas de compresión (ó en piezas compuestas, de tensión, **B**); para una longitud de 1.5 á 2×el ancho ó la altura de la pieza, 3.5 á 4×diámetro del remache, **G**.

En vigas de remache, para los remaches del entramado á la tabla superior que soporta la vía, máx=3 pulgadas (7.5 cm), **R**.

**Remaches.** Diámetro generalmente de $^{3}/_{4}$ ó $^{7}/_{8}$ de pulg (19 á 22 mm). Cabeza hemisférica, **G**. Altura de la cabeza, mínimo=.6 del diámetro, **R**.

**La remachada.** Evítese remachar á mano. Usense máquinas de acción directa, á vapor, de presión hidráulica ó aire comprimido, capaces de mantener la presión aplicada después de ensanchar el extremo del remache, **G**.

## Piso.

**Vigas del piso.** Altura mínima=$^{1}/_{8}$×su longitud, **Y**. En puentes para ferrocarriles y puentes para calzadas importantes, remachadas á los postes de las armaduras ó al entramado de las vigas laminadas, **G**. También se les da un apoyo en la tabla inferior de la viga ó se apuntalan, **G**. A falta de estos apoyos auméntese en un 25 por ciento el número de los remaches, **R**.

Los suspensores, cuando se emplean, no deben ser ajustables, **C**, **Cc**. Éstos deben ser de lámina ó de forma, **Oo**.

**Vigas longitudinales.** Altura mín,=$^{1}/_{8}$×la longitud, **Y**. En puentes para ferrocarriles, las clases A1 y A2 de acero; las clases B, C y E, las vigas que van debajo del riel son de acero; clase D, de madera ó acero, **Cc**. En puentes de ferrocarril, y con preferencia en puentes para calzadas, remachadas al entramado de las vigas del piso, sostenidas por sus tablas ó por ángulos, **B**, **R**. No se tome en consideración la fuerza de estos apoyos al fijar el número de remaches necesarios, **R**.

Separación de centro á centro, 6 pies 6 pulgadas (1.98 m), **A**, **B**, **C**, **D**, **Y**; 5 pies (1.52 m), **E**; tablero inferior de doble vía, generalmente 6 pies (1.83 m), **R**. En vía simple, 8 pies (2.44 m), **R**.

**Pisos divididos en cajuelas.** Cajuelas rectangulares, construídas de láminas y ángulos, remachadas á las vigas principales ó armaduras, por ángulos, y, cuando fuese posible, por escuadras por debajo de las láminas horizontales inferiores. Placas angulares remachadas á las vigas y á las cajuelas á distancias no mayores de 8 pies (2.44 m), **Y**.

El fondo se llena con una pega compuesta de un pie cúbico de granzón limpio cernido en un tamiz de un cuarto de pulgada, con 1½ galones (5.67 lit) de asfalto n.º 4 para pisos, ó lo suficiente para llenar los vacíos. Se calienta primero el granzón á 300° F (149° C) y se hace toda la mezcla á esa temperatura, **Y**.

**Pisos de madera.** Se continúan por encima de los estribos, **A**, **B**, **C**, **B**.

**Durmientes ó vigas del piso.** Pino amarillo ó roble blanco, **G**.

Anchura, 8 pulgadas (20.3 cm), **A**, **B**; 9 pulgadas (22.8 cm), **R**.

Espesor, 8 pulgadas (20.3 cm) para 7 pies (2.13 m) de largo de luz del durmiente, á 14 pulgadas (35.6 cm) para 12 pies (3.66 m), **B**; 12 pulgadas (30.5 cm), **R**; 10 pulgadas (25.4 cm), **Y**.

Tájese media pulgada (12.7 mm); máx, 1½ pulgadas (38 mm), **R**.

Separación. Generalmente 6 pulgadas (15.2 cm) libres; 16 pulgadas (40.6 cm) de centro á centro, **R**. Cada 3.er, 4.º ó 5.º durmiente asegurado á las vigas con pernos de ¾ pulgadas (19 mm) ó con tornillos, **G**.

**Las vigas de madera en puentes para calzadas.** Ancho mínimo, 3 pulgadas (7.6 cm), ó .25×altura; separación máx, 2 á 2.5 pies (.61 á .76 m). Sus extremos descansan sucesivamente en sus puntos de encuentro sobre las vigas del

**A**, **Aa**, Am B Co; **B**, B y O; **C**, **Cc**, Cooper; **D**, D L y W; **E**, Erie;

suelo, con .5 pulgada (12.7 mm) de separación entre sí para la circulación del aire.

**Vigas de madera para pisos en puentes para ferrocarriles eléctricos.** Las clases E1 y E2. Mín, 6×6 pulgadas (15.2×15.2 cm), separación máx, 6 pulgadas, con tajaduras de media pulgada (12.7 mm) y aseguradas á las vigas por pernos de tres cuartos de pulgada (19 mm) separados por no más de 6 pies (1.83 m). Desde el centro de la luz hacia los extremos rebajadas á fin de reducir la flecha de curvatura de la viga.

**Guardarriel.** 6×8 pulgadas (15 × 20 cm) de pino amarillo ó blanco, **G**. Superficie interior á no menos de 3 pies 3 pulgadas (.99 m) del centro de la vía, **A**; 3 pies 7½ pulgadas (1.07 m), **B**; 5 pies 4 pulgadas (1.62 m), **Y**; 7 pies 1¼ pulgadas (2.16 m) de separación libre, **R**. Tajaduras de ½ á 1½ pulgadas (13 á 38 mm) sobre los durmientes, **G**. Aseguradas cada 3 ó 4 durmientes (á cada durmiente, **R**) y á los empates con pernos de tres cuartos de pulgada (19 mm) ó con tornillos, **G**. Los empates sobre los maderos del piso, con ensambladuras á medio corte de 6 pulgadas (15.2 cm) de largo, **G**.

**Guardarruedas y aceras en puentes para calzadas.** Guardarruedas 6×4 pulgs (15.2×10.1 cm) aseguradas á las planchas del piso por tacos de 2×6 pulgadas y (5×15.2 cm) y 12 pulgadas (30.5 cm) de largo, á no más de 5 pies (1.52 m) de separación, fijas por pernos á las vigas longitudinales á través de los tacos con pernos de tres cuartos de pulgada (19 mm), **G**. En puentes para ferrocarriles eléctricos (**Cc**, clase E) los maderos de las guardas, mín, 5×7 pulgadas (12.6×17.8 cm), con tajaduras de 1 pulgada (25.4 mm) sobre los maderos del piso y aseguradas por pernos de tres cuartos de pulgada á cada tercer madero y en cada empalme.

**Planchas convexas.** Mín $^{5}/_{16}$ de pulgada (8 mm) de espesor para calzada y un cuarto de pulgada (6.3 mm) para las aceras, flecha 2 pulgadas (5 cm) para anchos de 4 pies (1.22 m) bajo la calzada, 5 pies (1.52 m) bajo las aceras. Son preferibles en láminas continuas del tamaño de las secciones. Pueden conformarse sin calentar.

## Apoyos sobre los estribos y pilares.

**Peso permitido en cimientos de mampostería**, máx, libras por pulgada cuadrada, 400 (28 kg por cm cuad), **A**, **Aa**, **P**; 300 (21 kg por cm cuad), **B**; 250 (15.5), **C**, **Cc**, **D**, **E**, **R**; carga muerta, 500 (35); carga viva, 250 (15.5), **Y**.

**Planchas de apoyo.** De acero mediano, **C**, **Cc**. Espesor mín, tres cuartos á una pulgada (19 á 25 mm); en puentes para calzadas, media pulgada (12½ mm). Máx de la resistencia de las fibras, 12,000 libras por pulg cuad (840 kg por cm cuad), **E**.

Cuando los extremos de dos luces descansan en una pila, se unen los tramos ó se les pone planchas de apoyo enterizas, debajo de ambas, de tres cuartos á una pulgada (19 á 25 mm) de espesor, **G**.

Láminas de plomo de un octavo á un cuarto de pulgada (3 á 6 mm) de espesor, entre la plancha de apoyo y la mampostería, **G**.

**Pernos de anclaje**, 1 á 1.25 pulgadas (25 á 31.7 mm) de diámetro, 9 á 12 pulgadas (22.8 á 30.5 cm) dentro de la mampostería, **G**; asegurados con azufre, **R**; con cemento, **C**, **Cc**, **Y**.

**Pedestales.** De láminas y ángulos remachados, **C**; ó de acero fundido, **Y**. Planchas de apoyo y ángulos de conexión, mín, tres cuartos á siete octavos de pulgada (22 mm) de espesor, **B**, **C**, **Y**. 2 hileras de remaches en las lados verticales, **C**, **Y**.

**Apoyos para la expansión.** Dispuestos para cambios de temperatura de 150° F (65.6° C), **A**, **C**, **E**, **P**, **R**; para expansión de 1 pulgada (25 mm) en cada 100 pies (30.5 m), **D**, **Y**.

Un extremo libre para deslizarse, generalmente en tramos no menores de 60 á 90 pies (18.3 á 27.4 m), **G**.

Un extremo sobre rodillos de fricción, generalmente en tramos de mayores dimensiones, **G**; en todas las armaduras, **Y**.

Balanceadores (véase *N. del T.*, § 208) á cada extremo, en tramos de 80 á 100 pies (24.4 á 30.5 m), **G**.

Los rodillos descansan en barras de 3×1 pulgadas (7.5×2.5 cm) separados 2 pulgadas (5 cm) y remachados á las planchas de apoyo, **B**. Los extremos libres se anclan para que no se levanten ni muevan lateralmente, **C**, **Y**.

Rodillos, de acero de máquina, **C**, **Cc**. Diámetro mínimo, 3 á 4 pulgadas (7.5 á10 cm), **A**, **B**, **D**, **E**, **P**, **R**; 3 pulgadas (7.5 cm) para luces hasta de 100 pies

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

( 80.5 m), una pulg más para cada 100 pies adicionales, **C**, **Y**. Máximo de presión sobre los rodillos, en kg, por cm lineal, $80.5\sqrt{d}$, **R**; $d$=diámetro rodillos en cm. Largo, en cm= $1{,}444\sqrt{d}$, **Y**.

## II. MATERIAL

### Acero y hierro laminados y colados.

**Acero laminado** en superstructuras, por regla general.
**Acero colado** en planchas de apoyo, en casos especiales, en maquinaria de puentes movibles.
**Hierro laminado** en barras de argolla soldadas, **P**; en piezas laterales y sin importancia, **R**.
**Hierro colado** en planchas de asiento, en casos especiales y en la maquinaria de puentes movibles.

### Acero laminado, calidades.

**Blando**. En todas las piezas principales, por regla general.
**Mediano**. En pasadores, rodillos de fricción, pernos laterales, planchas de apoyo, barras de ojo, planchas corredizas y de asiento; se puede permitir (**C**) para compresiones, en los cordones, postes y pedestales.
**En remaches**.
**Mecanismos**. En rodillos para la expansión, **C**.

### Acero laminado. Manufactura.

Todas deben hacerse por horno de regeneración.
Las planchas de donde se sacan las láminas se hacen á martillo ó en laminadores de lingotes que tengan por lo menos el doble de la sección transversal de aquéllas, **A**, **B**.
Las láminas hasta 36 pulgadas (.91 m) de ancho se hacen en laminadores de rodillos horizontales y verticales (estos últimos aplanan el borde. *N. del T.*) (*universal-mill*), **D**, **R**; ó cizallando las orillas, **D**.

### Acero laminado. Manipulación.

Temple. Barras de ojo calentadas á un rojo obscuro uniforme, se dejan enfriar lentamente, **P**; las piezas llevadas á un rojo azul se calientan al rojo brillante uniforme (no expuestas directamente á las llamas) y se dejan enfriar lentamente, **B**.
El acero no se debe soldar, **B**. No se debe confiar en el acero soldado, **C**.

### Acero laminado. Su manejo en el taller.

Las aristas del acero de más de $^{5}/_{8}$ de pulgada (16 mm) cortado á cizallas deben acepillarse, **B**.
Todas las aristas cizalladas (de acero mediano, **D**) deben rebajarse .25 de pulgada (6 mm), **D**, **Y**; excepto en planchas para almas de vigas de más de 36 pulgadas (.91 m) de altura cuando van coronadas con tablas, y en las piezas para rellenar cuando no se les vean las aristas, **D**. No se debe aceptar que se limen las aristas en vez de acepillarlas, excepto en el caso de las barras para celosías, **Y**.
No se deben permitir rincones agudos ó sin llenar, **D**, **Y**. Cuando se ha cortado una lámina, un ángulo ó una pieza de forma, tanto el relleno como el corte deben igualarse con un instrumento muy cortante, ó con cincel y lima, de manera que no queden señales del corte á cincel, ó de las cizallas, **D**.
Los ángulos ó las piezas flexadas, empleadas como conexiones á los extremos de las vigas laminadas, ó de las vigas transversales y longitudinales, se deben ajustar muy bien, de manera que cuando la pieza se corte en su longitud no se les quite á estas conexiones más de un $^{1}/_{16}$ de pulgada (1.5 mm), **D**.
El material flexado por el taladro debe enderezarse antes de fijarse con los pernos, **R**. Cuando las planchas para los tramos estén deformadas, se deben repasar en frío para enderezarlas, **D**.
Las secciones empatadas de los cordones deben armarse en el taller, en trozos no

**A**, **Aa**, Am B Co; **B**, B y O; **C**, **Cc**, Cooper; **D**, D L y W; **E**, Erie;

menores de tres secciones, y después de ponerlas en contacto en sus empates y colocadas en sus respectivos lugares, se harán los agujeros para los remaches con exactitud antes de desarmarlas, y las partes así armadas, con sus respectivas planchas de empate, deben marcarse, **D**.

Todas las piezas armadas á remache deben asegurarse y juntarse entre sí antes de remacharlas, **D**.

En el caso de alguna obra oblicua, ó de conexiones complicadas, ó de un gran número de piezas de una misma clase, se armarán y se ajustarán en el taller, lo suficiente para evitar un mal ajuste.

Es necesario, generalmente, preparar las superficies que se tocan en los extremos de las secciones de las piezas de compresión, así como en las piezas que se han de armar.

## Acero laminado. (Requisitos.)

*Ensayos de tensión.*

Muestras de acero mediano, blando y de remaches. Para los ensayos de barras de ojo enterizas, véase á continuación.

Resistencia máxima *u* y límite de elasticidad, *el*, en millares de libras por pulg cuadrada *. Estiramiento, *s*, y reducción del área, *a*, en tanto por ciento de las dimensiones originales. El estiramiento medido en una longitud de 8 pulgadas (20.3 cm).

(*N. del T.* — Entre paréntesis van los kg por cm cuad equivalentes á las lbs por pulg cuad del número superior. La unidad, también el millar de kgs.)

* *N. del T.* — Cada 1,000 lbs por pulgada cuadrada equivalen más ó menos á 70 kg por centímetro cuadrado.

**G**, general; **Oó**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

*Pruebas de flexión.*

En acero mediano, la muestra debe doblarse en un ángulo de 180° alrededor de una barra de diámetro = 1 á 1½ × el espesor de la muestra, sin presentar fracturas del lado fuera de la flexión; en acero flojo y de remache, debe doblarse sobre sí mismo.

*Ensayo de hebra.*

Cuando se haya sacado el filamento alrededor de la barra y doblado ésta, el acero para remaches debe presentar una ruptura gradual fina, sedosa y homogénea, **D**.

*Prueba al punzón.*

El centro del agujero como en la práctica ordinaria, ó 1.5 á 1.87 pulgadas (37.5 á 47.5 mm) ó 2 diámetros del borde de la lámina; y ensánchese hasta 1.25 á 1.50 de diámetro, **G**.

*Prueba angular.*

Los ángulos de todo espesor deben poder abrirse planos (*flat.*). Los ángulos de no más de ½ pulgada (12.5 mm) de espesor deben cerrarse por completo, al frío, á golpes de martillo, sin dar señales de ruptura, **B**.

*Piezas de ensayo.*

Sección mínima, generalmente de ½ pulgada cuadrada (1.56 cm cuad). Longitud mínima, 8 á 12 pulgadas (20 á 30 cm). Generalmente deben hacerse pruebas de fundición ó golpe.

*Ensayos de las barras de ojo de grandes dimensiones.*

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| | Carga máxima kg por cm cuad (mín). | Límite de elasticidad en kg por cm cuad (mín). | Percentaje del alargamiento. |
|---|---|---|---|
| **A, Aa**.... | 350 menos que las piezas pequeñas | | 10 entre cuellos |
| **B**..... | 3,850 | .5 de la máx | 12 entre cuellos §<br>10 entre cuellos ‖ |
| **C, Cc**..... | 3,920 | | 10 entre cuellos |
| **D**..... | 4,060 | 2,100 | 12 en 3.05 m |
| **E**..... | | | 15 |
| **Oo**..... | 3,850 | | 12.5 en 4.5 m |

| **Y**..... | 4,060 | 2,310 | 10 en 6.1 m |

Por regla general no *más* del 4 por ciento del número total de las barras de un puente se deben someter á prueba, **R**; por lo menos 4 por ciento y no menos de 3 barras, **B**.

75 por ciento de las fracturas deben ser sedosas, el resto de grano fino, **R**.

Roturas en las cabezas puede no ser causa de rechazo.

(a) Si la barra desarrolla 10 por ciento de estiramiento (12.5 por ciento en 15 pies (4.57 m), **Oo**) y la resistencia máxima requerida (máxima 56,000, **C**, 55,000, **Oo**) (3,920 kg por cm cuad, **C**, 3,850, **Oo**), y si no, más de una tercera parte de todas las barras se rompen en la cabeza, **A, C, Oo**.

(b) si la barra se estira en 14 por ciento y si una segunda barra se rompe en el cuerpo y si el promedio del alargamiento de las dos barras no es menor de 16 por ciento, **P**.

La Compañía paga sólo por las barras que corresponden á los ensayos, **G**.

*** Acero mediano. * Barras de no más de 10 pulgs cuadradas (64.56 cm cuad). ** 20 pulgadas cuadradas (129.03 cm cuad). Valores proporcionales para las áreas intermedias. *** Acero blanco. § En barras de no más de 20 pies (6.1 m) entre cuellos. ‖ En barras de más de 20 pies (6.1 m) entre cuellos. **** Máx. 16.

**A, Aa,** Am B Co; **B,** B y O; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

*Prueba sobre la construcción ya completa.*

La carga especificada, ó su equivalente, se pasa por encima de la construcción (en puentes de ferrocarril á una velocidad no mayor de 60 millas (96½ km) por hora, y detenida en cualquier punto por medio de frenos de aire comprimido ú otros) ó se coloca el máximo de la carga sobre la construcción por 12 horas. Después de la prueba, la obra debe volver á su posición original sin presentar señales de alteración permanente en ninguna parte, **C.**

*Composición.*

Fósforo, mayor percentaje:
En acero ácido, .06 á .08; en acero básico, .04 á .06; en piezas coladas, .08.
Azufre, mayor percentaje, .04 á .06.

*Máxima variación permitida en las secciones transversales y los pesos especificados.*

2.5 por ciento, **G**, excepto en planchas de ancho extraordinario, **D, Oo, P.**
En planchas de más de 40 pulgadas (1.02 m), en proporción del ancho, hasta el 5 por ciento en planchas de 90 pulgadas (2.29 m) ó más, **D.**
1.5 por ciento; cuando el 40 por ciento del total es de planchas de 36 pulgadas ó más de ancho, se aumenta el 2 por ciento, **Y.**
Planchas largas, de ½ pulgada (12½ mm) de desvío en 20 pies (6.1 m), ¾ pulgada (19 mm) en 40 pies (12.2 m), **R.**
Piezas de forma, 3 por ciento menos de espesor; planchas de 80 pulgadas (2.03 m) de ancho, 5 por ciento, **R.**

## Piezas de acero colado.

**Fabricación.** Acero Martín Siemens, **A, Aa, D, P, Y**; ácida, **Y**; templadas **P, R, Y.** Carbón, percentaje de .25 á .40, **G.**
Fósforo, percentaje, máx, .08, **B, Y.**

*Pruebas de tensión.*

(*N. del T.* — Para tener la tabla en ambas unidadas inglesas y métricas hemos puesto entre paréntesis las equivalencias en el sistema métrico.)

| | Tamaño de la pieza de la prueba en pulgs y cm. | Mayor resistencia en lbs por pulg cuad y kg por cm cuad mín. | Límite de elasticidad en libras por pulg cuad y kg por cm cuad mín. | Tanto por ciento de extensión en 2 pulgs (5 cm) mín. | Tanto por ciento de reducción del área. |
|---|---|---|---|---|---|
| **C, D, E, P, R.** | 1/2 cuadrada (1.56 cm cuad) ó 3/4 redonda (19 mm) | 65000 (4550 kilos) á 70000 (4900 kilos) | 33000 (2300 kilos) ó .5 últ. | 10 á 15 | 20, **P** |
| **Y.** | 3/4 redonda (19 mm) como 6 (15.2 cm) de largo | (a) 55000 (3850 kil) á 65000 (4550 kil) | ..... | 20 | |
| | | (b) 72000 (5040 kil) á 80000 (5600 kil) | 0.5 últ. | 15 | 25 |

*Prueba de flexión.*

**Y** (a), para usos generales como planchas de asiento, pedestales, etc., debe doblarse á 90°, para un radio=al diámetro de la pieza que se prueba.
**Y** (b), para rodillos de puentes levadizos ó giratorios, etc.

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

### Hierro laminado.

Condiciones de las especificaciones de Osborn para puentes de calzadas, **Oo**. Hecho con hierro pudelado ó laminado de atados ó montones de recortes de hierro forjado n.º 1, solo, ó con hierro de primera laminación. Tensión mín, 48,000 libras por pulg cuad (3,360 kg por cm cuad) (50,000) (3,500), **R**); punto *cedente* (véase *N. del T.*, § 31 de Resistencia de Materiales) (1,750 kg por cm cuad) (1,820 kg por cm cuad), **R**); estiramiento, 20 por ciento en 8 pulgadas (20.3 cm); en secciones de peso menor de .654 libra por pie lineal (.97 kg por m), 15 por ciento. Las piezas de prueba cortadas de la barra original deben doblarse en un ángulo de 180º con una serie de golpes ligeros, al ser tajada alrededor y doblada; la fractura debe ser generalmente fibrosa y libre de manchas gruesas cristalinas; no más del 10 por ciento de la superficie fracturada debe ser granular. Las muestras calentadas al rojo vivo deben doblarse completamente con golpes suaves sucesivos no dados directamente en el doblez. En barras planas y cuadradas, se pueden permitir variaciones en cualquiera de las dos dimensiones, de $^1/_{32}$ de pulgada (.8 mm), y en las redondas, .01 pulg (.25 mm), **Oo**.

### Hierro fundido.

Hierro gris duro de fundición, **A**, **D**, **E**, **R**; á menos que se especifique de otra manera, **A**, **R**.

Resistencia transversal. Barras de 1 pulg en cuadro (6.45 cm cuad), largas de 12 pulgadas (30.5 cm), soportarán 2,500 libras (1,134 kg) de carga central. Deben flexarse .15 pulgadas (3.8 mm) antes de romperse, **G**. Barras de 1 pulgada en cuadro (6.45 cm cuad) y de 4.5 pies (1.37 m) de largo, soportarán 500 libras (227 kg) de carga central, **E**, **R**.

### Bronce fosfórico.

Un cubo de una pulgada (16.38 cm cúb) bajo compresión, límite de elasticidad, 20,000 libras (9,076 kg). Bajo 100,000 libs (45,359 kg), deformación permanente, máxima $^1/_{16}$ de pulgada (1½ mm), **B**.

### Maderas.

No se debe emplear más del 10% de madera de savia en piezas de la misma calidad, y no se aceptarán piezas que presenten capas de savia de más de .25 × el ancho de la pieza en cualquier punto de sus caras, ó más de la mitad del espesor de cualquier tablón, **Oo**.

## III. CARGAS

### 1. Cargas verticales.

(Cargas muertas, vivas y choques.)

### Cargas muertas en puentes de ferrocarriles á vapor.

Carga muerta = peso del metal + $n$ kg, por m lineal de vía, **C**, **D**, **E**, **R**, **Y**. $n = 600$, **C**, **D**, **E**; $n = 750$, **R**; $n = 924$, **Y**.

La madera calculada á 4.5 libras por pie (6.7 kg por metro), **B**, **M**, **G**. Balasto 110 libras por pie cúbico (1,763 kg por m cúb), **C**.

Carriles, bridas y empates, calculados á 100 libras por pie lineal de vía (149 kg /m), **A**, **B**, **C**.

Carriles, bridas, guardacarriles, etc., á 160 libras por pie lineal de vía (238.4 kg por m), **P**.

Se supone que las dos terceras partes de la carga muerta la sostiene el cordón cargado, **Y**; en luces de menos de 300 pies (91.5 m), **B**; en luces mayores calcúlese la distribución, **B**.

### Cargas muertas en puentes de calzadas y de ferrocarriles eléctricos.

Hierro, 3.33 libras por pie lineal (4.96 kg por m) de barra de 1 pulgada cuadrada de área (6.45 cm cuad), **Oo**.

**A**, **Aa**, Am B Co; **B**, B y O; **C**, **Cc**, Cooper; **D**, D L y W; **E**, Erie;

Acero, 3.40 libras por pie lineal (5.06 kg por m) de barra de 1 pulgada cuadrada (6.45 cm cuad) de área, **Oo**.

Madera por pie (medida de tabla)*, 4, **Aa**; creosotada, 5, **Oo**; roble, 4.5, **Cc**, **Oo**; otras maderas duras, 4.5, **Cc**; pino amarillo, 4, **Oo**; abeto y pino blanco, 3.5, **Cc**; pino blanco y cedro, 3, **Oo**.

Concreto, etc., 130 libras por pie cúb (2,084 kg por m cúb), **Aa**; concreto de piedra 125 (2,003), **Oo**; concreto de escoria 100 (1,603), **Oo**. Piedra, 150 (2,404), **Oo**; granito, 160 (2,560), **Aa**.

Ladrillo, 150 (2,404), **Aa**; 125 (2,003), **Oo**; arena, 100 (1,603), **Oo**. Asfalto, 130 (2,084), **Aa**; 90 (1,440), **Oo**.

Carriles, ligazones, bridas y guardas de maderos, 100 libras por pie lineal (149 kg por m) de vía, **Aa**.

## Cargas vivas para puentes de ferrocarril á vapor.

### (CARGAS NORMALES DE TEODORO COOPER)

El número (27 á 50) que sigue á la letra E (Locomotora) en la clase que se expresa (véase la tabla abajo) da el peso $d$ en millares de libras sobre un par de ruedas motrices. En cada clase, $d = 2\,b = 40\,t \div 26 = 10$ U. Como son constantes estas proporciones para todas las clases, los esfuerzos, producidos por cualquier clase, son proporcionales al número de la clase. El peso del metal, en puentes, es, en cada clase, un 10 por ciento mayor que en la clase menor inmediata.

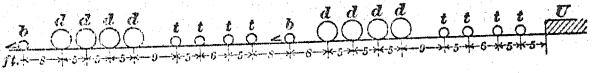

**Fig. 1.**

(*Obs. del T.* — Para tener en metros las distancias entre dos pares de ruedas (indicadas en pies, véase fig. 1) se multiplica la distancia expresada en la fig. por .305.)

*Dos locomotoras « Consolidation »** con sus tender y vagones.*

Carga en libras sobre un par de ruedas para cada vía.

(*Obs. del T.* — Hemos puesto entre paréntesis las equivalencias en sistema métrico.)

| Clase. | Carretilla delantera. | Motrices. | Ténder. | Tren cargado, lbs por pie lineal y kg por metro lineal. |
|---|---|---|---|---|
| | *b* | *d* | *t* | U |
| E 27 | 13,500 (6,124 kg) | 27,000 (12,247 kg) | 17,500 (7,938 kg) | 2,700 (4,023 kg) |
| E 30 | 15,000 (6,804 kg) | 30,000 (13,608 kg) | 19,500 (8,845 kg) | 3,000 (4,470 kg) |
| E 35 | 17,500 (7,938 kg) | 35,000 (15,876 kg) | 22,750 (10,319 kg) | 3,500 (5,215 kg) |
| E 40 | 20,000 (9,072 kg) | 40,000 (18,144 kg) | 26,000 (11,793 kg) | 4,000 (5,960 kg) |
| E 50 | 25,000 (11,340 kg) | 50,000 (22,680 kg) | 32,500 (14,742 kg) | 5,000 (7,450 kg) |

**A**, cargas de Cooper.
**B**, clase E, 50 de Cooper, á menos que se especifique de otra manera.

* *N. del T.* — Véase Tablas, págs. 273, etc. Un pie (medida de tablas) = á un pie cuad por una pulg de espesor. Mil pies = 2.360 m cúb. Entran 424 pies más ó menos (medida de tablas) en un metro cúbico.

** *N. del T.* — Llaman los americanos « *Consolidation* », las locomotoras que tienen cuatro pares de ruedas acopladas, como se ve en *dddd*, fig. 1. Este nombre proviene del que le dió la Compañía del ferrocarril Lehigh Valley á la primera de aquella clase fabricada en 1866. (*The Century Dictionary.*)

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

**C**, véase arriba.

**Y**, clase de Cooper E, 40.

**D**, **E**, **P**, **R**, las separaciones difieren poco de las de Cooper. Las cargas como aparecen abajo *.

| | *b* | *d* | *t* | U |
|---|---|---|---|---|
| **D** | 22,000 (9,979 kg) | 50,000 (22,680 kg) | 28,000 (12,700 kg) | 4,500 (6,705 kg) |
| **E** | 15,000 (6,804 kg) | 35,000 (15,876 kg) | 23,000 (10,433 kg) | 4,000 (5,960 kg) |
| **P** | 21,000 (9,526 kg) | 44,000 (19,958 kg) | 30,000 (13,608 kg) | 5,000 (7,450 kg) |
| **R** | 19,200 (8,709 kg) | 43,200 (19,595 kg) * 48,000 (21,773 kg) | 24,600 (11,158 kg) * 27,000 (12,247 kg) | 4,800 (7,152 kg) |

*Cargas alternativas.*

Empléese la fig. 1 ó las alternativas, fig. 2 ó 3, la que dé mayores esfuerzos.

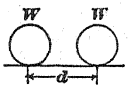

**Fig. 2.**

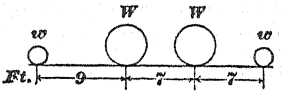

**Fig. 3.**

Carga sobre un par de ruedas.

Fig. 2. { *d*=6 pies (1.83 m); W=W=50,000 lbs (22,680 kg), sobre E 40, 60,000 lbs, 27,228 kg) **C**. *d*=7 pies (2.13 m); W=W=65,000 lbs (29,497 kg), **D**. *d*=7 pies (2.13 m); W=W=60,000 lbs (27,228 kg); U=4.500 lbs por pie lin (6,705 kg por m), **Y**.

Fig. 3. W=W=60.000 libras (29,951 kg); *w*=*w*=30,000 lbs (13,614 kg), **R**.

Agréguese 30 por ciento al calcular las vigas del piso, las riostras, soporte colgante, tirantes, y demás conexiones del piso. Agréguese de 0 á 30 por ciento por luces desde 100 pies (30.5 m) hasta 25 pies (7.62 m), **D**.

*En las curvas.*

Distribución de la carga viva entre las dos armaduras.

$W = P\,\frac{m+b}{2b}$; siendo W = la parte de la carga viva sobre a armadura de afuera; P=la carga viva en el tramo que se estudia; *m*=la ordenada media de toda la curva en la luz; *b*=la distancia entre los centros de las armaduras. Calcúlense ambas armaduras por igual, **B**, **Y**.

*Cargas especiales.*

Para los remaches que unen los ángulos superiores de las tablas con el alma de las vigas de tablero superior, que soportan el piso directamente sobre las tablas (ó alas) superiores, y en los tramos del tablero con las vigas de madera del piso, cuando la distancia entre las armaduras pasa de 6 pies (1.83 m), 50,000 lbs (22,690 kg) sobre un par de ruedas motrices, distribuídas por igual entre tres durmientes del piso, **P**.

Para pisos, la carga de un solo par de ruedas sencillas de locomotora distribuída entre 4 durmientes, **B**; entre 3 durmientes, **C**. Para piso de cajuelas, 60,000 libras (27,228 kg) en un par de ruedas distribuídas entre dos cajuelas, **Y**.

*Puentes de tres armaduras.*

En tramos de tablero superior de doble vía, las tres armaduras de la misma fuerza, **C**.

* Los ejes de la motriz y del tender con cargas desiguales, **R**.

**A, Aa**, Am B Co; **B**, B y O; **C, Cc**, Cooper; **D**, D L y W; **E**, Erie;

En puentes de vigas laminadas de más de una vía, la viga del centro se calcula en .75 × el peso de la carga viva, **E**.

*Aumento futuro de carga viva.*

Sólo el 70 por ciento (50 por ciento, **R**) de la carga muerta se debe considerar como efectiva al neutralizar la fuerza de la carga viva, **A, R**. Usese 1.5 × el peso de la carga viva, **E**.

---

« No es improbable que la más pesada de estas locomotoras (véase arriba « **C** » en Cargas normales) esté muy próxima al máximo posible, considerando los límites permitidos para las secciones transversales en los ferrocarriles existentes y los detalles mecánicos de dibujo y proporciones. Es de esperarse que la tendencia económica hacia el constante aumento de peso de las locomotoras alcanzará pronto la clase más pesada, E 50, en los principales ferrocarriles. Los vagones también seguirán la misma tendencia para muchas clases de tráficos, pues la experiencia justifica este desarrollo. Existen hoy en uso vagones para carbón de descarga automática de capacidad nominal de 100,000 libras (45,380 kg), que tienen, en cuatro ejes, una carga total de 146,000 libras (66,138 kg) (10 por ciento de aumento sobre su capacidad nominal) en una base de rueda, para dos carros adyacentes, de 17 pies 2 pulgadas (5.23 m). Estos vagones en todos los puentes corrientes producen esfuerzos equivalentes á los de E 33. » — Theodore Cooper.

Las piezas sujetas al cambio de signo del esfuerzo deben disponerse de manera que una carga viva, *n* por ciento mayor que la especificada, no aumente sus unidades de esfuerzo en más de *n* por ciento, *n* = 25, **C**; 50, **B**; 100, **P**.

## Cargas vivas para puentes en calzadas y ferrocarriles eléctricos.

(*N. del T.* — Hemos puesto entre paréntesis los equivalentes en sistema métrico.)

| **Aa**, (Am. Bridge Co.) y **Cc**, (Theo. Cooper.) Clase ★. | Para pisos y sus apoyos. Concentrada. Vagones (a). tons. | Concentrada. Carros (b). en cada vía. tons. | Uniforme (c). Por pie cuad lbs | Para armaduras. Por pie lineal de vía simple. (Proporcional para luces intermedias.) Luz hasta 100 p (30.5 m) lbs. | Luz 200 p (61 m) y más lbs. | Por pie cuad del resto de piso. (Proporcional para luces intermedias.) Luz hasta 100 p (30.5 m) lbs. | Luz 200 p (61 m) y más lbs. |
|---|---|---|---|---|---|---|---|
| A..... | 24 | .. | 100 (488 kg por m cuad) | 1,800 (817 kg) | 1,200 (545 kg) | 100 (45.38 kg) | 80 (36.30 kg) |

| E2..... | .. | 18 | ... | 1,200 (545 kg) | 1,000 (454 kg) | ... | ... |

(a) En dos ejes 10 pies (3.05 m) entre centros (y **Aa**, 5 pies (1.52 m) entre carriles); en las clases **A, B** y **C**, que se suponen ocupan un ancho de 12 pies (3.66 m) en una línea (ó **Cc**, 22 pies (6.71 m) en línea doble) en cualquier parte de la vía.

(b) Sobre dos ejes 10 pies (3.05 m) entre centros.

---

★ Clase A, puentes urbanos.
» B, puentes foráneos.
» C, calzadas foráneas de gran tráfico.
Clase D, calzada foránea corriente.
» E1, ferrocarril eléctrico de gran tráfico (sólo).
» E2, ferrocarril eléctrico de poco tráfico (sólo).

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

(c) En las clases A, B y C, en el resto del piso, incluso las aceras. En la clase D, en toda la superficie del piso.

**Oo** (Osborn Engineering Co). Calzada. Se puede especificar cualquier combinación de las siguientes cargas, según la condición del puente y de la carga.

Cargas uniformes, kg por metros cuadrados. Para luces hasta de 150 pies (45.75 m), 488 en la calzada y 390 en las aceras, ú 390 en ambas. Para luces de 150 pies (45.75 m) pies, 390 ó 290 en ambas.

Un aplanador de rodillos movido por vapor; ejes á 11 pies (3.36 m) de separación, rodillo delantero de 4 pies (1.22 m) de frente, dos rodillos posteriores de 5 pies (1.52 m) entre centros y cada uno de 20 pulgadas (50.8 cm) de frente, 15,000 (6,795 kg) ó 9,000 lbs (4,086 kg) en el rodillo delantero y 10,000 ó 6,000 libras (4,538 ó 2,723 kg) en cada uno de los rodillos posteriores.

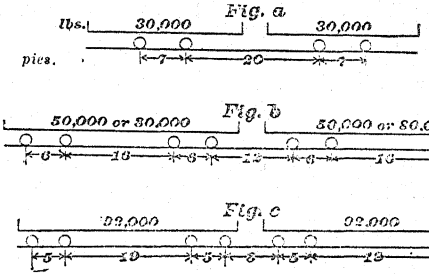
Un aplanador de rodillo tirado por caballo, 12,000 lbs (5,448 kg) en el rodillo, 5 pies (1.52 m) de frente.

Una carga de vagón, 10,000 libras (4,538 kg) en dos ejes, á 8 pies (2.44 m) de separación, 5 pies (1.52 m) entre carriles.

Dos vagones eléctricos en cada vía; fig. *a*.

Un tren de vagones (eléctrico) en cada vía; fig. *b*.

Un tren de vagones de carbón de 60,000 libras (27,228 kg) de capacidad; fig. *c*



(*N. del T.* — Las lbs se convierten en kgs multiplicándolas por 0.453 y los pies en metros por 0.305.)

*Aumento futuro de carga viva. Calzadas.*

En puentes para ferrocarriles eléctricos de la clase E, tan sólo se considerará como efectivo el 70 por ciento del esfuerzo de carga muerta al equilibrar el de la carga viva, **Aa**. En puentes por donde pasan tranvías eléctricos ó carros automotores, se emplean contradiagonales proporcionadas de manera que un aumento futuro de 25 por ciento de carga viva especificada no aumente la unidad del esfuerzo en más de 25 por ciento, **Cc**.

### Choques.

$I = S \frac{91.5}{l + 91.5}$; en que I=á la fuerza del choque que se debe agregar al esfuerzo de la carga viva; S=al máximo esfuerzo, calculado, de la carga viva; $l$=la longitud en m de la distancia cargada que produzca el mayor esfuerzo en la pieza, **A**.

En puentes para calzadas; I=25 por ciento de los esfuerzos de la carga viva, **Aa**.

### 2. Fuerzas horizontales.

(De arrastre Centrífuga y del viento.)

#### (a) Longitudinal.

**Arrastre.** En puentes para ferrocarriles de vapor y eléctricos, téngase en cuenta una fuerza longitudinal en los rieles= .2 del máximo de la carga viva. En vías dobles (**Y**) calcúlese para trenes en marcha en ambas direcciones.

**A, Aa,** Am B Co; **B,** B y O; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

## (b) Transversales.

### (1) Fuerza centrífuga.

**F**=fuerza centrífuga; W=peso del tren sobre el puente; $d$=grado de curvatura=ángulo central subtendido por una cuerda de 100 pies (30.5 m); $v$=velocidad en millas por hora (1 milla = 1609 m); $c$=un coeficiente.

**A,** F=$c$, $d$, W. Para $d$ hasta 5°, $c$=.03. Dedúzcase de $c$ .001 por cada grado sobre los 5°. Tren en cada vía.

**B, R,** F=.02 de la carga viva para cada grado de curvatura. **B,** hasta 5°. Dedúzcase .001 para cada grado sobre los 5°.

**D,** $v$=60 = 96.54 kilómetros.

**E,** F=fuerza debida á la carga uniforme que produciría el momento flexor de máximo de la carga viva, especificada, sobre la luz; $v$=60 = 96.54 kilómetros.

### (2) Viento.

*(a) En puentes de ferrocarril.*

La presión del viento, en libras por pie cuadrado ***, = $w$; en libras por pie lineal = W.

$w$=30 libras por pie cuadrado (146.4 kg por m cuad) en las superficies expuestas de las armaduras y del piso y en la de un tren de un promedio de 10 pies (3.05 m) de altura, comenzando á 30 pulgadas (76 cm) sobre la base del riel; ó de 50 libras por pie cuadrado (244 kg por m cuad) en las superficies expuestas de las armaduras y del piso; cualquiera de las dos da el mayor esfuerzo, **A, P.**

En luces de armaduras de 200 pies (61 m) y en vigas laminadas, $w$=30 libras por pie cuadrado (146.4 kg por m cuad) de superficie expuesta de 1 viga y del piso, + W sobre el tren para el cordón inferior, como sigue, **B.**

W=L+U. L=presión en libras por pie lineal en el cordón cargado, U en el cordón sin carga. W comprende ambos vientos sobre el puente y sobre el tren ***.

Viento sobre el puente. L=U=150 (223.5 kg por metro lineal), **B, C** *, **D, R**; =200 (=298 kg por m lineal), **E.**

L=200 (298 kg por m lin), en doble vía 300 (447 kg por m lin) obrando á 8 pies (2.44 m) sobre el tope del riel;
U=150 (223.5 kg por m lin), en doble vía 225 (335.26 kg por m lin), obrando en el centro del cordón; } **Y.**

Viento sobre el tren. L=300 (447 kg por m lin), **B, D, R** **, **C,** §=400 (596 kg por m lin), **E.**

**A.** El esfuerzo del viento, S$w$ en cualquier pieza de la armadura, **C** (pieza de la armadura principal, **D**; cordón ó poste extremo, **R**), debe considerarse tan sólo (1) cuando S$w$ excede de 30 por ciento, **C** (25 por ciento, **D, R**), del esfuerzo máximo, S, producido por las cargas viva y muerta. Luego auméntese la sección para llevar á S$w$ á sus límites, **C, D, R.** (2) Cuando S$w$, sola ó combinada con la acción de la temperatura, puede equilibrar ó neutralizar á **S, C.**

Anclaje. Al determinar el anclaje necesario para la estructura cargada, se calcula que el tren pesa 800 libras por pie lineal (1,192 kg por m), **A, B, C, P**; 600 libras por pie lineal (894 kg por m), **R.**

*(b) En puentes para calzadas y para ferrocarriles eléctricos.*

30 libras por pie cuadrado (146.4 kg por m cuad) en las superficies expuestas de todas las armaduras y el piso, + 150 libras (223.5 kg por m) por pie lineal, (180 = 268.2 kg por m, **Oo**) de un tren que abarque toda la luz; ó 50 libras por pie cua-

---

* En luces de más de 300 pies (91.5 m agréguese á U 10 libras (4.53 kg) por cada 30 pies (9.15 m) adicionales, **C.**

** Obrando á 75 pies (22.87 m) sobre el riel, **R.**

§ Obrando á 6 pies (1.83) sobre la base del riel. Incluye las vibraciones laterales de los trenes.

*** Las conclusiones son equivalentes, ya se usen las unidades inglesas (lbs por pie lineal, lbs por pie cuad) ó las métricas (kgs por metro lineal, kg por m cuad).

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

drado (244 kg por m cuad) en la superficie expuesta de todas las armaduras y del piso; cualquiera de las dos dará el esfuerzo máximo, **Aa**, **Oo**.

En cada cordón 150 libras por pie lineal (223 kg por m) de luz, para el puente, y en el cordón cargado 150 libras por pie lineal (223 kg por m) de luz adicional, para el tren. Para luces mayores de 300 pies (91.5 m), agréguese 10 libras (4.54 kg) en cada cordón por cada 30 pies (9.1 m) adicionales, **Cc**.

Se provee contra el esfuerzo del viento (en las piezas de las armaduras, **Cc**; en los cordones y postes extremos, **Oo**) tan sólo cuando el esfuerzo del viento exceda del 25 por ciento del esfuerzo máximo de las cargas muerta y viva (de la suma de todos los demás esfuerzos, **Oo**), ó cuando el esfuerzo del viento (solo ó en combinación con la acción de la temperatura, **Cc**) puede (neutralizar ó, **Cc**) invertir el esfuerzo sobre las piezas, **Cc**, **Oo**.

## IV. ESFUERZOS Y DIMENSIONES

### Luz y alturas verdaderas.

En las armaduras de pasadores la luz y la altura se miden entre los centros de los pasadores. En armaduras de remaches, se mide la luz entre los centros de los apoyos extremos, y su altura entre los centros de gravedad de las secciones del cordón. En las vigas laminadas se mide la luz entre los centros de los apoyos extremos, y la altura entre los centros de gravedad de las áreas de las tablas (de las vigas) ó detrás de los ángulos de las mismas, la que resulte menor. En las vigas del piso se mide la luz entre los centros de las armaduras, y en las longitudinales entre los centros de las vigas del piso, **G**.

### Limitación de la unidad de esfuerzos.

### Tensión.

**Sección neta.** La sección neta de cualquier pieza de tensión se determina por un plano que corte la pieza en ángulo recto en cualquier punto. El mayor número de perforaciones para remaches que pueda cortar el plano, ó que se encuentren á una pulgada (2.54 cm) del plano, se restan del total de la sección, **B**. La ruptura de una pieza de tensión remachada se considera tan sólo como igualmente probable, ya sea á través de una hilera transversal de perforaciones de remaches, ó á través de una línea diagonal de perforaciones donde la sección neta no excede en un 30 por ciento de la sección neta á lo largo de la línea transversal, **C**, **Cc**.

Al restar los agujeros de los remaches de la sección neta, se calculan sus diámetros en un octavo de pulgada (3 mm) más que el del remache frío, **G**; para remaches de cabeza embutida (**Oo**), un cuarto de pulgada más (6 mm).

**Máximas tensiones permitidas**, en libras por pulgada cuadrada.

(*N. del T.* — Los números que están entre paréntesis son los kg por cm cuad equivalentes á las libras por pulg cuad del número superior.)

| | Acero mediano. | Acero blando. |
|---|---|---|
| **A, Aa.** Bajo fuerzas verticales ú horizontales solamente.... | 17,000 (1,190) | 15,000 (1,050) |
| Bajo fuerzas verticales y horizontales combinadas.. | 21,000 (1,470) | 19,000 (1,330 |

**B.** Para acero blando (de puentes) y para remaches, como para el acero mediano rige **A**.

| **D.** Para acero blando : | Para carga muerta. | Para carga viva. |
|---|---|---|
| Barras de ojo..... | 14,000 (980) | 9,000 (630) |
| Secciones armadas..... | 12,500 (875) | 8,500 (595) |
| Contradiagonales..... | | 8,500 (595) |

**A, Aa**, Am B Co; **B**, B y O; **C, Ce**, Cooper; **D**, D L y W; **E**, Erie;

| | Para cargas viva y muerta. |
|---|---|
| Montantes, barras que suspenden las vigas del piso, piezas sometidas á cargas bruscas | 7,500 (525) |
| Tablas de tensión de las vigas laminadas y vigas laminadas | 9,000 (630) |
| Riostras y refuerzos | 12,000 (840) |

En las piezas principales de las armaduras, tablas y entramado de las vigas y las vigas del piso para vías dobles, tablas del piso y vigas con suelo para balasto, agréguese 10 por ciento.

Para acero mediano, agréguese 10 por ciento.

**Oo.** (Puentes para calzadas.) Acero mediano, 22,000 (1,540 kg por cm cuad); acero blando, 20,000 (1,400 kg por cm cuad); hierro forjado, 18,000 (1,260 kg por cm cuad).

**P.** M=esfuerzo máximo (calculado) en la pieza;
$m$=esfuerzo mínimo (calculado) en la pieza.

Hágase $r = \frac{m}{M}$; y $k = \frac{1-r}{1+r}$. Entonces M $(1 + k)$ no debe exceder de 15,000 (1,050 kg por cm cuad).

Los montantes verticales largos deben tener 25 por ciento de exceso de resistencia; las barras cortas que sostienen las vigas del piso, 50 por ciento de exceso, **P.**

**Y.** Acero blando. Los cordones y piezas del entramado de las armaduras y las tablas de las vigas laminadas y vigas de piso.

| | |
|---|---|
| Carga muerta y tracción | 16,000 (7,261 kg) |
| Carga viva y fuerza centrífuga | 8,000 (3,630 kg) |

*Resistencia máxima de las maderas, en libras por pulgada cuadrada.*

(*N. del T.* — Los números que están entre paréntesis, son los kg por cm cuad equivalentes á las lbs por pulg cuad del número superior.)

| Para puentes de calzada, **Oo.** | Carga transversal. | Apoyo extremo. | Columna corta *. | Carga á través de la fibra. | Esfuerzo cortante á lo largo de la fibra. |
|---|---|---|---|---|---|
| Roble blanco | 1,400 (98) | 1,300 (91) | 1,000 (70) | 550 (38.5) | 300 (21) |
| Pino de hoja larga | 1,600 (112) | 1,300 (91) | 1,000 (70) | 350 (24.5) | 200 (14) |
| Pino blanco | 1,100 (77) | 900 (63) | 700 (49) | 200 (14) | 150 (10.5) |
| Abeto | 950 (66.5) | 850 (59.5) | 650 (45.5) | 200 (14) | 100 (7) |

Resistencia máxima de la fibra, en vigas de piso, en pino amarillo y roble blanco, 1,200 libras por pulg cuad (84 kg por cm cuad); y pino blanco y abeto, 1,000 (70 kg por cm cuad), **Aa, Cc.**

* Longitud no mayor de 12 × lado menor.

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas

## Compresión **.

$p$ = el esfuerzo de trabajo permitido en las piezas de compresión, en kgs por cm cuadrado.
$f$ = esfuerzo generalmente permitido en las piezas de tensión, en kgs por cm cuadrado.
$a$ = un coeficiente.
L = longitud de la pieza, en cm, entre centros de conexiones.
$r$ = menor radio de giración de la sección transversal de la pieza, en cm.

$$p = \frac{f}{1 + \frac{L^2}{r^2 a}}$$

(*N. del T.* — Los números que van entre paréntesis son los kg por cm cuad equivalentes á las libras por pulg cuadrada del número superior ó anterior.)

| | | $f$ | $a$ |
|---|---|---|---|
| **Aa.** | En acero mediano | 17,000 (1,190) | 11,000 |
| | En acero blando | 15,000 (1,050) | 13,500 |
| **B.** | En acero blando | 17,000 (1,190) | 11,000 |

**C.** Véase más abajo.

| | Carga muerta. | | Carga viva. | |
|---|---|---|---|---|
| | $f$ | $a$ | $f$ | $a$ |
| **D.** | 12,000 (840) | 18,000 | 8,000 (560) | 18,000 |
| | á | á | á | á |
| | 12,500 (875) | 24,000 | 8,500 (595) | 24,000 |

**E.** $f = 560\left(1 + \frac{\text{resistencia mínima}}{\text{resistencia máxima}}\right)$; $a = 36{,}000$ con ambos extremos fijos $a = 24{,}000$ con un extremo fijo; $a = 18{,}000$ con ambos extremos articulados.

**Oo.** (Puentes para calzadas.) $f = 22{,}000$ (1,540) para acero mediano, 20,000 (1,400) para acero blando, 18,000 (1,260) para hierro forjado; $a$ como en **E**, arriba.

**P.** $f = 15{,}000$ (1,050); $a = 13{,}500$.

**R.** $f = 455\left(1 + \frac{\text{resistencia mínima}^*}{\text{resistencia máxima}}\right)$; $f$ máx = 8,000 (560); $a = 40{,}000$ con extremo chatos; $a = 20{,}000$ con extremos articulados.

Cuando un extremo está articulado, $p$ = promedio de valores deducidos arriba.

Para puntales angulares de hierro, véase más abajo.

**Y.** Acero blando en cordones y en piezas del entramado:

| | $f$ | $a$ |
|---|---|---|
| Para carga muerta y tracción | 16,000 (1,120) | 18,000 |
| Para carga viva y fuerza centrífuga | 8,000 (560) | 18,000 |

* Resistencia mínima = carga muerta — carga viva.

** *N. del T.* — Hemos modificado las fórmulas y coeficientes para hacerlas aplicables al sistema métrico.

**A, Aa,** Am B Co; **B,** B y O; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

**C, Cc.** $p = M - c\frac{L}{r}$.

Para acero mediano en estructuras fijas.

| | Carga muerta. M | Carga muerta. c | Carga viva. M | Carga viva. c |
|---|---|---|---|---|
| Segmentos de cordón y piezas de refuerzo | 20,000 (1,400) | 6.33 | 10,000 (700) | 3.16 |
| Para puentes de calzada | 24,000 (1,680) | 7.73 | 12,000 | 3.87 |
| Postes finales y otros | 17,000 (1,190) á 18,000 (1,260) | 6.33 á 5.62 | 8,500 (595) á 9,000 (630) | 3.16 á 2.81 |
| Para puentes de calzada | 20,000 (1,400) á 22,000 (1,540) | 6.33 á 5.62 | 10,000 (700) á 11,000 (770) | 3.16 á 2.81 |
| Para puntales laterales, refuerzos rígidos para puentes de ferrocarril y de calzada | 13,000 (910) | 4.2 | 8,666 (607) | 2.81 |

Para acero blando dedúzcase 15 por ciento; para estructuras movibles dedúzcase 25 por ciento.

**R.** Puntales angulares de hierro.

Con extremos chatos, $p = 630 - 2.1\frac{L}{r}$; con extremos de pasador, $p = 630 - 2.4\frac{L}{r}$.

La puntales laterales y transversales agréguese 30 por ciento.

**Longitud** de las piezas de compresión, máxima = 40 á 45 diámetros, ó 100 *r* á 120 *r*. En puentes para calzadas, 120 *r* á 140 *r*, **Aa**; 100 *r* á 120 *r*, **Cc**; 125 *r* á 150 *r*, **Oo**, en que *r* = al menor radio de giro.

**Anchura sin apoyo** (distancia entre remaches) de las planchas sometidas á compresión, máx = 45 × espesor, **Oo**; 30 × espesor, **C, Cc, D**; en planchas de tapa de los cordones y postes extremos, 40 × espesor, **C, Cc, D**; ó si se emplea mayor anchura, se tomará la sección real como 40 × espesor, **C, Cc**. Distancia entre apoyos en la línea de resistencia, máximo = 16 × espesor, **Oo**.

Columnas de madera cuyo largo no exceda de 12 × sus lados menores, para puentes de calzada, **Oo**.

$$\text{Unidad de esfuerzo máximo} = \frac{C}{1 + \frac{L^2}{1{,}000\,d^2}}$$

en que C = 70 kg por cm cuad para roble blanco y pino de hoja larga, 49 para pino blanco, 45 para pinabete; L = largo de la columna, entre apoyos, en cm; *d* = lado menor, en cm, **Oo**.

### Esfuerzos alternativos.

El área total de la sección de la pieza se hará = la suma de las áreas necesarias para ambas resistencias, **A, B**.

Area suficiente para resistir cualquiera de los esfuerzos, .8 (.6, **R**; 1.0, **Y**) × la menor resistencia, **C, Cc, D, R, Y**.

Trabajo permitido, en kg por cm cuad:

$$a = 560\left(1 - \frac{\text{resistencia máxima de la menor clase}}{2 \times \text{resistencia máxima de la mayor clase}}\right)\ \textbf{E}.$$

M = resistencia máxima (calculada) de la clase mayor.

*m* = resistencia máxima (calculada) de la clase menor.

Sea $r = \frac{m}{M}$, $k = \frac{2 + r}{2 - r}$. Entonces M (1 + *k*) no debe exceder de 1,050 kgs por cm cuad. **P.**

**G**, general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

*Puentes para calzadas y ferrocarriles eléctricos.*

En las clases A, B, C y D, las piezas proporcionadas para aquel esfuerzo que requiera la sección mayor. En las clases E1 y E2, hágase el área de la sección = á la suma de las áreas requeridas para las dos resistencias, **Aa**. Las piezas se hacen para resistir cualquiera de los dos esfuerzos y se les dan 25 por ciento de exceso de resistencia en sus uniones y conexiones, **Oo**.

### Esfuerzo cortante y fuerza de apoyo *.

**Esfuerzo cortante** en las almas, su máximo por pulgada cuadrada. 10,000 (700), **B**; 4,000 (280), **E**; 5,000 (350), **R**; 13,000 (910), **P**; en acero mediano, 10,000 (700), **A**, **Aa**; en acero blando, 9,000 (630), **A**, **Aa**; á través de la fibra, 6,000 (420), **D**; en la dirección de la fibra, 5,000 (350) (sección neta), **D**; carga muerta, 10,000 (700), **Y**; carga viva, 5,000 (350) (sección bruta), **Y**.

**Esfuerzo cortante y fuerza de apoyo sobre los remaches, pernos y pasadores.** Máximo en libras por pulg cuadrada.

| | Esfuerzo cortante. | | Resistencia (apoyo). | |
|---|---|---|---|---|
| | Acero mediano. | Acero blando. | Acero mediano. | Acero blando. |
| **A, Aa, B**..... | 12,000 (840) | 11,000 (770) | 24,000 (1,680) | 22,000 (1,540) |
| **C**..... | 9,000 (630) | 9,000 (630) | 15,000 (1,050) | 15,000 (1,050) |
| **Cc**..... | 10,000 (700) | 10,000 (700) | 18,000 (1,260) | 18,000 (1,260) |
| **Oo**..... | 10,000 (700) | 10,000 (700) | 22,000 (1,540) | 20,000 (1,400) |
| **D, R**..... | 7,500 (525) | 7,500 (525) | 12,000 (840) | 12,000 (840) |

**Y**, Esfuerzo cortante = .75 S; fuerza apoyo = 1.50 S.S = unidad de tensión permitida.

Al remachar (es la práctica), aumentar en 25 por ciento el número de los remaches, **A, Aa, B, Oo, P**; si son puestos á máquina 10 por ciento, **A, Aa, P**; en las vigas longitudinales y del piso, un tercio, **P**. Tómese .66 á .80 × esfuerzo como se dijo antes, **C, Cc, D, R, Y**.

En las conexiones del piso empléese .8 × los esfuerzos, como se dijo arriba, **C, Cc**; agréguese 20 por ciento al número de los remaches, **Y**.

En las riostras y contravientos empléese 1.25 á 1.5 × los esfuerzos, como se dijo antes, **C, Cr, D, R**.

Los remaches con cabezas embutidas se calculan en .75 × la resistencia de los de cabeza exterior, **P**.

**Apoyo**; en discos de bronce fosfórico, 5,000 libras por pulg cuad (350 kg por cm cuad), **B**.

### Resistencia á la flexión *.

Resistencia de las fibras extremas bajo los momentos flexores, máximo en libras por pulg cuad.

En pasadores y pernos, 25,000 (1,750), **B**; 18,000 (1,260), **C**; 20,000 (1,400), **Cc**; 15,000 (1,050), **D, R**; 16,000 (1,120), **Y**; en pasadores muy unidos, 25,000 (1,750), **Oo**; de acero mediano, 25,000 (1,750); de acero flojo, 22,000 (1,540), **A, Aa, P**. Los centros de apoyo de las piezas sometidas al esfuerzo se toman como puntos de aplicación de los esfuerzos, **A, Aa, R**. Las fuerzas aplicadas se consideran como uniformemente distribuídas sobre la línea media del apoyo de cada pieza, **C, Cc**. La flexión se calcula por las distancias entre los centros de apoyo, **Oo**.

En vigas laminadas ó vigas en U. 14.000. (980) **P**.

En vigas de madera para el piso, 1,000, (70) **A, B, C, P**.

---

* *N. del T.* — Los números que van entre paréntesis, son los kg por cm. cuad equivalentes á las lbs por pulg cuad del número superior ó anterior.

**A, Aa,** Am B Co; **B,** B y C; **C, Cc,** Cooper; **D,** D L y W; **E,** Erie;

### Esfuerzos combinados **.

**Combinados** (axil y de flexión), máximo en libras por pulgada cuadrada.

En los postes de extremo en luces de vía inferior, carga muerta+carga viva+presión del viento+flexión máxima=15,000 (1,050), **R.**

Proporciónense las piezas para resistir la suma del esfuerzo directo más .75 de la flexión, **A, Aa, B, P, R.** Máximo $= \frac{560}{1 + \frac{L^2}{40{,}000\, r^2}}$, en que L = longitud en cm; $r$ = radio menor de giro en cm.

Si los pasadores están fuera del eje neutro de la sección, el máximo debe contener el esfuerzo adicional debido á la excentricidad, **R.**

El momento de flexión en los puntos de división de los tramos se supone igual y opuesto al del centro, **A, Aa.** Si el esfuerzo de la fibra producido por el peso de la pieza sola excede de 10 por ciento de la unidad del esf permitido en dicha pieza, se debe considerar el exceso en proporción á las áreas, **C, Cc, R.**

### Dimensiones mínimas.

Espesor mínimo de las láminas para puentes de ferrocarril, $^3/_8$ de pulgada (9.5 mm) para las piezas principales, $^5/_{16}$ de pulg (8 mm) para las laterales; en puentes para calzadas y ferrocarriles eléctricos, $^5/_{16}$ á $^1/_4$ de pulg (8 á 6.5 mm). Diámetro mínimo de las barras, $^3/_4$ de pulgada (19 mm), **Oo.** Mínima sección de las barras, 1 pulgada cuadrada (6.45 cm cuad), **D, R;** contradiagonales, 1.5 pulgada cuadrada (9.7 cm cuad), **D, P.** Postes en luces de pasadores, ancho mínimo 10 pulgadas (254 mm), **A.** En postes de luces de vía inferior y vigas en U, mínimo 10 pulgadas (254 mm), **B.** Angulos, mín $3.5 \times 3 \times {}^5/_{16}$ (8.9×7.6×.8 cm), **B.**

## V. PROTECCIÓN

**En el taller.** Al quitar las conchas sueltas y el orín; una mano de aceite de linaza puro, hervido, **A, Aa, B, D, E, P, R;** aceite de linaza crudo, **C, Cc;** con 10 por ciento en peso de negrohumo, **D;** pintura roja de plomo *, **Y.**

**Partes inaccessibles.** 2 manos de pintura de mineral de hierro en aceite puro de linaza, **A, Aa, B, C, Cc, E, R;** pintura de plomo roja *, **Y;** una mano, **D;** una mano espesa de pintura de plomo roja en aceite de linaza crudo, **P;** dos manos, á 18 lbs de pintura roja de plomo en 1 galón (3.78 lit) de aceite de linaza cocido, **Oo.**

**Mano final.** Capa de plomo blanco y sebo, **G.**

**Superficies en contacto.** Píntense antes de unirse, **A, Aa, B, C, Cc, R, Y;** con dos manos gruesas de rojo de plomo en aceite de linaza crudo en cada superficie, **Y.**

**Después de armar la obra.** 2 manos adicionales de pintura en aceite puro de linaza, **A, Aa, B, C, Cc;** dos manos de pintura de diversos colores, **R;** 2 manos gruesas de barniz de asfalto, **Y.**

Por lo menos se debe dejar secar cada mano durante 48 horas, **Y.**

**Columnas, etc.,** para 5 pies (1.52 m) sobre la superficie del suelo en calles, etc., dos manos espesas de charol de asfalto; **en los lados inferiores de los puentes,** resto de las columnas, etc., 2 manos espesas de pintura blanca *; lado del balasto en los pisos de cajuelas, 1 parte, por peso, de asfalto de Trinidad refinado y 3 partes de alquitrán fino á 300° F (149° C), **Y.**

En dondequiera que exista una tendencia á depositarse el agua, se deben llenar los espacios con un material impermeable, **C, Cc.**

La primera mano de pintura debe ser de grafito, **Oc.**

---

* Pintura de rojo de plomo. 5 galones (19 lit) conteniendo 100 libras de rojo de plomo puro, 4 galones (15.12 lit) de aceite crudo de linaza puro, media pinta (1/4 lit más ó menos) de copal sin bencina, **Y.**

Pintura de blanco de plomo. 5 galones (19 lit) conteniendo 42 libras (19 kg) de blanco de plomo puro en aceite, 21 libras (9.5 kg) de blanco de cinc en aceite, 3 galones (11 1/3 lit) de aceite puro de linaza cruda, **Y.**

Por lo menos 48 horas entre las manos, y entre la última mano dada en el taller y la remoción de la pieza, **Y.**

** Véanse *N. del T.* al pie págs. 825 y 827.

**Gt** general; **Oo**, Osborn; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas.

En puentes para calzadas, la superficie superior de las láminas metálicas de piso deben cubrirse enteramente con asfalto, **Oo**.

## VI. ERECCIÓN

El contratista está generalmente obligado :

(1) A descargar los materiales después de su entrega, á suministrar andamios y aparatos, á remover el puente viejo, á modificar los apoyos existentes del puente;

(2) A hacer taladros para los pernos de anclaje y poner éstos, á erigir y ajustar la superstructura, y á veces á suministrar y colocar las vigas de madera del suelo;

(3) A quitar los andamios y aparatos;

(4) A mantener libre la vía para el tráfico y no interceptar otras vías de comunicación por tierra ó por agua, y á no obstaculizar á otros contratistas; á suministrar y pagar vigilantes; á mantener el material limpio y en buen estado; y á asumir todos los riesgos de perjuicios personales ó de propiedad por causa de tempestades, inundaciones y otros accidentes (*Obs. del T.* — Creemos que estos últimos, son casos de fuerza mayor);

(5) A suministrar las piezas para la protección de las puntas de los pasadores al entrar en las vigas.

---

## (2) RESUMEN DE ESPECIFICACIONES PARA PUENTES MIXTOS DE FERROCARRILES *

**(Por la Baltimore and Ohio Railroad Co., 1901.)**

## I. PROYECTO GENERAL

Tipo Howe.

Barras de acero, con extremos recalcados; tuercas normales y tuerca de cierre en cada extremo.

Fundiciones de hierro para uniones.

Láminas de acero para chavetas desde 1.25 pulgadas (32 mm) de espesor para barras de 1.25 pulgadas (32 mm) hasta 1.75 pulgadas (44 mm) de espesor para barras de 2.5 pulgadas (63 mm).

Las bridas (chapas de empalme) del cordón inferior son generalmente de acero.

## II. MATERIAL

Maderamen. Pino amarillo de Georgia, roble blanco ó pino blanco.

Acero laminado. Martín-Siemens. Resistencia máxima 60,000 lbs por pulg cuad (4,200 kg por cm cuad), variación permitida, 5,000 libras (350 kg); límite de elasticidad, 30,000 libras (2,100 kg); alargamiento 25 por ciento en 8 pulgadas (20.3 cm); flexión 180° sobre sí mismo.

## III. CARGAS

### Carga muerta.

Los maderos se calculan á razón de 4.5 libras (2 kg) por pie (en medida de tablas=2.36 litros). Enrielado 100 libras por pie lineal (149 kg por metro lineal).

### Carga viva.

Carga máxima calculada+25 por ciento para prever los aumentos y choques.

---

* Para usarlos temporalmente.

**A, Aa**, Am B Co; **B**, B y O; **C, Cc**, Cooper; **D**, D D y W; **E**, Erie;

## IV. ESFUERZOS Y DIMENSIONES

### Límite de las unidades de esfuerzos.

(Véase *N. del T.*, pág. 827)

| Maderos, libras por pulg cuad. | Pino amarillo. | Pino blanco. | Roble blanco. |
|---|---|---|---|
| Flexión ó tensión directa..... | 1,200 (84) | 800 (56) | 1,000 (70) |
| Columnas de menos de 17 diámetros de largo..... | 900 (63) | 600 (42) | 750 (52½) |
| Columnas de más de 17 diámetros de largo..... | 1,200-15 *n* (84—1.26 *n*) | 800-12 *n* (56—0.84 *n*) | 1,000-15 *n* (70—1.05 *n*) |
| en que *n*=longitud ÷ menor grosor: *n* máx=40. | | | |
| Esfuerzo cortante á lo largo de la fibra ..... | 150 (10½) | 100 (7) | 200 (14) |
| Resistencia en dirección de la fibra. | 1,500 (105) | 1,000 (70) | 1,250 (87½) |
| Resistencia perpendicular á la fibra. | 350 (24½) | 200 (14) | 500 (35) |

En columnas hechas con varias piezas juntas y sujetas á intervalos por pernos cada pieza se tratará como una columna independiente.

Barras de acero, unidad máxima de esfuerzo=12,000 libras por pulgada cuadrada (840 kg por cm cuad).

Vigas del piso destinadas á soportar la carga muerta y las más pesadas locomotoras en uso, sin margen para choques. Refuércense para prever aumento futuro de cargas.

Para cargas mayores que las calculadas, redúzcase la velocidad de 60 á 15 millas (96.50 á 24.13 k) por hora, á medida que las cargas aumenten hasta el límite de 25 por ciento de los aumentos de pesos.

## V. PROTECCIÓN

Barras de acero, etc., 1 mano de pintura en el taller; 2 después de concluído.
Las maderas deben pintarse en los puntos de contacto.
Los agujeros de los pernos y barras deben llenarse con pintura.

---

## (3) RESUMEN DE ESPECIFICACIONES PARA ARMADURAS DE TECHOS, ARMADURAS DE ACERO Y EDIFICIOS

### (Por el Baltimore and Ohio R. R. Co, 1901.)

## I. PROYECTO GENERAL

Se hace principalmente de piezas de forma. No deben emplearse piezas de ajuste, excepto en las trabazones laterales. Las riostras deben proporcionarse á la total presión del viento de 30 libras por pie cuadrado (146.4 kg por m cuad) de superficie expuesta, obrando en cualquier dirección. Las piezas de tensión en los cruceros deben siempre tirar directamente hacia un poste rígido. Si la construcción está encerrada y expuesta á la acción de gases, no se deben dejar espacios abiertos menores de 1 pulgada de ancho entre las piezas, para poderlos pintar bien.

## II. MATERIAL

Grosor mínimo, .25 pulgada ($6^1/_4$ mm). Cuando esté sujeta á la acción de gases, $^5/_{16}$ de pulgada (8 mm) si la construcción está al aire libre y .37 5pulg (9.3 mm) si está encerrada.

**G**, general; **Oo**, Osbora; **P**, Pa; **R**, R'd'g; **Y**, N Y C; **Aa**, **Cc**, **Oo**, Calzadas

## III. CARGAS

Nieve, 20 libras por pie cuadrado (97.6 kg por m cuad) de la proyección horizontal del techo. Viento, en cualquier dirección, 30 libras por pie cuadrado (146.4 kg por m cuad), horizontal. Total mínimo, 40 libras por pie cuadrado (195.2 kg por m cuad).

Cubiertas. Para techos y costados, á menos que se ordene otra cosa, hierro acanalado, n.º 22, de 26 pulgadas de ancho (66 cm); canales de 2.5 pulgadas (63 mm); 3 pulgadas (76 mm) de inclinación de 1 por 2; 6 pulgadas (152 mm) para inclinaciones menores. Clavados á no más de 4 pies (1.22 m) de distancia entre centros.

## IV. ESFUERZOS

Las columnas que sostienen el techo se consideran enterradas en la base, á menos que estén ancladas de manera absolutamente fijas.

La unidad de esfuerzo, si no está expuesta á ninguna otra carga movible que la del viento, véase **B**, en el Resumen de especificaciones para puentes de acero, y el Resumen (2) de especificaciones para puentes mixtos, de la B. and O. RR. Las resistencias dadas en el último se deben aumentar en un 25 por ciento.

## V. PROTECCIÓN

Tres manos de pintura. Sthay exposición á gases úsese pintura para puentes (véase **B** en las Especificaciones para puentes de acero); si no, úsense las pinturas corrientes para edificios.

# PUENTES COLGANTES

**Art. 1. Tabla de los datos que se requieren para calcular las cadenas ó cables principales de los puentes colgantes.** Original.

| Flexión * en partes del cordón. | Flexión en fracciones decimales del cordón. | Longitud de las cadenas principales entre las pilas de suspensión, en partes del cordón. | Tensión de todas las cadenas principales en una ú otra pila de suspensión, en partes del peso total del puente suspendido y de su carga. | Tensión en el centro de todas las cadenas principales, en partes del peso total del puente suspendido y de su carga. | Ángulo de la dirección de las cadenas en las pilas. | | Seno natural del ángulo de la dirección de las cadenas en las pilas. | Coseno natural del ángulo de la dirección de las cadenas en las pilas |
|---|---|---|---|---|---|---|---|---|

| 3-20 | .15 | 1.058 | .972 | .833 | 30 | 58 | .5145 | .8574 |
| 1/6 | .1667 | 1.070 | .901 | .750 | 33 | 41 | .5547 | .8320 |
| 1-5 | .2 | 1.098 | .800 | .625 | 38 | 40 | .6247 | .7808 |
| | .225 | 1.122 | .747 | .555 | 42 | 0 | .6690 | .7433 |
| 1/4 | .25 | 1.149 | .707 | .500 | 45 | 00 | .7071 | .7071 |
| 3/5 | .3 | 1.205 | .651 | .417 | 50 | 12 | .7682 | .6401 |
| 1/3 | .3333 | 1.247 | .625 | .375 | 53 | 8 | .8000 | .6000 |
| 2/5 | .4 | 1.332 | .589 | .312 | 58 | 2 | .8483 | .5294 |
| 9-20 | .45 | 1.403 | .572 | .278 | 60 | 57 | .8742 | .4855 |
| 1/2 | .5 | 1.480 | .559 | .250 | 63 | 26 | .8944 | .4472 |

Estos cálculos están basados en la suposición de que la curva formada por las cadenas principales sea una parábola, lo cual no es estrictamente exacto. En un puente concluído, la curva está entre una parábola y una catenaria, y no es susceptible de una determinación rigurosa. **Puede evitarse algún trabajo al hacer los planos** de un puente colgante, acordándose que cuando la flexión no excede de $^1/_{10}$ de la luz más ó menos, puede usarse un segmento de un círculo en lugar de la curva verdadera, ya que las dos coinciden muy aproximadamente, y más todavía si la flexión es menor de $^1/_{10}$.

Las dimensiones tomadas en un segmento sirven para apreciar las cantidades del material necesario.

**La flexión* adoptada generalmente por los ingenieros** para grandes luces es de $^1/_{12}$ á $^1/_{15}$ de la luz. En luces pequeñas solamente se usa por lo general $^1/_{10}$. El puente será más fuerte, ó requiere menos área de cable, si la flexión es mayor; pero entonces son mayores sus undulaciones, y como éstas tienen tendencia á destruir el puente aflojando las juntas ó uniones y aumentando

* Relación de la flecha á la cuerda.

el « momento », debe tenerse especial cuidado de evitarlas cuanto sea posible. El modo más usado para conseguir esto es armando, entramando, las barandas ó parapetos del puente que para este fin pueden hacerse más altas, y de maderas más fuertes de lo que hubiese sido necesario. En luces grandes, puede sustituirse por vigas armadas ordinarias de puente, suficientemente altas para que puedan unirse con riostras por sus partes superiores, como en el puente del ferrocarril del Niágara, en el cual las vigas armadas tienen 5.49 m de alto y sostienen un ferrocarril de una sola vía en su parte superior, y una calzada ordinaria de 5.80 m de ancho en la parte inferior *.

Otro auxiliar muy importante se encuentra en los maderos longitudinales de piso de mucho espesor, unidos firmemente en sus extremidades. Ellos ayudan á distribuir el peso de las fuertes cargas que atraviesan el puente, entre varias barras de suspensión, y así sobre una extensión considerable de los cables principales, impidiendo la undulación que tendría lugar si la carga fuese concentrada solamente sobre dos barras de suspensión opuestas. En vista de esto, las vigas longitudinales de madera, debajo de los rieles del puente sobre el Niágara, son de 1.22 m de espesor. El mismo principio se aplica evidentemente también á los puentes de vigas armadas.

Otro modo de aliviar los cables principales es por medio de barras de hierro, ó cables metálicos, extendidos como *cy*, fig. 1, de los asientos en los puntos de suspensión *c*, *d*, oblicuamente al piso ó á alguna parte de la viga armada. En el puente del Niágara hay 64 de estos cables de 35 mm de diámetro; los más largos alcanzan á más de la cuarta parte de la abertura. Ellos transmiten gran parte de los esfuerzos debidos al peso del puente y de su carga directamente á las partes superiores de las torres, aliviando de este modo á los cables principales y disminuyendo la undulación. Las extremidades de ellos, *c* y *d*, no están sujetas á los cables, sino á las torres mismas.

**El mayor peligro proviene de la acción de vientos fuertes contra la parte inferior del piso,** sea suspendiendo la plataforma entera y dejándola caer repentinamente, ó sea comunicándole violentas undulaciones semejantes al movimiento de las olas. El puente en Wheeling, Ohio, de 308 m de abertura, construído por C. Ellet, Jr., fué destruído de este modo. Se dice que antes de caer hizo undulaciones verticales hasta de 6.10 m. No se tomaron precauciones contra las undulaciones, pues aunque tenía barandas ó parapetos armados, eran demasiado bajos y livianos para que sirvieran de mucho en una luz tan grande. Muchos otros puentes han sido destruídos ó deteriorados de igual manera. Si la altura de la calzada sobre el agua lo permite, puede adoptarse como medio de precaución, la colocación de tirantes ó vientos, que fijos en diferentes puntos, de la parte inferior de piso á lo largo de la abertura, vayan inclinados, á terminar en los estribos, donde pueden fijarse fuertemente. En el puente del ferrocarril del Niágara existen 56 de estos tirantes, hechos de cuerdas metálicas de 31 mm de diámetro, que se extienden diagonalmente desde el fondo del puente hasta las rocas que están debajo. Pero afean mucho el aspecto de una construcción.

El Sr. Brunel empleó también en algunos casos, para contrarrestar las undulaciones producidas por los fuertes vientos que chocan por debajo de la plataforma, *cables invertidos* con la convexidad *hacia arriba*, colocados por debajo del piso, con sus extremidades fijas fuertemente en los estribos á algunos metros más abajo de la plataforma, y conectados á ésta, tirando de ella hacia abajo.

**Art. 2.** El **ángulo** *adg* ó *aci*, fig. 1, que una tangente *dg* ó *ci* á la curva en ambos puntos de suspensión *c* ó *d*, forma con la línea *horizontal cd*, se llama **ángulo de suspensión del cable** ** en estos puntos; las extremidades *ch* y *dr* de los cables, llamadas **fiadores**, se colocan frecuentemente en línea recta desde los pilares ó

---

* El autor cree haber sido el primero que sugirió la idea de la adición de vigas armadas muy altas y ligadas transversalmente, para puentes colgantes largos. Proyectamos un puente tal, de cuatro tramos de 305 m cada uno, y dos de 152.5 m, con cables de alambre, y vigas armadas de 6.1 m de alto. Este puente fué propuesto para cruzar el río Delaware en la calle « Market », en Filadelfia. El plano se expuso públicamente durante varios meses en el Instituto « Franklin » y en la Bolsa; y fué finalmente robado del salón de este edificio. El puente del Niágara, por el Sr. Roebling, con luz de 244 m y vigas armadas de 5.49 m de alto, no se principió sino en los últimos meses del 1852, ó más ó menos 18 meses después de haberse expuesto públicamente nuestro proyecto.

** *N. del T.*— Parece más sencilla esta definición que la del autor, y es la adoptada por E. Andrés en su *Manual del Const.de Puentes y Calzadas*, pág. 541, tabla de materias.

torres de suspensión hasta las placas de amarra, en cuyo caso los ángulos *ldr*, *ech*, formados por la línea horizontal *el*, y el cable mismo, se convierten en ángulos de dirección de los tiradores.

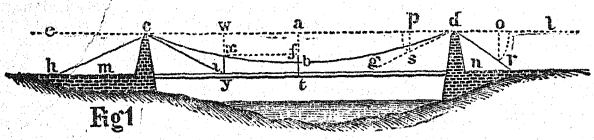

Fig 1

**Seno del ángulo de suspensión** *adg* $= \dfrac{\text{Doble de la flecha } ab.}{\sqrt{(\text{doble de la flecha})^2 + (\text{mitad de la cuerda})^2}}$

*Observación* 1.ª La dirección de la tangente *dg* ó *ci*, puede trazarse de esta manera: Prolónguese la línea *ab*, una cantidad igual al doble de su longitud, luego, las líneas trazadas por *d* y *c* hacia su extremidad inferior, serán las tangentes de la curva parabólica en los puntos de suspensión.

*Observación* 2.ª **Si la cuerda** *cd* **no es horizontal**, como sucede muchas veces, debe medirse el ángulo formado con una línea horizontal, trazada por cada punto de suspensión; los ángulos en este caso son desiguales, porque la altura de los pilares es desigual.

**Tensión de los cables principales juntos, en cualquiera de los pilares** *c* ó *d*, **fig. 1** $= \dfrac{\text{Mitad del peso suspendido en la parte libre de la luz y su carga}}{\text{Seno del ángulo de suspensión } adg.}$

ó $= \dfrac{\sqrt{(\frac{1}{2}\text{ abertura})^2 + (2\text{ flechas})^2}}{2\text{ flechas}} \times$ La mitad del peso total suspendido en la abertura y su carga.

**Tensión de todos los cables juntos en el medio** *b*, **de la luz, fig. 1.** $= \dfrac{\text{Mitad del peso total suspendido en la luz y de su carga} \times \text{Coseno del ángulo } adg}{\text{Seno del ángulo } adg.}$

**ó bien** $= \dfrac{\text{Mitad del peso total suspendido en la luz y su carga} \times \text{La mitad de la luz.}}{\text{Doble de la flecha}}$

La diferencia entre las tensiones del centro y las de los puntos de suspensión, es tan insignificante con la relación de la cuerda á la flecha generalmente adoptada en la práctica, de $^1/_{10}$ á $^1/_{15}$, más ó menos, que por lo común no se hace caso de ella; en tanto que lo que se gana en el peso del metal estaría más que compensado por el aumento de trabajo en la fábrica para reducir gradualmente las dimensiones de los cables de los extremos de suspensión hacia el centro, y en la preparación de los ajustes de las partes de diferentes tamaños. Esta reducción, sin embargo, se ha hecho en algunos puentes grandes en los cables de hierro forjado, pero nunca en los de alambre.

**Art. 2 A.** Como algunas veces es conveniente formarse una idea ligera en un momento dado, de las dimensiones de los cables de un puente, damos la regla siguiente para hallar aproximadamente el área metálica neta (*solid iron*) de alambre que se requiere en centímetros cuad para sostener, bajo un coeficiente 3 * de seguridad, el peso del puente mismo, junto con una carga extraña de 3.34 toneladas por m corrido de abertura, lo que corresponde á 488 kg por m cuadrado de plataforma de un ancho útil de 8.23 m. Esto basta para una calzada doble de

* No debe creerse que estamos por un coeficiente 3 de seguridad para 488 kg por m cuad además del peso del puente para todos los casos. Si creemos que aquel límite sea casi suficiente para un puente colgante bien calculado de alambres, para tráfico ordinario, pero para un puente de ferrocarril importante, preferiríamos adoptar (según la posición, exposición, etc.) un coeficiente de seguridad por lo menos de 4 á 6 para la carga máxima posible, más el peso del puente. Un tren de carros opone una gran superficie á la acción de los vientos laterales; y los trenes tienen que circular durante tempestades fuertes lo mismo que en tiempo de calma; pero en un puente grande descubierto de tráfico común, no se aglomera la gente durante una fuerte tempestad.

vía carretera con dos aceras. Se supone una flecha igual á $^1/_{12}$ de la luz; y el alambre de una resistencia máxima de 5.58 toneladas por cm cuadrado neto.

**Para luces de 100 pies (30.5 m) ó más**, tenemos la siguiente regla: Multiplíquese la luz en pies por su raíz cuadrada; divídase el producto por 100, y al cociente agréguese la raíz cuadrada de la luz. O expresando esto en una fórmula, tenemos:

$$\text{Area metálica neta de todos los cables, en pulgadas cuadradas, para luces de más de 100 pies} = \frac{\text{luz} \times \text{raíz cuad de la luz}}{100} + \text{raíz cuad de la luz.}$$

(*N. del T.* — Damos la fórmula que sigue como equivalente á la anterior, pero en sistema métrico. Llamando L la luz en *metros*, se tendrá:

$$\text{Area metálica neta de todos los cables en cm cuadrados} = 11{,}674\ \sqrt{L}\ (1+.0328\ L).$$

Para luces menores de 100 pies (30.5 m) tómese el área en proporción á la de 100 pies (30.5 m).

Adoptando una flecha de $^1/_{10}$, en lugar de $^1/_{12}$, el área de los cables puede reducirse casi $^1/_7$ parte.

**La tabla siguiente se ha hecho de acuerdo con esta regla.** La tercera columna da el área de todos los cables de alambre juntos, incluyendo los espacios vacíos.

(*N. del T.* — Hemos convertido la del autor al sistema métrico.) (Original.)

| Luz en metros. | Área metálica neta de todos los cables. | Area total de los cables terminados. | Luz en metros. | Área metálica neta de todos los cables. | Área total de los cables terminados. | Luz en metros. | Área metálica neta de todos los cables. | Área total de los cables terminados. |
|---|---|---|---|---|---|---|---|---|
| | cm cuad. | cm cuad. | | cm cuad. | cm cuad. | | cm cuad. | cm cuad. |
| 304.800 | 2245.156 | 2877.409 | 121.920 | 645.159 | 825.803 | 45.720 | 197.418 | 252.902 |
| 274.320 | 1935.480 | 2483.862 | 106.680 | 541.933 | 696.772 | 38.100 | 162.580 | 206.486 |
| 243.840 | 1638.704 | 2103.218 | 91.440 | 445.159 | 574.491 | 30.480 | 129.031 | 165.160 |
| 213.360 | 1367.738 | 1754.832 | 76.200 | 354.837 | 458.063 | 22.860 | 96.774 | 123.870 |
| 182.880 | 1103.222 | 1412.898 | 60.960 | 270.967 | 348.386 | 15.240 | 64.516 | 82.580 |
| 152.400 | 864.513 | 1109.673 | 53.340 | 234.838 | 301.289 | 7.620 | 32.258 | 41.290 |

Conociendo el área de todos los cables podemos fácilmente hallar el diámetro de cada uno. Así, supongamos que para una luz de 152.4 m, queremos aplicar 4 cables, el área de cada uno será 1,109.6÷4=277,4 cm cuad, y en la tabla de círculos, pág. 181, vemos que el diámetro correspondiente á un área de 277.59 es 18.8 (centímetros en este caso).

Las áreas arriba dadas se suponen calculadas tomando en cuenta el aumento en peso debido á la altura de la viga armada, y otras adiciones necesarias para defender el puente contra la acción de los vientos fuertes y contra las vibraciones indebidas ocasionadas por el paso de las cargas.

Cuando no se tengan en cuenta estas consideraciones, y se suponga una carga máxima más pequeña, las descripciones siguientes de los puentes de Wheeling y Freyburg indicarán las reducciones que pueden hacerse.

Es de gran utilidad para reducir las undulaciones dotar al puente de suficiente peso.

Al tablero del puente debe dársele una curvatura hacia arriba, digamos de 1/200 de la luz.

**Art. 3. Tensión de los fiadores *ch* y *dr*, fig. 1, y esfuerzos que obran sobre los pilares** ó torres. Si el ángulo de suspensión *adg* y el ángulo *ldr*, formado por los fiadores y la horizontal, son iguales, la tensión de los fiadores será igual á la de los cables principales en la parte superior de los pilares, y la presión que obre sobre éstos será vertical; pero si los dos ángulos son desiguales, estas tensiones y presiones dependerán, en gran parte, del modo como estén sujetos los cables á los pilares, ó del modo como estén colocados sobre la parte superior de ellos.

**Art. 4. En las figs 2, 3 y 4**, los pilares ó torres *dnm* se suponen inmóviles, y los cables *kdu*, que pasan por encima de ellos, descansan inmediatamente sobre rodillos horizontales, que *no tienen otro movimiento que el de girar alrededor de sus*

*ejes horizontales; y el marco, al cual están sujetos, está firmemente atornillado en la parte superior del pilar.* Los cables se deslizan sobre estos rodillos cuando las variaciones de carga ó de temperatura producen cambios en sus direcciones.

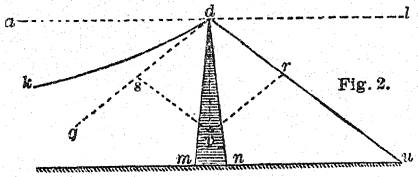

Fig. 2.

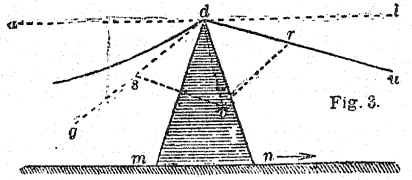

Fig. 3.

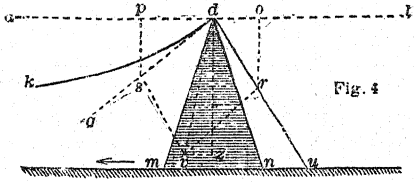

Fig. 4

En este caso **la tensión del fiador** es igual á la del cable. Véase Máquina funicular.

Para hallar la dirección é intensidad **de la presión que obra en el pilar**; por *d*, figs. 2, 3 y 4, trácese *ds* y *dr*, ambas iguales, por escala, á la tensión del cable que actúa en *d* (en toneladas), y por *s* y *r* fórmese el paralelogramo *dsvr* y su diagonal *dv*. Esta diagonal *dv* da la *dirección* é intensidad de la presión que obra en el pilar.

Cuando, como en la fig. 2, los ángulos *adg* y *ldu* son iguales, la presión *dr* será vertical, é igual al peso total del puente en la luz y su carga.

Si, como en las figs. 3 y 4, dichos ángulos *adg* y *ldu* son desiguales, la presión *dv* no será vertical, sino inclinada desde *d* hacia el ángulo más pequeño.

Si *adg* excede á *ldu*, fig. 3, la presión *dv* es *menor* que el peso total en la abertura y su carga.

Cuando, como en la fig. 4, *ldu* excede á *agd*, la presión *dv* es *mayor* que el peso total de la abertura y su carga.

Si suponemos que se usan en cada caso pilares simétricos *dnm*, la base *mn* del de la fig. 2 puede ser más angosta que la de las otras dos figuras, porque, siendo la dirección de *dv* vertical, la presión no tiene tendencia á volcar el pilar. En la fig. 2, la mampostería debe ponerse en hiladas horizontales como de costumbre, para que sus juntas estén en ángulo recto con la presión que obra sobre ellas.

Pero, en las figs. 3 y 4, si las bases se hicieran tan angostas como en la fig. 2, las líneas *dv*, dirección de la presión, caería, afuera de las bases, y por consiguiente los pilares estarían expuestos á volcarse. También las piedras de la mampostería, colocadas en hiladas horizontales, tendrían una tendencia á deslizarse unas sobre otras. Para evitar esto, las hiladas de piedra deben colocarse en ángulo recto á *dv*.

En la fig. 3, la oblicuidad de la presión tiende á que resbale la base del pilar *hacia afuera*, como se indica con la flecha; pero en la fig. 4, *hacia adentro*. Esta tendencia está producida por la componente horizontal de la fuerza *dv*; y su intensidad puede

hallarse en cualquiera de las figuras, así: Trácese una línea vertical de *d* hacia abajo como en la fig. 4, y desde *v* una horizontal, que la encuentre en *z*, luego *vz*, medida en la misma escala, dará esta fuerza horizontal, y *dz* será la componente vertical de la presión *dv*. El efecto de la presión *dr* sobre el pilar, es exactamente el mismo que produciría sobre él una fuerza vertical igual á *dz*, y otra horizontal igual á *vz*, actuando á un mismo tiempo, como se explica en la Composición y Descomposición de las Fuerzas.

Si en cualquiera de las figuras trazamos líneas verticales *sp* y *ro*, fig. 4, entonces *do*, medida por la escala anterior, dará las toneladas de tensión horizontal, y *ro* la presión vertical, producida en el pilar por el fiador, y *dp* y *ps*, darán, del mismo modo, las fuerzas correspondientes producidas por el cable. Si sumamos á *ro* y *ps*, se encontrará dicha suma igual á *dz*, y si restamos *do* de *pd*, la diferencia será igual á *vz*. Es esta diferencia solamente la que tiende á hacer resbalar ó á volcar el pilar; las otras partes de *do* y *pd* se neutralizan á este respecto mutuamente.

Los esfuerzos antedichos pueden calcularse así:

**Esfuerzo de tracción** (*pull*) **horizontal hacia adentro ejercido por el cable principal**=Tensión × Coseno de *adg*.

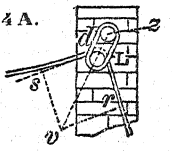
**Esfuerzo de tracción horizontal hacia afuera ejercido por el fiador** =Tensión × Coseno de *ldu*.

**Presión vertical ejercida por el cable**=Tensión × Seno de *adg*.

**Presión vertical ejercida por el fiador**=Tensión × Seno de *ldu*.

**Art. 5.** Si los cables pasan libremente por encima de un pasador suelto *d*, fig. 4 A, sostenido por el eslabón L, que cuelga del pasador fijo *z*, y capaz de moverse libremente en ambos apoyos, la tensión del fiador será, como antes, igual á la del cable, y la dirección é intensidad del esfuerzo que obra en el pilar se halla del mismo modo que en las figs. 2, 3 y 4; es decir, trácese *ds* y *dr*, ambas iguales á la tensión, y constrúyase el paralelogramo *dsvr*. Luego *dv* dará la intensidad y dirección del esfuerzo que obra en los pilares. Esta última será por supuesto transmitida por los pasadores y el elsabón. La intensidad de la tensión sobre el eslabón la dará la longitud de *dv*, y el eslabón (libre para moverse) estará en la misma línea de la tensión. El esfuerzo cortante que se ejerce sobre cada pasador está dado también por *dv*.

Fig. 4 A.



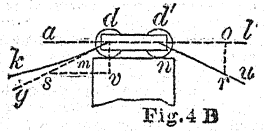


Fig. 4 B

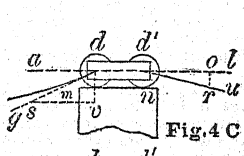

Fig. 4 C

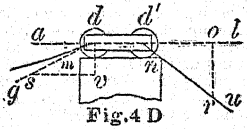

Fig. 4 D

**Art. 6.** Pero si las extremidades del cable y del fiador, figs. 4 B, 4 C y 4 D, en la parte superior del pilar, se fijan á un carrito apoyado sobre rodillos en una plataforma lisa colocada en la parte superior del pilar, y estando los ejes de los rodillos fijos á la carretilla, entonces el esfuerzo del fiador no será el mismo que el del cable, á menos que los ángulos *adg* y *ldu* sean iguales, como en la fig. 4 B.

Si *adg* excede á *ld'u*, como en la fig. 4 C, el esfuerzo que obra sobre el fiador será menor que el que actúa sobre el cable, y viceversa, fig. 4 D.

Pero, en uno ú otro caso, si la parte superior es horizontal, como lo es generalmente, las componentes horizontales de los esfuerzos de los cables y los fiadores serán iguales y contrarias, y de consiguiente se destruyen sus efectos, y por tanto no obrará ningún esfuerzo de tensión horizontal ú oblicuo sobre el pilar; es decir, que el esfuerzo que obra en él será vertical.

**Para encontrar la intensidad de la tensión del** fiador, y de la **presión que obra en el pilar**, tómese sobre *dg*, en cualquiera de las figs. 4 B, 4 C, ó 4 D, en escala, *ds* igual á la tensión del cable en *d*. Trácese *dv* perpendicular á la super-

ficie *mn* sobre la cual descansan los rodillos. Suponemos que *mn* es horizontal como lo es generalmente; *pero no necesariamente*, y por tanto que *dv* es vertical. Hágase *sv* horizontal ó paralela á *mn* *.

Entonces *sv* dará el esfuerzo de tensión horizontal del cable sobre el carrito, y *dv* dará la presión vertical del rodillo *d* sobre el pilar (á cuya presión tiene que agregarse todavía la del rodillo *d'*). En *d'*, trácese *d'o* horizontal é igual á *sv*, y trácese *ro* vertical. Luego *d'r* dará la intensidad del esfuerzo de tensión del fiador y *ro* la presión vertical del rodillo *d'* que actúa sobre el pilar, que debe agregarse á *dv* para obtener la presión vertical *total*.

También pueden calcularse los diversos esfuerzos así:

**Esfuerzo de tensión horizontal *sv* ó *d'o* en la parte superior del pilar** = Esfuerzo de tensión horizontal en el centro de la abertura = Tensión *ds* en el cable en *d* × Coseno de *adg*

**Esfuerzo de tensión *d'r* en el fiador** = esfuerzo de tensión horizontal *sv* ó *d'o* en la parte superior del pilar ó en el centro de la abertura ÷ coseno de *ld'u*.

**Presión sobre el pilar**, perpendicular á la superficie en que descansan los rodillos $= dv + ro = \left(\begin{matrix}\text{Tensión } ds \text{ sobre el cable en } d\end{matrix} \times \text{seno de } adg\right) + \left(\begin{matrix}\text{Tensión } d'r \text{ sobre el fiador}\end{matrix} \times \text{seno de } ld'u\right)$

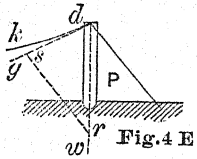

Fig. 4 E

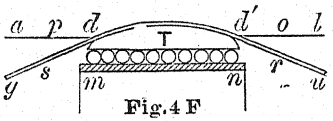

Fig. 4 F

**Art. 7.** Cuando, como alguna vez sucede en los puentes livianos, los pilares son postes, P, fig. 4 E, de madera ó de hierro, con los cables y fiadores sujetos firmemente en sus partes superiores; desde *d* trácese *ds*, igual por escala, á la tensión del cable principal en *d*, y *dw* hacia el pie del poste. Desde *s* trácese *sr* paralela al fiador, y que encuentre á *dw* en *r*. Entonces *sr* dará el esfuerzo en el fiador, y *dr* dará la intensidad y dirección de la presión sobre el poste.

**Art. 8.** Del mismo modo que en el puente del Niágara, los cables descansan á menudo simplemente sobre carritos movibles T, fig. 4 F, curvos aquéllos en su parte superior para evitar dobleces repentinos en los cables y apoyados sobre rodillos sueltos, colocados en una plancha gruesa de hierro, horizontal, remachada á la parte superior del pilar; los rodillos pueden moverse con libertad horizontalmente. En estos casos, los ángulos *adg* y *ld'u* permanecen siempre iguales; de este modo los esfuerzos de tensión *ds* y *d'r* serán iguales, como lo son también sus componentes horizontales *pd* y *d'o*; y las presiones que obran sobre el pilar son verticales; y si variaciones de temperatura o de cargas producen pequeñas variaciones en los ángulos *adg* y *ld'u*, el carrito de rodillos se moverá (por causa de la desigualdad producida en las componentes horizontales) lo suficiente para restablecer la igualdad de los ángulos y las componentes horizontales, y en consecuencia la presión sobre el pilar será siempre vertical.

**Art. 9. Para hallar, aproximadamente, la longitud de un cable** *cbd*, fig. 1, conociendo la abertura *cd*, y la flecha central *ab*. Véase la tabla que precede, art. 1.

La mitad de la longitud del cable $= \sqrt{1\,^1/_3\ (\text{flecha}^2) + (\tfrac{1}{2}\ \text{cordón})^2}$.

En el puente de Menai, la cuerda *cd* tiene 176.86 m (579.874 pies), y la flecha (43 pies) 13.11 m.

Según la fórmula anterior, la extensión total es de 179.4 m (588.3 pies). Según la medida efectiva, la cadena tiene exactamente 180 m (590 pies).

La regla aproximada que se da más abajo da 179.75 m.

---

* Las líneas *al* y *sv* deben trazarse *paralelas á la superficie*, mn, *sobre la cual descansa el carrito con sus rodillos, aunque dicha superficie sea horizontal, ó inclinada.*

*Nota.* Las longitudes obtenidas por esta regla son aproximadas solamente; porque el cálculo está basado sobre la suposición de que la curva de las cadenas sea parabólica, mientras que en realidad la curva de un puente concluído, no es precisamente una parábola, ni una catenaria, sino una curva intermedia entre las dos.

La regla sencilla que sigue, del autor, es tan aproximada como la molesta regla que antecede, cuando la flecha no es mayor de $^1/_{12}$ parte de la cuerda, ó luz, como sucede generalmente.

Longitud del cable ó cadena cuando la flecha no excede de $^1/_{12}$ de la abertura = cuerda + .23 de la flecha.

**Art. 10. Encontrar, aproximadamente, la longitud de las péndolas *x*, *y*, etc., fig. 1, suponiendo la curva una parábola.**

Sea *x*, fig. 1, un punto cualquiera de la curva; y trácese *xw* perpendicular á la cuerda *cd*; y *xf* perpendicular á *ab*; tenemos en cualquira parábola, que $ac^2 : aw^2 = ab : bf$. Y *bf* hallado de este modo sumado con *bt* (que se supone ya conocida, por el pendolón) da á *xy*, longitud de la péndola que se requiere en el punto *x*, y así en cualquier otro punto.

**Si se resta á *bf*, así encontrada, de la flecha del centro *ab*, el residuo será *wx*.** Asimismo puede hallarse cualquiera otra.

En la regla que antecede, se supone que el tablero del puente es recto; pero generalmente está algo elevado en el centro, y en este caso las péndolas deben calcularse primeramente como si el tablero fuese recto, y después deben hacerse las deducciones necesarias. Cuando se eleva según dos líneas rectas que se encuentran en el centro, el modo de hacerlo salta á la vista. Cuando se emplea un arco de círculo, sus ordenadas deben calcularse y deducirse de las longitudes obtenidas por esta regla. O habiendo trazado la curva por el método usado para trazar una parábola, las dimensiones pueden tomarse aproximadamente por la escala. Los ajustes, para obtener las longitudes exactas, deben hacerse durante la construcción del puente aplicando tuercas en los tornillos de los extremos inferiores. Por consiguiente basta sólo, al principio, hacer las barras de longitud suficiente.

Las torres, ó pilares, que sostienen las cadenas ó cables, admiten variaciones infinitas. Según las circunstancias, pueden componerse de una simple pieza de madera vertical; ó de un pilar de hierro forjado ó fundido, ó de dos ó más de éstos, puestos oblicuamente con piezas de conexión ó sin ellas, como los inclinados de una pila armada en puentes de hierro; ó de planchas de hierro fundido (con cualquiera ornamentación), como los frentes de las casas de hierro; ó de mampostería de piedra, de ladrillo, de concreto ó de cualquiera de estos materiales combinados.

**Cada una de las péndolas** que mantienen suspendido de los cables, al piso ó tablero del puente, necesita sólo la resistencia suficiente para sostener, con seguridad, la carga máxima que pueda actuar en el intervalo formado por los dos espacios comprendidos entre cada una de ellas y el centro de la distancia á la péndola más próxima incluyendo el peso de la plataforma, etc., en el intervalo expresado.

Al fijar los fiadores en tierra es necesario dotar á las planchas de amarra, de una resistencia suficiente para que soporten con seguridad el esfuerzo de tensión igual al que obra en el fiador.

Con respecto á la fijación de los cables bajo la superficie del suelo, las rocas naturales de carácter firme constituyen el material más á propósito que pueda presentarse. Donde no exista dicho material, hay que hacer serios gastos de mampostería en aberturas grandes para obtener el peso capaz de resistir la tensión de los cables. Las figs. 4½ dan una idea de los métodos adoptados frecuentemente. Para un puente muy pequeño destinado al tráfico á pie, por ejemplo, los fiadores pueden fijarse simplemente á piedras grandes *t*, fig. A, enterradas á una profundidad suficiente. Si la tensión es demasiado grande para tan sencilla precaución, pueden agregarse bloques de mampostería *mm* que cubran el fiador. Una buena cubierta con el mortero ó cemento de la mampostería constituye una capa protectora del hierro.

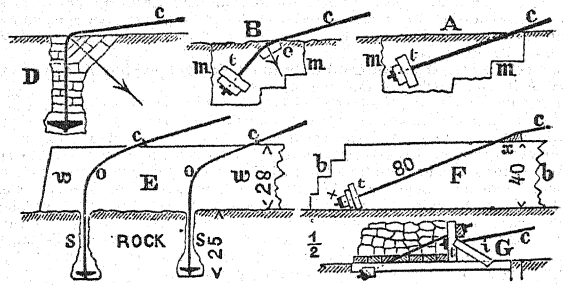
Para evitar la necesidad de prolongar los fiadores á gran distancia debajo de la tierra, se los encorva generalmente cerca del punto en donde penetran bajo la superficie del suelo, como se indica en B, D y E, con el fin de llegar así más pronto á la profundidad necesaria.

Esta curva, sin embargo, produce un nuevo esfuerzo en la dirección indicada por las flechas en las figs. B y D. La naturaleza de este esfuerzo, y el modo de hallar su intensidad (conociendo la tensión del fiador), es muy sencillo, y está claramente explicado en el capítulo Máquina funicular. La mampostería debe estar dispuesta como para resistir este esfuerzo así como el de tensión directo del fiador. En vista de

esto, los bloques de piedra, sobre los cuales descansa la extremidad doblada del fiador, debían estar colocados como se ven en la fig. D, ó como el bloque solo en B. Algunas veces se hace el doblez sobre un asiento ó pedestal de hierro fundido *x*, fig. F, fijo firmemente á la mampostería por medio de pernos.

La fig. E muestra la disposición adoptada en el puente de ferrocarril del Niágara, de 250.5 m de luz. Los fiadores de alambre terminan en *cc*, y de este punto hacia abajo hasta el anclaje, están formados de cadenas pesadas, cuyos eslabones están compuestos (alternativamente) de 7 ú 8 barras de ojo paralelas, de hierro chato, por las cuales pasan pernos.

Cada una de estas 7 barras es de 36 mm de grueso, por 178 mm de ancho cerca de las partes más bajas de la cadena; pero aumentan gradualmente de allí hacia arriba, hasta que en *cc*, donde se unen con el alambre, el área de la sección de cada eslabón sea de 600 cm cuad Estos fiadores de cadena atraviesan en curva los muros macizos



de acceso (de 8.54 m de alto) y descienden verticalmente por una cavidad *ss* á 7.6 m debajo de la roca sólida. Aquí pasan por las planchas de amarra de hierro fundido, á las cuales están fijas por un perno de 9 cm de diámetro. Las planchas de amarra son de 2 metros en cuadro, y 63 mm de grueso, con excepción de un espacio de 50 por 65 cm más ó menos, en el centro, por donde pasan las cadenas y donde tienen un espesor de 305 mm.

Esta parte gruesa está provista de una abertura para cada barra de que se compone el último eslabón. Las cavidades *ss*, tienen los lados ásperos como si fueran hechos con barrenos de pólvora y tienen de .91 por 2.10 m de sección transversal, excepto en el fondo, donde tienen 2.44 m en cuadro.

Están llenos completamente de mampostería de cemento, en capas bien dispuestas y bien en contacto con las caras de la cavidad; todas las juntas bien cogidas y macizadas, y cubriendo perfectamente, de este modo, las cadenas por todas partes; la mampostería de los muros *ww*, se eleva 8.54 m sobre la superficie del terreno con 1.83 de espesor en la parte superior y 3.05 m en su base sobre la roca natural.

En D, fig. 4½, está indicado el método que se usa en la mayor parte de los casos, para puentes de cualquiera abertura. La profundidad del pozo y el área de la sección transversal, y en consecuencia, la cantidad de mampostería, depende principalmente de si el pozo se hace en roca ó en tierra.

Si se hace en roca firme y las caras de la excavación son irregulares y se hace penetrar bien la mampostería en las irregularidades, puede confiarse en que contribuirá á que el peso de aquélla resista á la tensión de los fiadores.

La tierra también contribuye bastante á este respecto.

F es la disposición adoptada en el puente de Chelsea, de 101.5 m de luz, sobre el Támesis, en Londres. El espacio comprendido entre un muro *bb* y el muro opuesto es de 13.72 m y está construído sólidamente de ladrillo y concreto, excepto un pasaje interior de 1.22 m de ancho y 1.52 m de alto, á lo largo del fiador, y una cámara pequeña detrás de las planchas de anclaje. La mampostería descansa principalmente sobre estacas.

La disposición adoptada por el Sr. Brunel, en el puente de Charing Cross, Londres, es muy semejante. También aquí descansa todo el estribo sobre estacas; tiene 12.2 m de alto y 9.1 m de grueso, es macizo con excepción de un pasadizo angosto á lo largo de las cadenas. Los fiadores se prolongan 18 m en la mampostería. Luz 206.18 m, flecha 15.2 m.

G es solamente una idea general, la cual, con modificaciones variadas, puede aplicarse á puentes pequeños ó provisionales, y aun á puentes permanentes; con respecto al número de piezas, *i*, *t*, etc., pueden aumentarse hasta donde fuera necesario, y hacerse de hierro ó piedra en lugar de madera.

**Á fin de que los fiadores puedan ser accesibles**, se pasan frecuentemente por aberturas dejadas al efecto en la mampostería. De esta manera las masas *mm*, de mampostería en A y B, fig. 4½, en vez de ser sólidas pueden consistir en dos muros paralelos entre los cuales puede pasar el fiador; y las piedras ó planchas de anclaje, se extenderán á través de los espacios vacíos entre los muros, con sus apoyos sobre los extremos de los muros. Se puede suponer que en D, E y F, el cable esté sólidamente rodeado de la mampostería y encajado en ella, ó rodeado de un pasaje cilíndrico semejante á una cañería, para que sea siempre accesible.

Se debe excluir cuidadosamente toda piedra blanda desmenuzable en aquellas partes del anclaje que se encuentren más directamente opuestas al tiro del fiador.

Si no se pueden conseguir bloques de piedra suficientemente grandes para obtener una buena trabazón, se pueden emplear ventajosamente con este objeto vigas pesadas de hierro en T, en I, ó simples carriles ó barras de hierro.

Las masas de mampostería deben cimentarse á tal profundidad que no puedan resbalar porque ceda ó se derrumbe el terreno.

Para mayor seguridad sería conveniente descartar el efecto de la fricción sin disminuir la tensión del fiador y considerar aquella tensión como si continuara uniforme por todo el fiador hasta su extremo, aun cuando el fiador fuese curvo y estuviese empotrado en la mampostería, como en E, fig. 4½.

**Los parapetos laterales** del puente deben ser altos y fuertes, para que obren como armaduras de refuerzo, y no se debe limitar su empleo á meras barandas ó protección. Como regla aproximada, su altura en m debe ser $= 0.276 \sqrt{\text{de la luz}}$, con tal que la altura no sea menor que la requerida para un pasamano. Los parapetos deben construirse bien fuertes, teniendo especial esmero en reforzar sus empates, pues éstos están expuestos, por las undulaciones y movimientos laterales del puente, á violentos esfuerzos en todas direcciones.

# ROBLONES Y ROBLONADURA

Los **pesos** que se indican en la **tabla que sigue** comprenden, por supuesto, la cabeza del remache; pero la **longitud**, como de costumbre, se toma «por debajo de ella», ó mejor dicho, es la longitud del fuste solamente. En la práctica pueden resultar discrepancias, en el peso, de 5 ó 6 por ciento.

(*N. del T.* — 1.ª Para convertir pulgs en mm multipliquese el número de aquellas por 25,399 ó conviértanse por medio de la tabla que va al pie.

Para convertir libs en kg multipliquese por .453.)

| Long del fuste en pulgs. | Diámetro del remache ó roblón en pulgs. | | | | | | | |

**El diám de los roblones** para trabajos de puentes es de ½ á 1 pulg (de 12½ á 25 mm); comúnmente de $^{5}/_{8}$ á $^{3}/_{4}$ (de 15.87 á 19.05 mm); y para planchas de más de .5 de pulg (12½ mm) de grueso, el diám es como 1.5 veces el espesor; para más delgadas como el doble; pero estas proporciones no son muy exactas. **La forma común de los remaches** que se ofrecen en venta se indica en R, fig. 3, una **cabeza** y el **fuste** en una sola pieza; y S muestra el mismo remache cuando después de habérselo calentado hasta el blanco se ha insertado en el hueco formándole una nueva cabeza (cónica) por el remachamiento rápido á medida que enfría. **Cuando tienen más de 6 pulgs de largo**, se los enfría cerca del medio antes de introducirlos, si no, su contracción al enfriarse rompería las cabezas. Las cabezas hemisféricas que á menudo se ven, llamadas **cabezas redondas**, se hacen en máquina. **Las dos cabezas solas requieren** una cantidad de hierro como de 3 diámetros en longitud de la espiga. **Longitud de la cabeza**=como 1 diámetro de espiga; y su **ancho** como 2 diámetros de espiga.

**Roblonadura ó remache de juntas impermeables al vapor y al agua.**

**Las juntas ó empates de calderas** y cisternas impermeables se hacen generalmente como por la tabla siguiente de Fairbairn; y se construyen como lo indica la fig. 1 ó la fig. 2. La fig. 1 se denomina **junta ó empalme de roblonadura sencilla**, y la fig. 2, de **recubrimiento y roblonadura doble**. La dist *aa* ó *cc*, es la superficie recubierta.

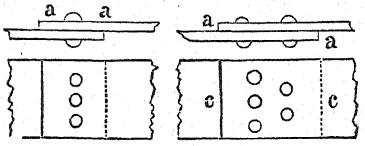

**Fig. 1.** **Fig. 2.**

Fairbairn considera la resistencia de la junta de roblonadura sencilla como de .56, y la de doble roblonadura, como .7 de la que corresponde á una placa sin agujerear, cuando ambas juntas están hechas con las proporciones indicadas en las tablas siguientes, de dicho autor.

Pero algunos experimentadores últimos consideran á .5 y .6 como término medio más próximamente exacto. Los experimentos hechos sobre esta materia son enteramente contradictorios, y es claro que ninguna serie de proporciones pueden precisamente convenir á todas las diferentes clases de placas de remaches. Con buenas clases de ambos hay razón para confiar en que .5 y .6 (ó como una séptima parte menos de lo que supone Fairbairn) sea una resistencia segura en la práctica. Esta proporción comprende el **rozamiento**, art. 4, sin el cual sería *como* .4 y .5.

**Tabla de Fairbairn que suministra las dimensiones proporcionadas de las roblonaduras de juntas solapadas impermeables al vapor y al agua.**

(*N. del T.* — Hemos convertido la tabla del autor al sistema métrico.)

| Espesor de cada placa. | Diámetro del roblón. | Long del fuste antes de insertarlo. | De centro á centro de roblón. | Recubrimiento con roblonadura sencilla. | Recubrimiento con roblonadura doble. |
|---|---|---|---|---|---|

## Roblonadura de vigas, puentes, etc.

**Art. 1. La cuestión roblonadura es asunto obscuro, de difícil comprensión**; está envuelto en dudas, y los resultados experimentales discrepan mucho. Nos proponemos aquí ceñirnos meramente á la que se considera como la mejor

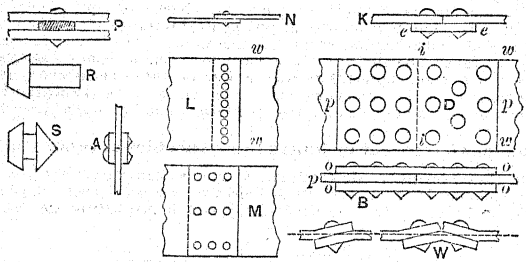

**Fig. 3.**

unión; y para mayor seguridad no contamos con el rozamiento; véase art. 4. En las vigas y trabajos de puentes, las juntas recubiertas arriba descritas se usan rara vez. En lugar de ellas, para unir las placas *p*, fig. 3, se empalman de tope una contra otra, formando de este modo **un empalme plano** *ii*, fig. D, y se unen por una **cubrejunta** *ee*, fig. K, ó mejor, por dos de ellas, como en A ó en *oo, oo*, fig. B. En lo que sigue, el término *plancha* ó *palastro*, según sea, jamás comprende las cubrejuntas. La cubrejunta sencilla semejante al recubrimiento permite tanto á las planchas como á las cubrejuntas doblarse bajo una fuerte tensión, como se indica más ó menos en W, debilitándolas, en tanto que la doble cubierta *oo, oo*, fig. B, mantiene la tensión directamente en el eje de las placas evitando la tendencia á doblarse. También somete á dos secciones de los remaches al esfuerzo cortante, doblando así su resistencia. Cuando no hay más que una cubierta, debe ser por lo menos del grueso de una placa, y cuando hay dos, la experiencia enseña que es mejor que cada una sea *dos tercios* del espesor de la placa, aunque la teoría exige que cada una tenga sólo la *mitad* de dicho grueso.

**La longitud** *ww* **de las cubrejuntas**, transversalmente á la junta, es igual á la de la junta. **La unión de los extremos, es decir el empalme plano requiere doble número de remaches** que los recubiertos, porque en éstos cada remache atraviesa las dos placas unidas, y en el empalme de tope ó plano, solamente una placa.

**Los remaches y placas de un solo lado** (á la derecha ó á la izquierda) de la línea *ii* de unión de cualquier **empalme plano ó de tope** D, de dimensiones adecuadas, representan la resistencia total de la junta, porque los de un lado ejercen tensión en una dirección contraria á los que se hallan del otro lado. Por esto al calcular tales juntas debemos tener presente únicamente los remaches y placas de un solo lado como se hace en lo que sigue: Así, **un empalme plano ó de tope** de roblonadura sencilla, doble ó triple, implica una, dos ó tres hileras de remaches **de cada lado** de la junta *ii*, paralelamente á ella. En una recubierta, de dimensiones adecuadas, el esfuerzo es como **todos** los remaches, porque la mitad de ellos no ejerce tensión contra la otra mitad, sino que un extremo de **cada** remache la ejerce en una dirección y el otro en la dirección opuesta.

**El hierro neto, la placa neta ó la junta neta** es aquella que queda comprendida **entre** los agujeros de los remaches y **del lado afuera** de los dos exteriores, todo en una línea recta trazada por los *centros* de los agujeros de *una* hilera. Su ancho y su área se denominan ancho neto y área neta de la junta. Los que se encuentran entre *otras* hileras no aumentan la resistencia.

En las figs. 3, N y K, están los remaches expuestos á esfuerzo cortante **simple**, es decir, que las tensiones opuestas de las dos planchas tienden á cortar á cada

remache transversalmente según una sola sección circular, mientras que por el contrario, en la fig. B, ó en la fig. A, cada remache está expuesto á un **doble esfuerzo cortante.**

**Art. 2. Las uniones ó juntas de los puentes no se requiere que sean impermeables al agua ó al vapor,** como las de las calderas ó depósitos, y por lo tanto, aumentando el ancho del recubrimiento superior ó la longitud de las cubrejuntas, pueden colocarse los remaches en varias hileras unas detrás de otras, como las tres hileras de á 3 remaches en M y D, en lugar de una sola hilera de 9 remaches como en L. Por este medio, sin que se pierda resistencia alguna de los 9 remaches ó del hierro **neto,** podemos disminuir el ancho de la placa hasta que se igualen los diámetros combinados (6 en este caso) de los agujeros omitidos en el caso de una hilera. Además, usando más de una hilera disminuímos el efecto debilitante que se ve en W. Este modo de colocar los remaches directamente unos detrás de otros en varias hileras, como se muestra en M y á la mitad izquierda de la fig. D, constituye el **roblonamiento de cadena** de Fairbairn; pero la junta será algo más fuerte si se colocan los remaches en **zizás,** como se ve en la mitad de la derecha de la fig. D.

**La separación de las hileras de centro á centro** no debe ser menor de 2 diáms. Es discutible hasta qué punto pueda llevarse este aumento en el número de hileras sin ocasionar una pérdida apreciable de resistencia en los remaches, proveniente de la imposibilidad de igualar los esfuerzos en las hileras separadas. Pero es probable que si no nos excedemos de dos ó tres hileras en los de recubrimiento, ó el mismo número *en cada lado* de la línea de juntura en los empalmes planos, podremos en la práctica suponer que cada hilera y cada remache están casi sometidos á iguales esfuerzos.

**Los agujeros** de los remaches son comúnmente como de un dieciseisavo de pulgada (1½ milímetro), mayor en diámetro que los remaches originales, de manera que permitan la introducción del remache caliente con facilidad.

Los golpes de martillo al recalcarlos aumentan el diámetro del remache hasta que éste llena el agujero. Podemos tomar este aumento del diámetro de los remaches en consideración, como lo hemos hecho al calcular su resistencia al esfuerzo cortante, como se explica adelante, ú omitirlo para aumentar la seguridad.

**Se cree que los agujeros de remaches, taladrados** son mejores que los hechos con punzón, porque el taladrado no maltrata al hierro que está á su alrededor, pero por otra parte se cree que sus aristas vivas cortan los remaches más fácilmente. Por eso, las aristas algunas veces se le desgastan ó suprimen. Estos dos puntos son discutidos y ambos modos son de uso común.

**La distancia del borde de un agujero** al extremo de una plancha ó cubrejunta no debe ser *menor* de 1.20 de diámetro, para evitar que los remaches rompan el extremo de la palanca, ni más cerca del borde del lado de una plancha que la mitad de la distancia exacta entre dos agujeros, como lo indica la Regla del art. 5. La primera es más bien más de lo que indica Fairbairn.

**Los agujeros de los remaches debilitan el hierro neto** que se deja entre ellos, no sólo por la pérdida de la parte de material extraído para hacer el hueco, sino también porque altera el hierro que los rodea, ó acaso porque cambia la forma de la línea neta de fractura, la que entonces no puede resistir las tensiones tan bien como cuando era una línea recta continua. Algunos niegan enteramente la causa y el efecto, basando cada cual su opinión en los experimentos. Pero por muchas razones cree el autor que el hierro pierde, por término medio, como un séptimo de la resistencia que tiene cuando es continuo. Por vía de seguridad, estableceremos en lo que sigue (mientras se resuelve la cuestión definitivamente) que **sí existe** tal pérdida de resistencia en el hierro.

**Las puntas remachadas para resistir compresión** deben depender, no, como podría suponerse, de los extremos que se junten, sino de su resistencia al cizallamiento ó á la distorción de los remaches, pues la contracción ó un trabajo mal ejecutado pueden traer la presión á obrar sobre los remaches. **El roblonamiento por medio de máquinas** es algo más fuerte que el hecho (como se supone en nuestros ejemplos) á mano. **El espesor de las planchas** que se usan en las vigas, puentes tubulares, etc., es comúnmente de .25 á .50 de pulgada (6¼ á 12½ mm); con las de mayor espesor se llega rara vez á 1 pulgada (25 mm) en los puentes largos. **Una pieza de guarnición ó cuña,** como la pieza sombreada en P, es la que se inserta entre dos placas para evitar que éstas se doblen ó se aproximen por causa de los remaches.

**Art. 3. Una junta remachada puede ceder de tres modos** (suponiendo que tiene las dimensiones convenientes), á saber : por el corte ó cizallamiento de los remaches; por la fractura de la placa continua comprendida entre los agujeros de los remaches, ó por el *desgarramiento* (especie de compresión, despachurramiento, ó distorción de la materia, etc.), de las placas por los remaches cuando se fuerzan las dos unas contra otras.

También se comprimen los remaches mismos transversalmente, **con un esfuerzo menor que el cortante**, y al ceder parcialmente las placas y los remaches, permiten á la junta **estirarse**, y puede de este modo originar fuerzas perjudiciales imprevistas en otras partes de la construcción, mucho antes de que haya verdadero peligro de fractura. También en las juntas impermeables al agua y al vapor, puede ocasionar filtraciones, sin posteriores inconvenientes ó peligros. Durante mucho tiempo, este efecto de la compresión se había escapado enteramente á la observación, y se suponía que lo único importante al hacer el cálculo de una junta remachada, era que la resistencia á la tensión de la placa neta, y la resistencia al esfuerzo cortante ó cizallamiento de los remaches debían ser iguales.

**La resistencia al desgarramiento * de una junta** es proporcional a número de remaches, en una junta de recubrimiento, ó al número de los que haya en un lado de la línea de unión, en las juntas de tope ó empalmes planos × diámetro × espesor de las placas unidas. Este producto da el *área de desgarramiento* (*crippled area*) de la junta ó empate. Podemos llamar aquí al producto diámetro × espesor de la placa, **área de desgarramiento del remache**. Si hay 2 ó más placas (no cubiertas) encima unas de otras, en una junta, su espesor total ó unido se emplea para hallar el **área de desgarramiento. La unidad del desgarramiento máximo** por la cual el producto de arriba debe multiplicarse para obtener la resistencia al desgarramiento máximo verdadero de la junta, puede tomarse con seguridad como en 60,000 lbs ó sea 26.8 tons por pulg cuad (como 4,200 kg por cm cuad).

**El diám en pulgs de un remache que resista con seguridad** un esfuerzo cortante dado, se encuentra así : Multiplíquese el esfuerzo cortante por el coeficiente de seguridad, esto es, por el número 3, 4 ó 6, etc. Llámese *g* el producto. Multiplíquese la resistencia máxima al esfuerzo cortante por pulg cuad del hierro del remache por la fracción decimal .7854. Llámese *b* el producto. Divídase *g* por *b*. Tómese la raíz cuad del cociente. La fuerza y la resistencia al esf cort deben *ambas* expresarse en libs ó en toneladas.

O empleando el sistema métrico (*N. del T.*), tendremos :

$$\text{Diám en cm} = \sqrt{\frac{\text{Esfuerzo cortante en kg} \times \text{coeficiente de seguridad} \times 8.214}{\text{Resistencia al esfuerzo cortante máximo en kg por cm cuad.}}}$$

**Si el remache está destinado á sufrir un doble esfuerzo cortante,** multiplíquese primeramente sólo la mitad del esfuerzo cortante por el coeficiente de seguridad, y después procédase como antes.

O lo que es suficiente en la práctica, multiplíquese el diám correspondiente al esfuerzo cortante sencillo por la fracción decimal .7.

**La unidad del esf cort máximo** del hierro de remaches, uno con otro, puede tomarse como en 20.1 tons por pulg cuad (3,163 kg por cm cuad), de sección circular cortada

### Tabla de la resistencia máxima (al esfuerzo cortante sencillo) de los remaches.

(dimensiones del mercado), expuestos al esf cort sencillo, á razón de 45,000 libs ó 20.1 tons por pulg cuad (3,163 kg por cm cuad).

**Esta tabla no debe usarse** cuando, como en nuestro « Ejemplo », art. 5, la resistencia al desgarramiento (*crippling*) del remache domine, sea mayor que la resistencia de la junta.

---

* *N. del T.* — La expresión es *crippling strength*, que el autor usa mucho en estos párrafos.

**Si el remache está expuesto al esfuerzo cortante doble,** tendrá el doble de la resistencia de la tabla.

**Para calcular el diám que corresponde á un remache sometido al esfuerzo cortante doble** para iguales resistencias de la tabla, multiplíquese el diám de la tabla por .7, lo que es suficiente en la práctica; lo estricto es .707.

| Diámetro en milímetros. | Kilogramos. | Toneladas. | Diámetro en milímetros. | Kilogramos. | Toneladas. | Diámetro en milímetros. | Kilogramos. | Toneladas. |
|---|---|---|---|---|---|---|---|---|
| 3.175 | 250.4 | .246 | 14.2748 | 5,072.5 | 4.990 | 25.400 | 16,031.2 | 15.800 |
| 4.749 | 563.3 | .554 | 15.8750 | 6,262.3 | 6.160 | 26.974 | 18,097.8 | 17.800 |
| 6.350 | 1,002.0 | .986 | 17.4498 | 7,577.3 | 7.460 | 28.575 | 20,289.6 | 20.000 |
| 7.924 | 1,565.8 | 1.540 | 19.0500 | 9,017.4 | 8.880 | 30.149 | 22,606.0 | 22.200 |
| 9.525 | 2,254.4 | 2.220 | 20.6248 | 10,583.2 | 10.400 | 31.750 | 25,049.0 | 24.600 |
| 11.099 | 3,068.6 | 3.020 | 22.2250 | 12,274.2 | 12.100 | 33.324 | 27,616.9 | 27.200 |
| 12.700 | 4,008.0 | 3.940 | 23.7998 | 14,090.3 | 13.900 | 34.925 | 30,308.9 | 29.800 |

**La resistencia á la tensión de una junta ó conexión de dimensiones bien calculadas** es igualmente proporcional al área neta de la sección de la plancha (no cubierta) hecha á través del centro de **una** hilera solamente de remaches ó al área del esfuerzo cortante ó de (*crippling*) desgarramiento (según el caso) de **todos** los remaches contenidos en un recubrimiento; ó como todos los remaches **situados de un solo lado** de la línea de unión en una junta de tope ó plana. La resistencia á la tensión de hierro en planchas de regular calidad, antes de que se le hagan los agujeros de los remaches, es por término medio como de 45,000 libs ó 20.1 tons por pulg cuad (como 3,163.93 kg por cm cuad); pero para mayor seguridad supondremos, como se dijo en el art. 2, que la hechura de los agujeros disminuye la resistencia del hierro continuo, **neto**, que queda como en una séptima parte, ó á 38,500 libs, 17.2 tons por pulg cuad (2,706.91 kg por cm cuad).

*Observación.* **Esto es todavía considerablemente grande** para las juntas de recubrimiento ó para las juntas de tope de una sola cubrejunta, debido al debilitamiento del hierro en tales juntas ó conexiones por el doblez que se indica en W, fig. 3. Pero no estamos tratando de eso.

**El rozamiento entre las planchas** en los recubrimientos ó entre las planchas y las cubrejuntas en una junta plana ó de tope, producido por la presión que las une estrechamente en la contracción de los remaches al enfriarse, añade mucho á la resistencia de una junta cuando está nueva, quizás 1.5 ó 3 tons por pulg cuad (236.24 ó 472.48 kg por cm cuad) de sección circular de todos los remaches en una junta recubierta, ó de todos los situados á un lado de una junta plana de cubrejunta sencilla, ó de 3 á 6 tons (472 á 944 kg por cm cuad) de todas las situadas á un lado de una junta plana de doble cubierta. En construcciones perfectas, este rozamiento podría continuar existiendo, totalmente ó en parte, por un período indefinido; pero en los puentes, etc., sujetos á choques y vibraciones incesantes y violentos, es probable que disminuya pronto ó desaparezca del todo. De aquí que autoridades competentes en la materia recomiendan no confiar en él, y se omite por tanto en lo que sigue.

**Art. 5.** Damos fórmulas para encontrar el número de remaches que se necesitan en **una junta plana de doble cubrejunta** (de cuya clase sólo trataremos) y la dist neta que los separa. Esta dist + un diám es la dist de centro á centro de los remaches. El principio en que se funda la regla se explicará más adelante en el art. 7.

**Primero.** Elíjase un diám de remache igual ó mayor que .85 veces el espesor de la plancha. En la práctica es generalmente 1.5 veces para planchas de ½ pulg (12½ mm) ó más gruesas; ó 2 para planchas de un grueso menor de ½ pulg.

**Segundo.** Multiplíquese la tensión total más grande en libs (ó en kg si se usa el sistema métrico) que pueda obrar sobre toda la junta, por el coeficiente (3, 4 ó 6, etc.) de seguridad, y llámese *p* el producto.

**Tercero.** Multiplíquese el área de (*crippling*) desgarramiento del remache (esto es, su diám × el espesor (en pulgs ó en cm, según el sistema empleado) de la plancha por 60,000 (libs por pulg cuad) (4,218.573 kg por cm cuad). El producto es la resistencia máxima al desgarramiento de un remache. Llámeselo *m*.

**Cuarto**. Divídase á $p$ por $m$. El cociente será el número de remaches necesarios para soportar el esfuerzo de tensión dado con el grado de seguridad que se requiere. Entonces **la dist neta de los remaches será :**

$$\textbf{Dist en pulgs} = \frac{\text{Número de hileras} \times \text{diám en pulgs} \times 60{,}000}{38{,}500}$$

$$\textbf{Dist en cm} = \frac{\text{Número de hileras} \times \text{diám en cm} \times 4{,}218.573}{2{,}707}$$

**Quinto**. La dist neta de uno y otro agujero extremo de una hilera al borde lateral de la plancha no debe ser menor que la mitad de la dist neta comprendida entre dos remaches en una hilera.

(*Obs. del T.* — Pondremos un ejemplo en sistema métrico análogo al que trae el autor en medidas inglesas.)

Ejemplo : Una junta plana ó de tope de doble cubrejunta para una plancha de 1.27 cm de espesor, tiene que soportar una tensión efectiva de 15,308.794 kg con una seguridad igual á 4, es decir, que no se rompe con menos de 15,308.794 × 4 = 61,235.176 kg. ¿Cuántos remaches debe llevar esta junta y á qué dist se deben colocar?

**Primero**. Tendremos que .85 veces el espesor de la plancha es 1.27 × .85 = 1.08 cm, por tanto estos remaches no deben tener un diám inferior á 1.08 cm, pero tomaremos 2 cm.

**Segundo**. La tensión más grande × coeficiente de seguridad = 15,308.794 kg × 4 = 61,235.176 kg = $p$.

**Tercero**. El área de desgarramiento de un remache × 4,218.573 (= 60,000 libs por pulg cuad) = 2 × 1.27 × 4,218.573 = 10,715.175 = $m$.

**Cuarto**. $\frac{P}{m} = \frac{61{,}235.176}{10{,}206.205}$ = más de 5.5 (digamos 6 remaches) que se requieren de cada lado de la junta.

**El espacio neto** ó **ancho neto** entre ellos será, **si los 6 remaches están en una hilera :**

$$\frac{\text{Diám} \times 4{,}218.573}{2{,}707} = \frac{2 \times 4{,}218.573}{2{,}707} = 3.117 \text{ cm.}$$

**La dist de centro á centro** = espacio neto + diám = 3.117 + 2 = 5.117 = 2.558 diáms. En la práctica, para evitar molestas decimales, podemos hacer el espacio neto = 3 cm, y la dist entre los centros 5 cm, pero para ilustrar mejor el manejo de la regla tomamos un número de decimales más exacto.

**Quinto**. La dist neta de cada agujero extremo al borde lateral de la plancha es la mitad de 3.117 = 1.558 cm.

**El ancho total de hierro neto** es igual á un espacio neto × número de remaches = 3.117 × 6 = 18.702 cm; y el ancho total de plancha es igual á una dist de centro á centro × número de remaches = 5.177 × 6 = 31.062 cm.

El área de la sección transversal de plancha no agujereada es 31.062 × 1.27 = 39.448 cm cuad; su resistencia á la tensión **antes de hacerle los agujeros** es 39.448 × 3,163.93 = 124,810.7 kg.

La resistencia de nuestra junta, omitiendo el rozamiento, es por tanto :

$\frac{61{,}235.18}{124{,}810.70}$ = .52 de la resistencia de la plancha primitiva no agujereada.

**Si los 6 remaches están en 2 hileras** de á 3 remaches cada una, **la dist neta entre dos remaches** de una hilera será el doble de antes, es decir (siguiendo el ejemplo en sistema métrico. *N. del T.*), el doble de 3.117 = 6.234 cm. **Dist de centro á centro** = 6.234 + 2 = 8.234 cm = 8.234 ÷ 2 = 4.117 diáms. **Dist neta del agujero** extremo al borde lateral de la plancha = mitad de 6.234 = 3.117 cm. **Ancho total de hierro neto** = 6.234 × 3 = 18.702 cm. **Ancho total de plancha** = 8.234 × 3 = 24.702 cm. **Área de la sección transversal de la plancha no agujereada** = 24.702 × 1.27 = 31.371 cm cuad. **Resistencia máxima á la tensión** de la plancha no agujereada = 31.371 × 3,163.93 = 99,255.64 kg. **Resistencia máxima de la junta remachada**, omitiendo el rozamiento = $\frac{61{,}235.18}{99{,}253.64}$ = .62 de la de la plancha no agujereada.

De esta manera vemos que la disposición adoptada de dos hileras presenta la misma resistencia que una hilera con menor ancho y menor área de plancha. De seguro que requiere *cubiertas más grandes*.

**Si los 6 remaches están en 3 hileras** de á 2 remaches cada una, el **área de la sección transversal de la plancha no agujereada** es 4.2565 pulgs cuad. **Su resistencia á la tensión** 191,542 libs. Resist de la junta remachada $\frac{135.000}{191,542}$ = .7 de la de la plancha sin agujerear.

El ancho total de hierro neto (7.0128 pulgs); su área (7.0128 × .5=3.5064 pulgs cuads); y su resistencia máxima á la tensión (3.5064 × 38,500=135,000 libs), son los mismos en cada caso. El último valor es la resistencia requerida de la junta á la ruptura, como al comienzo de nuestro ejemplo, y es igual á la resistencia al aplanamiento combinada de los seis remaches.

Efectuando los cálculos en sistema métrico obtendremos resultados análogos, para el caso de que los **6 remaches estén dispuestos en tres hileras de á dos remaches**, á saber:

**Área de la sección transversal de la plancha no agujereada** es =27.46019 cm cuad (4.2565 pulgs cuad). **Su resistencia á la tensión** =86,882.132 kg (191,542 libs). Resistencia de la junta remachada = $\frac{61,235.176}{86,882.132}$ = .7 de la de la plancha no remachada.

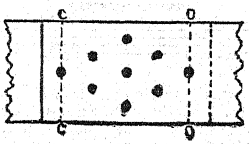
El ancho entero de hierro neto=17.8122 cm (7.0128 pulgs); su área=17.8122 × 1.27=22.6215 cm cuad (3.5064 pulgs cuad); y su resistencia máxima á la tensión 22.6215 × 2707=61,236.4 (135,003 libs), son los mismos en ambos casos. Este último valor es la resistencia á la ruptura de la junta requerida, como al comienzo de nuestra ejemplo; y es igual á la resistencia combinada de desgarramiento de los 6 remaches.

**Art. 6. La dist que separa las hileras de remaches,** de centro á centro de remahe, no debe ser menor de dos diámetros del agujero del remache.

*Nota* 1. Con nuestras constantes para tensión, esfuerzo cortante y compresión, **los remaches no ceden primero por el esfuerzo cortante** en una junta plana ó de tope de doble cubrejunta (y por supuesto sometida al doble esf cort), excepto cuando el diám es igual ó **menor** de .85 del espesor de la plancha, lo cual acontce rara vez. Cuando es igual á .85, la resistencia al desgarramiento y al esfcorte te un remache son iguales cuando se usan los coeficientes supuestos de desga ameto y esf cort.

*Nota* 2. Nuestro ejemplo fué escogido para ilustrar la regla. Rara vez ocurrirá en la práctica que la regla dé un número de remaches sin una fracción, ó que podamos dividirlo por 2 ó por 3 sin que quede un residuo. En el caso de una fracción, es claro, que será mejor tomar á ésta por un remache entero, aunque por ello sea el empate un poquito más resistente de lo necesario. Si el número de remaches resulta ser, por ejemplo, 7 ó 9, podemos formar dos hileras: una de 3 y otra de 4 ó una de 4 y otra de 5, etc. Además, el ancho de la plancha se fija frecuentemente de antemano por alguna necesidad de la construcción, y debemos disponer los remaches teniendo cuidado en todos los casos de conservar el área calculada de hierro neto en una hilera, etc.

*Nota* 3. Nos hemos limitado (como dijimos al principio que lo haríamos) á la junta plana ó de tope sencilla de dos cubrejuntas con los remaches colocados en 1, 2 ó más hileras paralelas á cada lado de la línea de unión, que es lo más resistente y lo que más comúnmente se usa en construcciones de ingeniería. La necesidad á veces



impone disposiciones más simples, para las cuales no podemos dedicar espacio en esta obra, y cuya resistencia no se calcula tan rápidamente. Éstas algunas veces dan resultados que parecen extraños á los poco conocedores; así esta junta recubierta se rompe transversalmente al hierro neto de una plancha por *cc* ó por *oo*, donde hay más hierro, y en donde, por lo tanto, podría creerse más resistente,

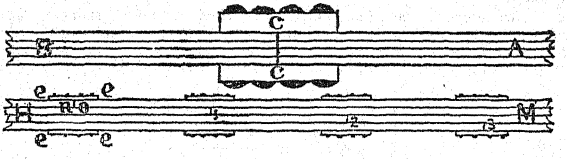
*Nota* 4. **La tabla siguiente** indica aproximadamente las resistencias relativas de las formas comunes de juntas de dimensiones adecuadas, variando con la calidad de las láminas y de los remaches

| | Con rozamiento. | Sin rozamiento. |
|---|---|---|
| La plancha primitiva sin agujeros | 1.00 | 1.00 |
| Junta plana ó de tope con roblonadura doble con dos cubrejuntas | .80 | .64 |
| Junta plana ó de tope con roblonadura doble con una cubrejunta | .65 | .52 |
| Junta plana ó de tope con roblonadura sencilla con una cubrejunta | .50 | .40 |
| Junta de recubrimiento con roblonadura doble | .65 | .52 |
| Junta de recubrimiento con roblonadura sencilla | .50 | .40 |

*Nota* 5. Las resistencias tubulares mencionadas para las **juntas de recubrimiento**, pueden obtenerse aproximadamente adoptando las dimensiones siguientes, según que la junta sea de roblonadura doble ó sencilla.

| | **Roblonadura doble en zizás.** | | **Roblonadura sencilla.** | |
|---|---|---|---|---|
| | En espesores. | En diáms. | En espesores. | En diáms. |
| Llamando los espesores de las planchas | 1 | .6 | 1 | .6 |
| Hágase entonces el diám del remache | 1.67 | 1.0 | 1.67 | 1.0 |
| — — ancho de la recubierta | 9.0 | 5.4 | 5.67 | 3.4 |
| — — dist de centro á centro | 7.0 | 4.2 | 4.5 | 2.7 |
| — — la dist del *extremo* de las planchas al *borde* de los agujeros | 2.0 | 1.2 | 2.0 | 1.2 |
| — — la dist de las hileras de remaches, de centro á centro | 3.33 | 2.0 | | |

*Nota* 6. **Si dos ó más planchas colocadas unas encima de las otras,** como las cuatro en AB ó MH, tienen que unirse de manera que actúen como una plancha del espesor *cc*, los diáms de los remaches y el espesor de las cubietras *cc*, *ee* dependerán de que las juntas de las planchas estén todas en una misma línea como *cc* en AB, ó de que se hallen formando una línea quebrada como en 0, 1, 2, 3 en MH;



Es claro que las cubrejuntas *cc* transmiten de A á B, por medio de los remaches ó pernos que las unen, á través de la junta *cc*, toda la resistencia que por partes compensa la que se pierde por la separación de las cuatro planchas en esa junta: mientras que las dos cubiertas *ee*, *ee* y sus remaches ó pernos, de un modo semejante transmiten de *n*, en una sola plancha, á *o*, en la plancha adyacente, á través de, la junta comprendida entre estas dos letras, solamente la resistencia que por partes compensa la que se pierde por la separación de esa sola plancha, y así respecto de las juntas 1, 2 y 3. Por tanto, las cubiertas *cc* y sus remaches, deben ser cuatro veces más resistentes que las que se hallan en una cualquiera de las cuatro juntas 0, 1, 1, 3. La primerá *cc* debe considerarse como uniendo dos planchas sólidas A y B, cada una de un espesor cuádruplo *cc*, y las otras como uniendo dos planchas de un espesor

sencillo: las cubrejuntas *cc* serán, por tanto, cada una como de dos tercios del espesor *cc*, y las otras tendrán cada una un espesor como de dos tercios del de una plancha sencilla. Así: supongamos que cada una de las cuatro planchas en AB ó en MH tienen un espesor de $^3/_4$ de pulgada (19 mm) siendo *cc* de 3 pulgs (76 mm). Cada cubierta *c* tendrá, en consecuencia, $^2/_3$ de 3 pulgs, es decir, 2 pulgs de espesor (ó $^2/_3$ de 76.2 mm=50.8 mm) ó las dos cubiertas *cc* juntas, cuatro pulgs (101.6 mm) que es el espesor real de la junta *cc*. Pero cada cubierta *ee* es sólo de $^2/_3$ de $^3/_4$ pulg ó de ½ pulg de espesor (es decir, $^2/_3$ de 19 mm=12.7 mm), y el espesor real de la junta en 0, 1, 2 ó 3, es el de las tres planchas enterizas (no desunidas) más el de las dos cubiertas, ó $(3\times\frac{3}{4})+(2\times\frac{1}{2})=3\frac{1}{4}$ pulg ó $(3\times19)+(2\times12.7)=82\frac{1}{2}$ mm).

**Art. 7. Principio en que se basa la Regla del art. 5.** Con nuestra constante del esfuerzo cortante (45,000 libs por pulg cuad=3,163.93 kg por cm cuad) y el de desgarramiento (60,000 libs por pulg cuad=4,218.573 kg por cm cuad), y con diáms de remaches iguales ó mayores que .85 del espesor de la plancha, según nuestra regla, la resistencia al desgarramiento de una junta plana ó de tope de doble cubrejunta será igual ó menor que su resistencia al esf cort. Por esto, para evitar gasto inútil de material, bien en las planchas ó en los remaches, debemos hacer.

Resistencia á la tensión de plancha neta transversalmente á una hilera de remaches = Resistencia al desgarramiento de *todos* los remaches. O, ancho total neto de plancha × espesor de plancha × unidad de tensión = área de desgarramiento (*crippling*) de un remache × unidad de desgarramiento × número total de remaches.

Ahora bien, por el art. 3, el área de (*crippling*) desgarramiento de un remache es = diám del remache × espesor de la plancha. Tomamos por unidad del esf cort 60,000 libs por pulg cuad = 4,218.573 kg por cm cuad, y por unidad de tensión 38,500 libs por pulg cuad = 2,707 kg por cm cuad y, deducido de lo anterior, tendremos (*N. del T.* — Damos las fórmulas métricas equivalentes á las del autor):

$$\text{Ancho total neto de la plancha en cm} = \frac{\text{Diám de remaches} \times \text{espesor de plancha} \times 4{,}216.573 \times \text{número total de remaches}}{\text{Espesor de plancha} \times 2{,}707.}$$

Haciendo la dist neta comprendida entre cada remache extremo de una hilera y el borde lateral de la plancha = la mitad de la dist neta comprendida entre dos remaches de una hilera; y llamando la suma de las dos dists extremas un espacio, tendremos, para ambos sistemas de medida:

$$\text{Número de } \textit{espacios} \text{ de una hilera de remaches} = \text{Número de } \textit{remaches} \text{ de una hilera}$$

De manera que

**La dist neta comprendida entre dos remaches de una hilera,** que es

$$= \frac{\text{Ancho neto total de plancha}}{\text{Número de } \textit{espacios} \text{ de una hilera}} = \frac{\text{Ancho neto total de plancha}}{\text{Número de } \textit{remaches} \text{ de una hilera}}$$

$$= \frac{\text{Diám de remaches} \times \text{Espesor de plancha} \times 4{,}218.573 \times \text{Número total de remaches}}{\text{Espesor de plancha} \times 2{,}707 \times \text{Número de remaches de una hilera}}$$

Pero

$$\frac{\text{Número total de remaches}}{\text{Número de remaches de una hilera}} = \text{Número de hileras.}$$

Por consiguiente, omitiendo el «espesor de plancha», común al numerador y al denominador, tenemos, como la regla del art. 5.

$$\textbf{Dist neta de los remaches en cm} = \frac{\text{Diám de remaches} \times 4{.}218{.}573 \times \text{Número de hileras}}{2{,}707}$$

**Pero si el diám de los remaches es menor que .85 veces el espesor de la plancha,** la resistencia *al esfuerzo cortante* de una junta plana ó de tope de doble cubrejunta (con nuestros coeficientes para esf cort y desgarramiento) es menor que su resistencia al desgarramiento. En tales casos, para la dist neta comprendida entre dos remaches de una hilera, tendremos:

$$\textbf{Dist neta} = \frac{\text{Area circular del remache} \times \text{unidad del esf cort}}{\text{Espesor de plancha} \times \text{unidad de tensión}} \times 2$$

*Nota* 1. **Por ser las juntas de dos cubrejuntas, expuestas al esf cort doble**, las únicas que aquí se consideran, y como los remaches pueden siempre tomarse con un diám mayor que .85 del espesor de la plancha, podemos en la práctica usar siempre la regla del art. 5 para tales juntas, y por eso dimos esa sola regla.

*Nota* 2. **Cuando se use esta regla para otra clase de juntas**, tales como de recubrimiento ó juntas planas ó de tope de cubrejunta sencilla, recuérdese que los remaches en dichas juntas están expuestos al esf cort **sencillo**, y por consiguiente podemos hacer uso de la regla del art. 5 (para el desgarramiento (*crippling*) solamente cuando el diám es 1.7 ó más veces el espesor de la plancha. **Si es menor**, úsese la regla que precede para el esf cort, todo en el supuesto de que se usen nuestros coeficientes precedentes de desgarramiento y esfuerzo cortante.

**Pero el coeficiente de tensión debe variarse** para cada clase de estas otras juntas, para tomar en cuenta los efectos de debilitamiento ocasionados por el doblez mostrado en W, figs. 3, como se ha deducido aproximadamente de los experimentos. El autor cree que las siguientes unidades de tensión darán resultados seguros aproximados, sin rozamiento. **Para juntas planas ó de tope**, de roblonadura doble, 38,500 libs por pulg cuad (2,707 kg por cm cuad) como se adoptó anteriormente. **Para juntas de recubrimiento de roblonadura doble**, ó juntas planas ó de tope de una cubrejunta, 28,000 libs por pulg cuad (1,968.67 kg por cm cuad). Para juntas de recubrimiento **de roblonadura sencilla** ó juntas planas de una cubrejunta, 24,000 por pulg cuad (1,687.43 kg por cm cuad). Pero como se dijo anteriormente, en materia de roblonadura no se llega á obtener gran certeza.

*Nota* 3. **Un empate ó unión puede ceder por desgarramiento** sin que se sepa y ni siquiera se haya sospechado, pues el hecho de que ceda no implica que alguna cosa se **rompa**, sino simplemente que la junta se ha **alargado**, y esto puede no descubrirse aun cuando se la observe *ligeramente*. Todavía puede suceder, y probablemente ha sido á menudo causa suficiente para dañar y aun destruir puentes y techos, el que se hayan desarrollado esfuerzos en donde no se habían tomado las precauciones necesarias.

# FERROCARRILES
## VÍA

### GENERALIDADES

**1.** La vía de ferrocarril como ordinariamente se construye en los Estados Unidos, se compone de las siguientes partes :

**2. Carriles,** ¶ 83. Las ruedas del material rodante ruedan sobre la cabeza del carril, el desgaste de la llanta de la rueda se verifica sobre la cabeza del carril y el de las pestañas sobre el costado de la cabeza del carril. Los carriles tambien sirven o hacen el oficio de vigas cortas cubriendo los espacios entre las traviesas, teóricamente la cabeza del carril trabaja por compresion, el alma por cizallamiento, y la base en tension; pero desde el momento que los carriles deben actuar como vigas *continuas*, los esfuerzos en las cabezas y bases necesariamente se reflejan sobre cada traviesa. La base del carril sirve tambien para distribuir la carga sobre la traviesa, y permitir que agarren los clavos; y ofrece la principal resistencia contra la flexion lateral.

**3. Uniones,** ¶¶ 145, etc. Los extremos del carril se unen entre sí y en línea por medio de bridas, las que se aseguran a los costados de los carriles, cerca de sus extremos por medio de tornillos que atraviesan las bridas y el alma del carril.

**4. Clavos,** ¶¶ 96, etc. Estos se introducen en las traviesas al lado de los carriles, asegurándolos en firme a las traviesas, y por medio de la cabeza que está ensanchada muerden los cantos de la base del carril; y la pata del clavo resiste el deslizamiento lateral de los carriles sobre las traviesas.

**5. Platinas,** ¶¶ 135, etc., se usan generalmente para distribuír las presiones del carril sobre una área mayor en la superficie de la traviesa. De este modo se reduce la unidad de presion y la tendencia a aplastar la traviesa por efecto de las cargas.

**6. Traviesas,** ¶¶ 31, etc., sirven para distribuir en, y al traves del balasto, las cargas verticales, y los empujes horizontales producidos por el material rodante.

**7. Balasto,** ¶¶ 19, etc., No solamente soporta las cargas y las trasmite al terreno sino que tiene la funcion adicional de prolongar la duracion de las traviesas, permitiendo que el agua fluya a traves de él.

**8. Lecho de la via.** La via propiamente, incluyendo el balasto, descansa sobre el lecho o apisonado, que no solamente debe ser de material firme para retener el balasto y la via a nivel, sino que debe también estar preparado para desalojar el agua que pueda recogerse. Con este objeto a menudo se provee de zanjas o cunetas a lo largo del apisonado para conducir el agua que fluye de la vía, excepto cuando la vía está en terraplen.

### Especificaciones.

**9.** En el curso de este artículo sobre Via, se ha hecho un uso liberal de especificaciones y otros testimonios de la práctica establecida; y cuando se hace mención de tales datos ó sintesis, el hecho se indica con notas al pie, la propia marca de llamada se coloca al comienzo y fin de cada párrafo o mencion, acompañado en algunos casos por números que denotan el año de su publicación.

Las referencias usadas con mas frecuencia son :

* nota al pie, se refiere a Asociacion Americana de Ingeniería de Ferrocarril; Manual 1915.

† nota al pie, se refiere a Especificaciones del Ferrocarril de Pennsylvania para la construcción y mantenimiento de Ferrocarril. Tipo 1909, y otras especificaciones del mismo ferrocarril, 1908-1914.

‡ nota al pie, se refiere al ferrocarril Unión Pacific. Reglas y Reglamentación para el mantenimiento de Via y Estructuras, 1909.

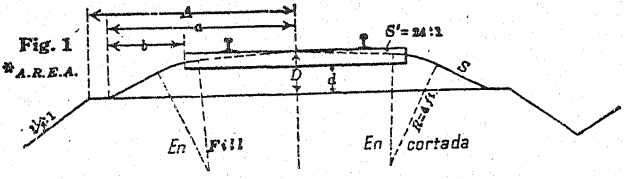
## Clasificación de las Vías.

Ascn Am de Ing de F. C. Manual 1915, p. 15.

**10.** Los ferrocarriles, y partes (región o zona) de ferrocarriles, estan clasificados por la Ascn Am Ing F. C. según el volumen y carácter de su tráfico como sigue: (*N. del T.* — Una milla son 1.609 metros.)

| Clase. | Clase A, B ó C incluye todas las regiones de un ferrocarril. | Millaje de vagon de carga por año por milla. | Millaje de vagon de pasajeros por año por milla. | Velocidad máxima tren de pasajeros millas/hor. |
|---|---|---|---|---|
| A | Teniendo (1) mas de una via principal, ó (2) vias únicas principales con tráfico < ..... | 150.000 | 10.000 | 50 |
| B. | Vía única, con tráfico < A, y < .. | 50.000 | 5.000 | 40 |
| C. | No llenando los requisitos de tráfico de las clases A y B ..... | | | |



**11. Vía única.**

*Ascn Am Ing F. C. Fig. 1.

Se recomienda sembrar yerba o raices en la parte saliente del apisonado próximo a la zanja o cuneta y en el talud de la zanja.

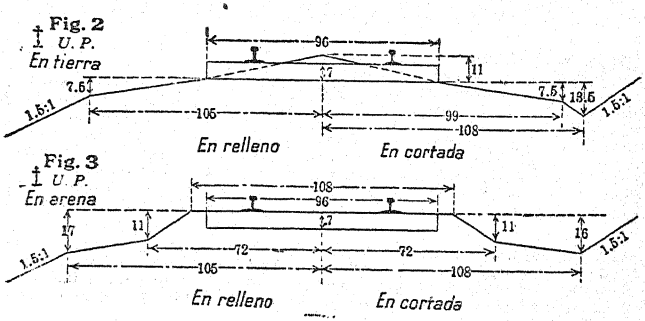
§ Las dimensiones de la clase A dan el hondo mínimo, *d* bajo las traviesas. Se recomiendan solamente en los afirmados más consistentes y provistos del mejor desague



‡ **Doble Vía.** 13 pies (3.965 m.) entre los centros de vía. * ‡

## LECHO DE LA VIA

**Especificaciones.** (Véanse los números y la tabla arriba.)

**12. Zanjas.** Las de amplias dimensiones y talud para buen desagüe, no son solamente esenciales para la mayor economía en la conservación, sino que, mejorando su corriente, pudieran también permitir el uso de balasto barato que de otro modo no se pudiera aceptar. En excavaciones largas de pequeña pendiente pudiera ser necesario darle á las zanjas un declive mayor que el del apisonado, necesitando un aumento gradual en su hondo de la cima hacia abajo, con el correspondiente aumento en su ancho. Las pendientes de las zanjas (comunmente de $\frac{1}{3}$ á $\frac{1}{2}$ por ciento) deben regirse por las condiciones en cada caso : tales como largo y hondo de la excavación; naturaleza del material (con materiales impermeables se necesitan zanjas más anchas y empinadas); costo del ancho del apisonado, área y condiciones de la vertiente, si el agua sale de los taludes de la excavación, etc. La sección transversal que facilita más el desagüe es la que da mayor área relativamente al perimetro mojado, véase páginas 558, 561, 603, etc.

**13. Para corrientes fuertes,** especialmente en material flojo, la zanja debe ser pavimentada ó cubierta con piedra.

**14.** El talud de la excavación y del terraplén se protegen con frecuencia con **zanjas de superficie** para desecar y que corren paralelas á la vía; hechas á unos 3 á 4, 5 m ó más del borde superior de la excavación.

**15. Desagüe inferior.** Algunas especificaciones exigen el uso de tubos de barro de 6" (15 cm) colocados 0,60 m por debajo de las zanjas ó cunetas.

**Miscelanea.**

**16.** Mr. Don J. Whittemore recomienda *redondear los angulos* que se ven con frecuencia en las secciones transversales del afirmado. Memorias de la Asociación de Ingenieros Civiles Americanos, Sept. 1894.

**17. Cima.** Para facilitar la desecación del balasto se acostumbra darle al apisonado una cima haciendo su elevación 4 ó 5 cm más alto en el centro que en los costados. El perfil de la sección transversal puede ser una curva, ó puede consistir en líneas rectas, descendiendo diagonalmente desde el centro.

**18. Línea de siembra.** En los terraplenes una tira de yerba de un pie (0,305 m) de ancho aproximadamente, á lo largo del afirmado próximo á cada borde protege el talud contra los arrastres que produce el agua y disminuye la pérdida del balasto.

---

* Asen Am Ingo F. C. † F. C. Pen. ‡ F. C. U. Pacific. Véase tambien especificaciones pag. 853.

## BALASTO

**19. Piedra.** * Piedra picada en pequeños fragmentos por medios artificiales. La piedra picada es la preferida universalmente como balasto. Las mejores piedras en orden de preferencia aproximadamente son : roca verdosa, granito (ó roca granitica conteniendo hornablenda en lugar de mica), piedra calcárea y piedra cuarzosa. La piedra cribada del triturador se usa comunmente para andenes, y como balasto para vías laterales, pero se revuelve mucho con el agua debajo de las traviesas. *Requisitos;* — † " Roca verdosa ó una piedra ignea aceptable ó igualmente dura y apropiada..... es considerada como material típico. Fuerza de compresión $<$ 844 kg por cm cuad; piedra calcárea $<$ 703 kg por cm cuad. Debe estar rota en forma cúbica. Debe pasar por un aro de 7,5 cm, pero no por un aro de 3 cm. †

**20. Cascajo.** Es barato cuando se encuentra cerca del trabajo y se coloca fácilmente. La arena y la greda en el cascajo impide el desecado; mientras que la arena y el polvo causan el desgaste de llantas y muñones. *Requisitos.* * Guijarros que pasen un aro de 6 cm y que no pasen la criba nº 10 (1915) * † $<$ 6 cm (1908 †).

**21. Escoria dura.** La escoria de los Altos Hornos, depositada y enfriada al aire. Si contiene poca cal libre, es dura y vidriosa y cuando se tritura rivaliza con la piedra picada como material para balasto; pero á veces afecta las traviesas químicamente. Un exceso de cal libre es propenso á desintegrarlo y algunas veces fragua como el mortero.

**22. Escoria granulada.** Escoria á la cual se le haya inyectado agua cuando esté derretida. Se compone de particulas de tamaño muy uniforme como los granos de arena gruesa. Se pone fácilmente y se usa en patios y vías laterales. Es propenso á desintegrarse, solidificarse, é impedir el desecado si hay presente mucha cal libre.

**23. Cisco. Cenizas.** Sacado de las fosas de las locomotoras, Balasto de ceniza deseca bien, pero cede con el tráfico pesado, á veces daña las traviesas químicamente en especial cuando se mojan *. Recomendado para ramales con tráfico ligero, en desvíos y vías de patio cerca de los puntos de origen; como sub-balasto en lugares mojados y esponjosos; como sub-balasto en trabajo nuevo donde el relleno está cediendo; y en lugares donde la vía se levanta por las heladas. Dispongase lo conducente para mojar las cenizas tan pronto se saquen 1915 *.

**24. Greda quemada.** Como balasto deseca bien, es fácil de trabajar y soporta bien el tráfico ligero. *Requisitos;* — * Use stratum negro ú otra greda cualquiera libre de arena ó cieno. Antes de establecer la estufa ú horno para este proposito pruebese el material en una estufa pequeña. Quemese bien todo. El combustible debe ser fresco y bastante limpio para que queme con fuego limpio. Tengase a mano suficiente combustible para evitar interrupciones mientras dure la operación. Enfrie el balasto antes de cargarlo fuera de la fosa. Absorción de agua $>$ 15 % en peso 1911 *.

**25. Arena cuarzosa *.** Particulas de cuarzo, aproximadamente tan grandes como granos de trigo. Es el residuo de los molinos en el que los minerales de zinc y plomo se separan de la roca que los contienen *. Este balasto se trabaja fácilmente. No deja crecer la yerba, soporta el tiempo de agua y retiene su superficie bien; pero debido á la falta de cohesión se rueda fácilmente de costado. A grandes velocidades levanta polvo.

**25a. Arena.** Se maneja fácilmente como balasto. No es plástico cuando se moja; pero se levanta con las heladas, y cuando se seca es muy polvoriento y por consiguiente molesto á los pasajeros, además dañino al material rodante y es causa de que se calienten las cajas de las chumaceras.

**25b. Lodo.** Como balasto, en tiempo de agua, se convierte en fango. Mientras más arena contenga mejor.

**25c. Estrata.** Una clase de arcilla bastante tenaz que no contiene arena.

**25d. Horsteno *.** Un pedernal impuro, que se produce en depósitos naturales *.

---

* Asch Am Ingo F. C. † F. C. Pen ‡ F. C. U. Pacific.

### Sección Trasversal del Balasto.

Vease figs 1-3.

**26. Profundidad.** El balasto debe ser de tal profundidad que la carga, distribuida sobre el afirmado no aplaste el balasto o rompa las traviesas.

**27. Ancho.** La sección del balasto debe ser bastante ancha de modo que retenga firmemente la via en su linea. El ancho necesario para esto depende del peso y angulosidades del material. El talud lateral del balasto debe ser de tal modo que la sección retenga su forma bajo la trepidación de los trenes.

**28.** La economia en el primer costo efectuada por la adopción de un afirmado *muy estrecho* puede ser contraproducente por el aumento en el costo de mantenimiento, debido a la dificultad en darle adecuado desagüe y en mantener el balasto en su lugar. En excavaciones, un apisonado estrecho aumenta las dificultades para reponer las traviesas.

**29. Traviesas en el balasto.** Con piedra picada, escorias y otros balastos favorables al desagüe, la superficie superior del balasto se hace pareja con la parte superior de las traviesas; y en materiales muy ligeros y que no apisonan el balasto, se extiende un pie o dos (30 a 60 cm) mas allá de los extremos de las traviesas a cada lado de la via, pero en materiales que no facilitan el desagüe, el extremo de la traviesa se deja descubierto a fin de facilitar la evaporación y evitar que se revuelva el balasto en tiempo de agua. En lugares húmedos el balasto debe ser mas hondo que lo acostumbrado.

*En vias de la clase C, úsese cualquier material que haga mejor via que la que haga el afirmado natural 1915*.

**Manejo, colocación, apisonado, limpieza y costo del balasto;** véase el epigrafe « Colocación y mantenimiento » ¶¶ 183, etc.

**30. Metros cúbicos por kilómetro de via.**

| Hondo total. | Via simple. Ancho superior en metros | | | | Via doble. Vias 3,96 m Aparte centro á centro. Ancho superior en ms. | | | | Hondo total. |

## TRAVIESAS

### * Definiciones.

**31. Grietas.** Pequeñas hendiduras en la madera debido a su curación.
Traviesa entresacada. Una traviesa que no se ajusta a la especificación.
Traviesa tildada. Afectada por enfermedad del moho.

**Cara.** La superficie superior ó inferior de una traviesa.

**Traviesa de mediacaña.** La que tiene mas ancho en la cara inferior que la superior **Cabezal.** Un miembro o miembros de un juego usado para soportar el mecanismo para operar las agujas de un chucho.

**Traviesa de corazon.** Cuando tiene savia en una o dos esquinas solamente; la albura que mida $\geq$ 3 cm en cualquier esquina en lineas trazadas diagonalmente a traves del extremo de la traviesa. Vease tambien Traviesa toda de corazón.

**Traviesas intermedias.** Cualquier traviesa, usada entre traviesas de junta.

**Traviesa intermedia.** Una traviesa que se usa en una unión de carriles.

**Traviesa picada.** Hecha del arbol ciprés afectada de una enfermedad que forma excrecencia parecida al hongo, conocida localmente como *picada*.

* Asen Am Ingo F. C. † F.C. Pen ‡ F.C.U. Pacific. Vea tambien especificaciones, p. 853.

**Traviesa de poste.** Hecha de un arbol de tamaño tal que no puede dar mas de una traviesa de una sección. Labrada o aserrada en 2 caras paralelas.

**Traviesas en cuartos.** Hechas de un arbol de tamaño tal que puede dar solo cuatro traviesas en su seccion transversal.

**Traviesa de savia.** La que muestra mas cantidad de savia que la prescrita.

**Venteada.** Separacion de las fibras de la madera debido a la accion del viento.

**Traviesa de plancha.** Una traviesa hecha del corte exterior de un tronco.

**Traviesa costera.** Aserrada en la cara de arriba y de abajo.

**Traviesa hendida.** Hecha al hendir un arbol de tamaño tal que pueden hacerse de una seccion dos ó más traviesas.

**Traviesa de corazón.** Que no tenga savia. Vease tambien traviesa de corazón.

**Traviesa de reemplazo.** Cualquier traviesa que no sea de madera.

**Traviesa de chucho (1).** Traviesa de una pieza usada para soportar un desvio.

**Traviesa sangrada.** Hecha de un árbol al cual se le ha extraído la resina o trementina antes de tumbarlo.

**Traviesa tratada.** Una traviesa que ha estado sujeta a un procedimiento con objeto de que se conserve.

**Traviesa escasa.** Es cuadrada y mostrando parte de la superficie original del arbol en una o mas esquinas *.

## Generalidades.

### Dimensiónes, Colocación, etc.

**32.** Una traviesa actuando como una viga contínua, sirve para distribuir la presión del carril sobre el balasto que esta debajo de él, y sus dimensiones deben ser tales que permitan efectuar esta distribución con uniformidad tolerable. Cuando haya una traviesa mas apoyada en el medio de su longitud que cerca de los carriles, se dice que está *calzada al centro*. Una traviesa de suficiente largo trasmite una buena proporción de la carga al balasto distante de los carriles. El grueso es usualmente 6 ó 7 pulgadas (15 a 18 cm). Una traviesa de 6 pulgadas no es lo bastante rígida para tráfico pesado, especialmente cuando haya posibilidad de calzarla al centro; y propensa a rajarse con los clavos, teniendo en cuenta que éstos llegan hasta muy cerca de la cara inferior. Como la rigidez de una viga varia como el cubo de su altura, la resistencia a la flexión en una traviesa de 7 pulgs es á la de 6 pulgs como 343 es á 216, o como 100 es a 63. Rara vez se excede el peralto de 7 pulgadas (18 cm) excepto en maderas flojas.

**33.** Si mas de un 40 % del largo de un carril descansa en las traviesas, la proximidad de las traviesas estorba el apisonado. La luz mínima entre las traviesas es de 30 cm aproximadamente. Con la separación usual de traviesas un peralto de mas de 7 pulgs estorba el trabajo de apisonar. Con traviesas extremadamente anchas, no siempre se utiliza, este exceso como apoyo porque raravez tales traviesas son apisonadas del todo como las estrechas.

**34.** Cuando el clavo entra en la madera tangencialmente á las vetas es fácil rajar la traviesa.

**35.** Las traviesas deben ponerse con la cara del corazón abajo, a fin de que las vetas queden en tal posicion que dejen correr el agua.

**36.** Las traviesas de poste dan al carril un asiento de corazón que resiste mejor al rozamiento que la savia y los lados combados dan una superficie adicional de apoyo.

**37. Cortaduras por el carril.** La humedad que se aloja entre el carril y la traviesa tiende a desmejorarla, y la carga ayudada por el movimiento ondulatorio del carril rompe las fibras. Esta « cortadura » es la causa principal de que fallen las traviesas.

**38.** Las traviesas deben *protegerse* del desgaste mecánico por medio de *placas* y tornillos « tirafond ». Ascn. Am. Ingo F. C. Memoria de 1915. Volumen 16, p. 522.

* « El uso de traviesas tratadas se recomienda donde quiera que sea viable »*.

---

* Ascn. Am. Igo F. C. † F. C. Pen. ‡ F. C. U. Pacific. Vease tambien especificaciones, p. 853.

(1) (*N. del T.*) Hemos adoptado el nombre de Chucho (usado en Cuba) para el conjunto de las agujas, etc., que se mueven al hacer un cambio.

## Maderas.

**39. Cedro.** Es liviano y resiste al deterioro bien; pero es aplastado fácilmente por el carril. En vias que tengan tráfico ligero, o donde esté protegido por sillas o platinas, las traviesas de cedro pueden durar de 15 a 20 años. Cedro sano viejo en traviesas dura tanto como el cedro fresco.

**Roble Blanco** es preferido para traviesas. Cuando está en sazón retiene los clavos bien; y resiste la acción cortante del carril mientras no se deteriora. Dura de 5 a 10 años; el promedio en muchas lineas, 8 años y ¼. Una traviesa de roble blanco en sazón de 7 pulgs × 9 pulgs, 8 pies largo (17,5 × 22,5 × 244 cm) pesa cerca de 185 lbs (85 kg).

**Roble roca** es menos sólido que el roble blanco. Su duracion es la misma poco mas ó menos.

**Pino amarillo del sur** en traviesas dura de 4 a 6 años en el sur; y de 8 a 12 años en el norte.

**Castaño** en traviesas dura de 7 á 9 años. Al sol se agrieta mucho; pero retiene los clavos bien y es de dureza mediana.

**Pino rojo**, es blando pero durable. Traviesas de pino rojo con platinas, duran de 10 á 14 años.

**Cerezo, Acacia y Nogal** en traviesas duran cerca de 8 años.

**40. Especificaciones.** * Maderas usables para traviesas sin *tratamiento preservativo*. La variedad de roble blanco, pino amarillo, todo de corazon de hoja larga, ciprés (que no sea blanco), pino rojo, cedro blanco, castaño, catalpa, acacia, nogal, cerezo negro *.

* Maderas preferibles que requieren *un tratamiento preservativo* aprobado por el comprador. La variedad del roble rojo, aya, olmo, meple, goma, *lodge pole*, pino amarillo del oeste, pino de Noruega, Carolina del Norte y otros pinos blancos, abeto rojo, pinabete, cicuta, alerce *.

**Traviesas para chuchos** (1). † Usables *sin tratamiento preservativo;* robles blancos, acacia negra, nogal negro, cerezo negro, pinos de hoja larga. Usables *unicamente despues del tratamiento preservativo;* robles rojos, aya, nogales americanos, meples duros, abedul 1913 †. Vease también bajo el epígrafe Desvios, Parte I, ¶ ¶ 128, etc.

## Dimensiones.

**41. Clasificación.** Dimensiones de **Asen Am Ingo F. C.** Manual, 1915, p. 59.

| * Clase. | Grueso en cm. | Ancho en cm. | Volumen de una traviesa, en decm cubs. Largo, 2.44 ms decm cubs. | Largo, 2.60 ms decm cubs. | Largo, 2.74 ms decm cubs. |
|---|---|---|---|---|---|
| * A | 17.50 | 25.40 | 113.00 | 117.00 | 124 00 |
| B | 17.50 | 22.86 | 99.00 | 105.30 | 111.30 |
| C | 17.50 | 20.32 | 88.00 | 93.40 | 99.00 |
| D | 15.00 | 22.86 | 85.00 | 90.00 | 95.40 |
| E | 15.00 | 20.32 | 75.50 | 80.10 | 85.00 |

***Exceso permitido:** — en grueso ½ pulg (1 ¼ cm); en ancho, 2 pulgs (5 cm); en largo, 1 pulg (2.5 cm). En traviesas de poste con costados redondos, y en traviesas de mediacaña, la cara puede ser < que lo arriba expuesto (< 15 cm), siempre que el área de la sección transversal < que la correspondiente a las dimensiones de la tabla, grueso < 15 cm *.

## Separación.

**42. Numero de traviesas** necesarias bajo un largo de carril: —

| | En vias de recorrido principal. | En vias laterales y ramales. | En patios y en desviaderos. |
|---|---|---|---|
| *Carril de* 33 *pies* (10,06). | 18 ≒ | 16 ≒ | 16 ≒ |
| ≒ Si las traviesas son < el modelo, | 20 ≒ | | |
| † Según el peso del tráfico, | 16 á 20 ≒ | 16 ≒ | 14 ≒ |
| *Carril de* 30 *pies* (9,15 m.). | 16 ≒ | 14 ≒ | 14 ≒ |
| Si las traviesas son < el modelo. | 18 ≒ | | |

* Asen Am Ingo F.C. † F.C. Pen. ≒ F. C. U. Pacific. Vea también Especificaciones, p. 853.

(1) Véase *N. del T.*, pag 858.

**Para carriles mas cortos** use un número proporcional de traviesas †.

**Distancia máxima permitida entre superficies de apoyo** †. Entre traviesas bajo uniones, 11 pulgs (28 cm); entre traviesas *intermedias* en vias de recorrido principal (18 pulgs) † 45 cm.

## Conservación de madera para traviesas.

**43.** Debido á la crecida escasez y costo de la madera para traviesas, se recurre (1) al tratamiento químico, ¶ ¶ 44, etc. (2), a la selvicultura, ¶ ¶ 54, etc., a la siembra de arboles para traviesas, (3) a la reducción del desgaste de las traviesas por medio de platinas, ¶ ¶ 135, etc., y (4) por el uso de traviesas de otros materiales, como acero ó cemento armado, ¶ ¶ 61, etc.

## Preservativos.

**44. La economia** producida por las traviesas tratadas no solamente consiste en su aumento de duración, sino en la reducción de jornales para renovarlas y la consiguiente alteración del lecho.

**45. Madera inferior.** El tratamiento químico y el uso de platinas, permite el uso de maderas que de otro modo no serian apropiadas y tambien el uso de la madera de savia muerta.

**46. Vapor.** Para traviesas del todo curadas al aire, un vacío preliminar $<$ 24 pulgs (60 cm) de mercurio mantenido $<$ 10 minutos *.

* Para traviesas no del todo curadas al aire una presión de 1,33 kg por cm cuad debe sostenerse durante 30 á 50 minutos y mantenerse (sin excederse) de 1 a 5 horas según la condición y estado de la madera. Un respiradero debe mantenerse abierto en el fondo del cilindro para desagüe y escape del aire y vapor condensado. Después de dar vapor, un vacío $<$ (24 pulgs) de 60 cm de mercurio al nivel del mar (y los grados correspondientes de vacío para otras alturas) mantenido por media hora. Entonces se admite el preservativo sin romper el vacío *.

* A las traviesas sin curar, que tienen que ser creosotadas, puede dárseles mas vapor o curarse en aceite de creosota caliente *.

**47. * Tratamiento al cloruro de zinc (Burnettizing).** Véase tambien *Conservación de la madera*, **mas adelante.** La solución se calienta á $<$ (140° Fahr) 60° centigrados, se admite sin reducir el vacío. La madera debe absorber 0.5 lb de cloruro seco soluble por (pie cub) (28 litros). La solucion debe ser lo suficientemente fuerte para que dé esta absorción y $>$ 5 %. La presion de vapor debe mantenerse en los serpentines de vapor de la máquina durante este tratamiento.

* El cloruro debe ser ligeramente básico, sin ácido libre; hierro $>$ 0,25% *.

* Muestras sacadas con barrenos deben observarse de vez en cuando, $<$ 6 traviesas tratadas en la misma remesa. Los agujeros deben taparse herméticamente con tarugos creosotados *.

* Las traviesas deben dejarse secar (a fin de que se endurezca su superficie) antes de colocarse en la via *.

**48. * Tratamiento al cloruro de zinc, tanino y cola.** Vease pag. 1180. Cloruro de zinc como se explica arriba. Se extrae la solución ó se desagua. Las traviesas se escurren 15 min. Solucion de 2 % de ácido tánico (6.67 lbs del 30 % del extracto de tanino en 100 lbs de agua) aplicado media hora bajo presión de 6.66 kg por cm². La solución de tanino se desagua y una solucion de 1 % de goma (2.1 lbs de goma que contenga un 50 % de gelatina en 100 lbs de agua) aplicada por media hora bajo la misma presion *.

**49. * Creosota.** (Vease pag. 1180). Alquitran aceite de creosota; a 38° centig, completamente liquido, y $<$ 1.03 de densidad; $>$ 3 % de agua; calentado a 170° centig. Presión, 6.33 kg por cm² *.

**50. * Emulsión de zinc creosotado.** La emulsión que contenga $<$ 10 % de creosota. Calentada á $<$ 60° centig, presion 6.33 kg cm². La madera que retenga un promedio de 0.4 lbs de cloruro seco soluble y de 1.25 a 1.5 lbs de creosota por 28 litros. La solución de cloruro de zinc a no mas de 35 %; que contenga $>$ 0.25 % de hierro.

---

* Asen Am Ingo F. C, † F. C. Pen ‡ F. C. U. Pacific. Vea también Especificaciones, p. 853.

**51. * Doble injección de creosota y zinc.** La solución de zinc de no mas de 5 %; calentada á $\lessdot$ 60° centig. La madera que reciba 0.3 lbs de cloruro seco soluble por 28 litros. La solución se desagua inmediatamente, se admite aceite de creosota a 60° centig y se le aplica presion; 3 lbs de aceite por 28 lits. El agua que exceda del 6 % debe extraerse *.

**52. Duración.** Las traviesas de pino creosotadas duran cerca de 15 años, roble creosotado 18 años y de haya creosotada 20 años en línea principal; y pueden dar un tercio mas de servicio utilizándolos después en vías laterales.

**53. Curación, etc.** Las traviesas sin curar se *amontonan para curarlas;* se separan las traviesas verdes de las que están curadas en parte; todas descansando en durmientes tratados, con $\lessdot$ 15 cm de espacio, de aire, bajo la hilera mas baja; la hilera de arriba puesta en declive de modo que escurra el agua. Entre las pilas dejense pasillos de 1.20 m de espacio en una dirección y 30 cm en la otra. El grado requerido de curación se determinará por pruebas, buscando el peso al cual cada madera recibirá mejor el tratamiento; las traviesas que esten amenazadas de agrietarse deben protegerse por hierros dispuestos en forma de S, por tornillos ú otros medios. El labrado de azuela ó barrenado para poner platinas ó tirafondos debe hacerse antes del tratamiento.

**54. Selvicultura.** El cultivo de la madera debe emprenderse solamente por selvicultores expertos. Aquí solamente esbozamos los fundamentos de interés general para los ingenieros.

**55. Tiempo de tumba.** Cualquiera que sea la estación para la tumba de los árboles, las traviesas hechas de estos deben tener cuando menos seis meses para curarse antes de ponerse en la vía. No obstante, las estaciones para cortar y renovar traviesas caen tan cerca una de otra, que es difícil observar las traviesas sin guardarlas por más de un año.

* La madera es preferible cortarla de octubre á marzo *†. Septiembre a marzo †.

**56. Corteza :** Debe quitarse pronto después de la tumba para activar la evaporación y que se pudran (*souring*). Poniendo traviesas en la via con la corteza no solamente se activa el deterioro, sino que hace las traviesas más inflamables. * La corteza debe quitarse de todas las traviesas antes de su entrega á la Compañía. 1915 *.

**57. Los métodos de cortar** árboles y de cortar traviesas de los árboles son generalmente obra de derroche. Frecuentemente se pierde madera dejando tocones grandes innecesarios, y con esto se daña el árbol; hay árboles grandes que de sus ramas se puede sacar traviesas. Frecuentemente se pierde mucho cortando árboles que son suficientemente grandes para dar una traviesa de poste (una de cada sección); mientras que si se esperara 5 o 10 años, dos traviesas pudieran obtenerse de una sección.

**58. Propagación de la selvicultura.** La práctica antigua era plantar solamente árboles que crecieran rapidamente; pero se ha encontrado que otras consideraciones importantes (tales como la posibilidad de ser atacados por parásitos, baja resistencia o poca duración, etc.) pudieran aconsejar la selección de árboles de crecimiento lento. En cada region de terreno disponible, debe estudiarse qué especies pueden producirse mejor. Tambien es frecuente fomentar las tierras que tienen maderas imperfectas, sin tratar de hacer la completa selvicultura desde la semilla.

**59. Para evitar el fuego** y sus pérdidas considerables, se establecen rondas de vigilancia especialmente en tiempo seco.

**60. * Clavos fechados.** De hierro o acero, de galvanizado uniforme de ¼ pulg (6 mm) diám; 2 ½ pulg largo (63 mm) cabeza de $^{3}/_{8}$ (15 mm) diám. Con 2 números estampados de $^{1}/_{10}$ de pulg (1.5 mm) hondo y $^{5}/_{8}$ (9 mm) largo, designando el año. El clavo se introduce en la cara superior de cada traviesa tratada, á 25 cm de la parte de adentro del carril el dia que se coloque en la via. Cada traviesa tratada debe llevar estampado el año en ambas cabezas; esto se hará en la planta del tratamiento antes de tratar la madera *.

---

* Ascn Am Ingo F. C. † F. C. Pen. ‡ F. C. U Pacific. Vea también Especificaciones, p. 780.

## Traviesas de reemplazo.

**61. Generalidades.** Una traviesa de reemplazo es « cualquiera otra traviesa que no sea de madera. » Memorias de la Asen Am Ingo F C 1915. Vol 16, pag. 522. Informe del Comité de Traviesas.

**62.** Debido al aumento rápido de la escasez de madera apropiada, las traviesas de reemplazo se están usando grandemente en Europa; y su uso se ha propagado en muchos ferrocarriles americanos, incluyendo algunos sistemas importantes.

El uso de la traviesa de reemplazo trae un cambio tan radical en la práctica de ferrocarril que se requiere una considerable experiencia en su implantación para determinar satisfactoriamente sus ventajas y desventajas relativas.

**63.** Las traviesas de reemplazo, debido a su sección uniforme en resistencia y en superficie de asiento (y especialmente las de acero), mantienen la vía en mejor alineación y superficie y el desgaste del carril es más uniforme. Las traviesas de madera, aun aquellas de la misma clase de madera, varían en su calidad cuando se ponen y se rinden desigualmente bajo una misma carga, y se deterioran desigual y rápidamente expuestas a la intemperie. Las traviesas de acero cuando están completamente balastradas se ruedan mas suavemente y la vía queda mas estable.

Las traviesas de reemplazo son mas pesadas que las de madera y mas costosas en principio. Se han experimentado dificultades en proveer medios satisfactorios para asegurar los carriles. Vease tirafondos, ¶ ¶ 107, etc.

Con el creciente uso de circuitos eléctricos de señal es importante producir el necesario aislamiento y en conjunto las traviesas de reemplazo ofrecen dificultades á este respecto.

Las traviesas de reemplazo alternadas con traviesas de madera precipitan el deterioro de estas últimas.

En igualdad de condiciones, el mayor peso de las traviesas de reemplazo tienden á dar mayor estabilidad a la vía.

Las traviesas de reemplazo son de acero o de concreto (usualmente armado) o compuesto (compuesto esencialmente de dos o mas materiales). Memorias de las Asen Am Ingo F. C., 1915. Vol. 6, pág. 522. Informe de la Comision de traviesas.

## Traviesas de acero.

**64. Tipos.** En Europa se han usado mucho las « **longitudinales** » o **durmientes** de acero, colocados debajo y paralelos al carril y de « tazas » invertidas de hierro fundido, colocadas opuestas unas á otras bajo los carriles á intervalos y conectados por traviesas extendidas al traves de la vía; pero en América la práctica y experiencia con traviesas de reemplazo se ha practicamente limitado a *traviesas cruzadas* con funciones similares a las que tienen las traviesas de madera.

**65.** Los primeros ensayos fueron con *traviesas de canal invertido* y todavía se estan usando en vias de tráfico ligero; pero la de *tipo de T invertida* llamada traviesa de acero de Carnegie, ¶ ¶ 70, etc., es la que más se usa.

**66.** Un fondo plano que se distingue de los que tienen proyecciones hacia abajo, facilita el apisonado.

**67. Las sujeciones** consisten generalmente en tornillos y presillas o en cuñas. Deben permitir el ajuste para la diferencia de ancho de vía y sección del carril.

**68. El costo** de las traviesas de acero es generalmente de 4 a 6 veces el de las traviesas de buen roble; pero las de acero deben tener mayor duración que la traviesa de roble y mucho más valor como desecho cuando no pueda utilizarse mas como traviesa.

**69. Ventajas y desventajas.** Las traviesas de acero *mantienen* la vía completamente á *cartabón.* Debido a su uniformidad en sección transversal, en resistencia y en superficie de asiento *mantienen la vía* en mejor *alineación y superficie*, y el desgaste del carril es mas uniforme que con traviesas de madera.

En la ausencia de datos suficientes de la experiencia su *duración* es dos o tres veces mayor que la de las traviesas de madera.

Debido á la pequeña sección transversal en metal las traviesas de acero necesitan *mas balasto* que las traviesas de madera de las mismas dimensiones exteriores.

Cuando las traviesas de acero han sido punzonadas con agujeros cuadrados, se encuentra que estos agujeros se empiezan á *rajar* por las esquinas de dichos agujeros.

Las traviesas de acero estan expuestas á *deteriorarse por el óxido*, especialmente en lugares húmedos, como túneles y bajo el goteo de la solucion de sal de los carros refrigeradores. Se han usado *cubiertas de proteccion*, pero son difíciles de aplicar a las traviesas que están en servicio.

La traviesa toda de acero es un substituto satisfactorio con tráfico pesado a media velocidad. Es durable. La alineación y superficie puede mantenerse. (Véase costos de mantenimiento, ¶ 73.) Tiene suficiente elasticidad y puede aislarse. La ligazón es generalmente inadecuada. Memorias de la Asen Am Ingo F. C. 1912, Vol 13, Comisión de Vía.

**70. Carnegie.** La fig. 4 representa la traviesa de acero de la Cía de Acero Carnegie. *A*, plano de toda la traviesa; *B*, elevación lateral; *C* y *D*, secciones transversales o mayor escala en *mn* y *op*, fig. *A*, respectivamente; *E* y *F* muestran la planta y elevación del carril y fijación tipica cuando el balasto es roca ó cascajo gordo ó en pendientes que tengan un tráfico pesado; la pestaña inferior de la traviesa puede rizarse como se muestra en *B* y *D*; pero este rizado obstrucciona el apisonado o calzada del balasto. La traviesa puede agujerearse para recibir dos pesos distintos de carril.

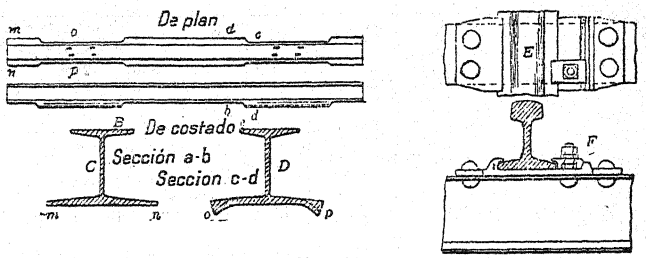

**Fig. 4.**

Dimensiones en pulgs., etc.

(*N. del T.* — Damos entre paréntesis las medidas métricas equivalentes en : Kgs por m; Kgs; cm y mm).

| Sección. | Lbs por pie. | Traviesa 8.5" largo, peso lbs. | Peralto. (21,60 cm). | Ancho pestaña inferior. | Ancho pestaña superior. | Grueso alma. |
|---|---|---|---|---|---|---|
| M 24 | 9.5 (14.15 kgs/m) | 81 (36.74 kg) | 3 (7.62 cm) | 5 (12.70 cm) | 3 (7.62 cm) | 1/4 (5.16 mm) |
| M 25 | 14.5 (21.60 kg/m) | 123 (60.32 kg) | 4 1/4 (10.66 cm) | 6 (15.24 cm) | 4 (10.16 cm) | 1/4 (6.35 mm) |
| M 21 | 20 (29.80 kg/m) | 170 (77.11 kg) | 5 1/2 (14.00 cm) | 8 (20.32 cm) | 4 1/2 (11.43 cm) | 1/4 (6.35 mm) |
| M 28 | 27.8 (41.42 kg/m) | 236 (107.40 kg) | 6 1/2 (16.50 cm) | 10 (25.40 cm) | 5 (12.70 cm) | 5/16 (7.94 mm) |

La *fijación del carril* deja 3 mm de juego vertical y horizontal en el carril.

**71. Aislamiento.** Este consiste en 1/8 pulg. (3 mm) de fibra del cual hay (1) una placa entre las traviesas de acero mostrada en la fig 4 F y la parte superior, de la traviesa, (2) una arandela bajo la arandela del remache, y (3) un buje alrededor de la espiga del remache.

**72. La primera** traviesa de acero Carnegie fué puesta en el Ferrocarril Bessemer y Lake Erie (que controlaba Carnegie) en 1904. Estas traviesas han sostenido bien el tráfico pesado de carga a velocidades moderadas. Sin embargo a velocidades altas su rigidez no ha sido satisfactoria.

Debido a lo restringido del movimiento entre el carril y la traviesa, se ha encontrado que *reduce la trepidación*.

*Cuando se renuevan*, se ha visto que una cuadrilla de peones puede remover, cambiar mas de estas traviesas que de las de madera en un tiempo dado.

Como *protección contra el óxido,* se han sumergido en alquitrán caliente, a un costo de 5 cts una.

*El aislamiento* (Véase ¶ 71). Es bueno mientras está en buen estado; pero a los 3 ó 4 años, las placas de fibra se gastan y los tornillos se aflojan en consecuencia. Véase ¶ 73.

Muchas se han quitado al ponerse instalaciones automáticas de señales.

*El costo* puede calcularse como de $2.00 a $2.60 por traviesa, con 20 cts adicionales por traviesa para la fijación. Esto casi es más que el doble del costo de la traviesa de madera.

**73.** *En el ferrocarril de Pittsburgh y Lake Erie,* las traviesas de acero Carnegie, con fijación de tornillo y grapa, fueron puestas en agosto de 1907 sobre un balasto de piedra calcárea en una extension de 1,342 mts de línea principal de carga y con velocidades de 49 km por hora. El costo de conservación fue como sigue :

| | 1908 | 1909 | 1910 | 1911 | 1912 | Total. | $ por mill. por año. | Por km por año. |
|---|---|---|---|---|---|---|---|---|
| Roble blanco..... | $ 417 | 95 | 128 | 116 | 94 | 850 | 204 | 128 |
| Acero Carnegie... | $ 280 | 153 | 428 | 184 | 348 | 1.393 | 334 | 209 |

En 1911 la via con traviesa de roble blanco fue renovada una vez; la via con traviesa de acero tres veces. Las 17 primeras placas de fibra se quitaron por estar cortadas por la base del carril; 20 tornillos se aflojaron en las presillas de las traviesas. En 1912 el costo comprende $102 por renovación de 1.000 placas de fibra. « Prácticamente no señalamos dificultad de ninguna clase. »

*Otras líneas* han dado informes de menos dificultades en mantenimiento que con traviesas de madera.

**74.** *La pérdida de peso* anual debido al óxido, frotación, etc., ha sido variablemente informado por diferentes ferrocarriles variando de (0.7 lbs), 0.317 kg por traviesa 0.40 % en escorias o cascajo, a (4.5 lbs) (2.041 kg) por traviesa, 0.2.55% en cenizas. Después de siete años de servicio han mostrado poca corrosión externa. De las traviesas puestas en el ferrocarril Pittsburg Shawmut Northern en 1907 se informó que daban « notable satisfacción » en 1913 y aparece que en 1915 estaban « fallando rápidamente. »

Traviesas de acero Carnegie, puestas en el F. C. Erie en abril 1909, se estaban oxidando en 1913 y « *deteriorándose en aire que contenía sal* ».

**75.** En el F. C. Duluth Missabe & Northern dieron gran resultado como reemplazantes de traviesas de madera que dieron mucho que hacer en *terreno pantanoso.*

**76.** Donde se ha usado la *fijación por cuñas* se han experimentado dificultades con materiales compactos, densos.

**77.** En el ferrocarril Lake Shore & Mich Southern; cerca de Sandusky, con *tráfico pesado a gran velocidad* en 1905-6 se pusieron traviesas de acero Carnegie con un bloque de madera asegurado en la parte de arriba de la pestaña superior debajo de cada carril en cada traviesa con un costo completo de $2.25 á $2.50 por traviesa. Los bloques quedaron asegurados con tornillos que pasaban al traves de abrazaderas de metal con forma de U bajo la traviesa. De este modo se aprisiona la fibra de la madera, aumentando la resistencia al tiro de los clavos. Hasta 1908 estas traviesas no dieron mas trabajo con respecto al aislamiento que si fueran de madera, pero mas tarde hubo dificultades con el aislamiento y todas las traviesas se cambiaron en 1915 debido á que se ablandó la madera.

**78.** El ferrocarril L. S. & M. S., cerca de Toledo, en 1907 puso traviesas de acero a las cuales se les quitaron las pestañas ó bordes superiores y se les atornillaron dos bloques de madera, uno á cada lado al traves del alma de la traviesa debajo de cada carril y descansando en las pestañas de la traviesa : los *carriles estaban clavados a los bloques de madera* como si fuera a una traviesa de madera. En 1910 se informó que estaban « en buen estado » y que « sostenían buena alineación y superficie como cualquier via en el ferrocarril L. S. & M. S. ».

**79.** *La traviesa de sección de canal ó artesa invertida,* debido a sus projecciones hacia abajo es desfavorable para el apisonado. De aquí el que se haga de poco peralto y así queda la traviesa débil verticalmente. Todavía se usa en tráfico ligero, como en vias industriales de construcción y vías de minas, etc.

**80.** La fig. 5 muestra dos formas de la traviesa de acero acanalada de Carnegie con sus fijadores.

Se hacen de las siguientes secciones, medidas en pulgadas.

(*N. del T.* — Damos entre parentesis las medidas métricas equivalentes en : kgs por metro; kgs, cm y mm.)

| Sección. | Lbs por pie. | Peralto. | Ancho mayor. | Grueso de l'Alma. | Fig. |
|---|---|---|---|---|---|
| M 19 | 2.5 | 5/8 | 4 | 9/64 | 5 *a* |
| | (3.72 kgs/m) | (15.87 mm) | (102 mm) | 3.57 mm) | |
| M 26 | 3.2 | 13/16 | 4 15/16 | 1/8 | 5 *a* |
| | (4.77 kgs/m) | (20.63 mm) | (126 mm) | (3.17 mm) | |
| M 20 | 6 | 2 | 6 | 3/16 | 5 *b* |
| | (8.94 kgs/m) | (51.6 mm) | (153 mm) | (4.76 mm) | |
| M 27 | 9 | 2 1/4 | 7 | 1/4 | 5 *b* |
| | (13.41 kgs/m) | (58 mm) | (178.60 mm) | (6.35 mm) | |

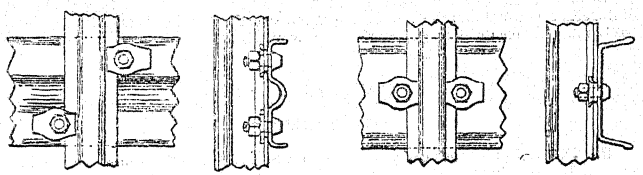

Fig. 5.

*Para trabajos de mina* las grampas son prensadas ó remachadas a la porción horizontal de la misma traviesa.

En 1900-1901 las traviesas de acero Carnegie *mas pesadas*, pesando (199 lbs) 91,5 kg cada una fueron instaladas en el ferrocarril *de Bessemer & Lake Erie*. Después de 8 años de servicio habían perdido (2.5 lbs) 1.15 kg por año y por traviesa = a 1.25 % por año y no mostraban bajo los carriles un desgaste apreciable.

## Traviesas de concreto y compuestas.

**81. Ventajas y desventajas.** Las traviesas de concreto y compuestas son generalmente mas pesadas que las de acero para el mismo servicio, pero mas costosas. Se necesitan meses para el preciso fraguado del concreto. Las superficies cóncavas, si no están protegidas por metal son vulnerables a los golpes como ocurre en los descarrilamientos. Se dificulta proveerla de fijadores satisfactorios. Su peso y lo basto de su superficie le favorecen para la estabilidad lateral, y la ausencia de proyecciones hacia abajo favorecen el apisonado y su cambio. El mismo concreto facilita un aislamiento tolerable para circuitos de señal; pero hay peligro de contactos al traves del metal de refuerzo.

**Generalmente han fallado** por razón de su fragilidad, peso excesivo (que hace su manejo dificultoso) y deterioro del relleno cuando éste es de masilla de asfalto.

Memorias de la Asen Am Ingº F. C., 1912, vol 13. Informe del Comité de Traviesas.

**82.** Las siguientes **relaciones de experiencias** con traviesas compuestas pueden ser de valor, pues indican lo que se ha hecho y lo que debe evitarse al hacer estas traviesas.

**82 a.** Concreto de 1 : 2 : 3 reforzado con tubos longitudinales de hierro dulce de 2 1/4 pulg (57 mm) y una lámina de tela alambrada pesada de 5 × 8,5 pulgs (13 × 21 cm) bajo cada carril. Peso 147 kg; 16,1 kg por fijadores (adicional) $1.50 a $1.75 cada uno.

**82 b.** Trapezoidal con extremos en talud. Reforzado con espirales de malla de alambre nº 16, ½ pulg (12 mm) de paso y con cabillas de ½". Costo $1,50 cada una En el patio de Scully Lineas del Oeste de Pennsylvania se instalaron en 1906 con

balasto de cenizas con tráfico pesado y lento. Los carriles clavados al traves de las placas de traviesas y bloques de madera; 16 traviesas por cada (30 pies) 9.15 m de carril de (85 lbs) 39 kg se desmenuzaron bajo los carriles, se aflojaron los tornillos. La trepidación hizo girar las presillas de fijación aflojando el carril.

**82 c.** Un carril desechado invertido de (65 lbs) 30 kg embebido en concreto. Extremos en talud. Estrechado al centro de la via, á un ancho de la base del carril. Esta sección estrecha evita el movimiento lateral, $0.95 + los fijadores y (180lbs) 82,8 kg, de carril de desecho. L S & M S. Todavía en la via en buen estado. Véase la gaceta de F. C., pag. 594, mayo 1.º 1908.

El ferrocarril Pg Ft W & C. Colocados en1903. Se cambió todo en 1906. El concreto se rompió y separó del acero.
Colocados en 1903. Tráfico ligero de media velocidad.
Se rompió. Se quitaron en 1903.

« La traviesa de concreto que ha tenido más éxito de las que he visto, y en condiciones favorables hace una via aceptable. » Sostiene los descarrilamientos bien. El balasto de roca puede ser demasiado rígido. Cascajo puede ser mejor. Véase la Memoria de 1907. Vol 8, p 465 de la Asen Am Ingo F. C. y mantenimiento de Via.

El Boletín 108, de Feb 1909, p 174 de la A. A. I. F. C. y M. de V. da unos informes favorables del F. C. de L. S. & M. S. y desfavorables de las Líneas de Pennsylvania, Enlace de Chicago, y Lake Erie & Western.

## CARRILES, etc.

### Generalidades.

**83. Peso.** Los carriles que pesan de 75 á 85 lbs por yarda (de 36,75 a 41,65 kg por metro) son de uso común en líneas de tráfico pesado; y carriles de 90 y 100 lbs (de 44 y 49 kg por metro) se usan donde el tráfico es extremadamente pesado. Carriles de más peso todavía se han laminado, pero algunas dificultades en su manufactura impiden que su uso se extienda.

**84. Largo** (standard) modelo —, * 33 pies á 60° Fahr (10,065 m á 15,6° C) 1915 *. † 33 pies á 60° Fahr el 10 % de la orden se acepta en largos de 30, 27.5 y 25 pies (9,15; 8,39 y 7,62 m). Se permite una variación de $\frac{1}{4}$ (6 mm) en los largos especificados, 1912. † Carriles con un largo de 60 pies (18,30 m) se usan algunas veces en cruceros de carreteras, etc., para evitar que hayan juntas bajo los tablones y pavimento donde serian inaccesibles al apisonado. También en general se usan para reducir el número de empates.

### Cómo se conserva el material.

**85. Desgaste.** Este es más rápido en las *curvas* cerradas donde las pestañas de las ruedas frotan contra el costado de la cabeza del carril. Disminuye á medida que disminuye lo cerrado de la curva. En curvas el desgaste de la parte superior del carril es muy pequeño comparado con el del costado de la cabeza del carril.

**86. En las tangentes.** El desgaste ocurre principalmente en la parte superior de la cabeza del carril, y es debido al esfuerzo de tracción de las ruedas motrices de las locomotoras y al resbalamiento de las ruedas de distintos diámetros en un mismo eje.

**87.** *En pendientes y en estaciones,* debido al necesario aumento de fuerza de tracción que se desarrolla para arrancar y parar, el desgaste del carril es mayor que en líneas a nivel o entre estaciones.

**88.** El *límite permitido* de desgaste en la parte superior de la cabeza del carril es generalmente de $\frac{3}{8}$ pulg (9 mm), pero, antes de llegar á este límite, el carril en muchos casos debe cambiarse debido a las asperezas de su superficie de contacto con las ruedas, causado (1) por el desgarramiento del metal, o (2) por deformación y excesivo desgaste de los extremos del carril, especialmente en el extremo que recibe el tráfico en doble vía.

**89. Duración de los carriles.** Está estimada mas o menos en 100 a 250 millones de toneladas en tráfico ,despendiendo en parte de su alineación pendiente y condiciones de la vía.

**90.** *Bajo tráfico pesado o en curvas cerradas*, los carriles deben volverse de un extremo al otro o renovarse una vez en dos años. En líneas de tráfico rápido, la renovacion de los carriles en las curvas debe en algunos casos hacerse en períodos menores de un año.

**91.** « **Corrugacion** ». En las cabezas de los carriles es asunto de mucha molestia y costoso, especialmente en curvas y en vias cruzadas por material rodante eléctrico. Consiste en una serie de desgastes parciales en la cabeza del carril, estos como lunares estan separados usualmente a una distancia de centímetros. No se ha llegado a un acuerdo en cuanto a la causa de esto a pesar de numerosas teorias planteadas. Una de las teorias mas aceptadas es la de que, al pasar una curva una rueda ó la otra de un par debe resbalar longitudinalmente; este resbalamiento puede ocurrir por tirones, y el marco de la carretilla donde van estas ruedas y el eje se deforman alternativamente para volver á tomar su forma.

El bajo coeficiente de fricción por resbalamiento daria lugar a permitir un deslizamiento apreciable (y por consiguiente excesivo desgaste) a lo largo de la parte superior del carril antes de que una rueda agarre junto con la otra. Entonces cuando el rodaje de ambas ruedas se restablece, el gran coeficiente de fricción estática evitaria el resbalamiento hasta que lo recorrido sobre la curva sea bastante para obligar a resbalar una vez más. Las ruedas cuando pasan una curva, deben también resbalar lateralmente, y este, lo mismo que el resbalamiento longitudinal, puede ocurrir por tirones simultaneos de ambos resbalamientos, y de estos combinados probablemente resulta un resbalamiento diagonal. Hay otra teoría basada sobre todo en la observación de que las corrugaciones varian con la reparación de las traviesas, etc., atribuyéndose estas corrugaciones a las vibraciones de la vía y del terreno.

## Composiciones, Requisitos, etc.

| Caída en ms. | 4,88 | 5,20-5,50 **R** | 4,50 | 4,88 | 5,20 | 5,50 | 5,80 **M** |

**Temperatura** de las piezas de prueba entre 32° y 100° F, (0° y 38° C.), **R.** El informe que especifique la temperatura atmosférica, **W, M, C.**

### Aceptación y rechazo.

Si las piezas al romperse no muestran picaduras, cavidades, (pipe) o defectos físicos, todos los carriles procedentes de esa fundicion son rechazados, **R.**

Si la pieza rota muestra cavidad o defecto físico, el carril de arriba de cada lingote de esa hornada es rechazado, y el inspector selecciona un pedazo de un carril que no sea de la parte de arriba del lingote. Si esta pieza rompe, el resto de los carriles de la hornada son rechazados; si no son aceptados, **R.**

Si la primera pieza de prueba no rompe, se prueba hasta su destruccion. Si entonces muestra cavidades (*pipe*) o defecto físico, el carril de arriba de cada lingote es rechazado, el resto aceptado. Si no, todos los carriles de la hornada son aceptados, **R.**

Si la pieza de prueba rompe, se hacen dos pruebas adicionales de otros carriles (tomados del lingote de arriba, **W, M, C**) de la misma hornada. Si alguna de las pruebas adicionales falla, todos los carriles de la hornada son rechazados. Si no, todos son aceptados, **W, M, C.**

**92.** Los carriles **de acero manganeso** fundidos y laminados, y carriles de otros aceros especiales, se usan en curvas de lineas de tráfico rápido en las ciudades. El acero manganeso se usa grandemente en ranas de cruceros y chuchos. Algunos de los primeros carriles de acero manganeso fundido usados en las curvas del subterraneo de Boston, aunque diez veces mas costosos que los carriles ordinarios, duraron veinte veces y mas tiempo.

Donde se usa un carril durable, la renovación de carriles son menos frecuentes. En las curvas de Boston mencionadas, los carriles ordinarios tenían que renovarse dos veces en tres meses aproximadamente.

## Sección de carriles.
## Secciones tipo de la Sociedad Americana de Ings Civiles.

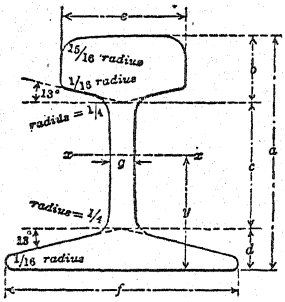

**Fig. 6.**

(*Nota del T.* — Para la concepción de la figura en sistema métrico : 15/16 = 23.8 mm; 1/16 = 1.5 mm; 1/4 = 6.25 mm.)

**93.** Fig. 6. Transacciones de junio 1893, vol. 28, No 6, pags. 425, etc. Informe final de la comision sobre sección de carriles.

En todos los tamaños.

Radio de la parte superior de la cabeza = al radio del lado del alma = 12 pulgs (30 cm).

Otros radios (en pulgs) y angulos, como se muestran en la fig.;

Ancho de la base *f* = altura del carril, *a;*

Distribución del area de la sección transversal; en la cabeza, 42 %; en el alma, 21 % en la base, 37 %.

Las siguientes propiedades de los carriles de la Asen de Ing Civiles americanos están tomadas del Libro de Bolsillo de Carnegie : —

*A* = area de la sección transversal;
*y* = altura del centro de gravedad sobre la base;
*I* = momento de inercia, pag. 490;
*X* = modulo de la seccion, pg. 489; } aprox. en el eje *x*.....*x*.
*r* = radio de giro = *I*/*A*.

Para secciones de carril tipo de la Sociedad Americana de F. C., veanse las dos pags siguientes.

Para los de la Asen Am de Ingo de F. C., vease ¶ 94.

Para los requisitos químicos y físicos de los carriles, véanse páginas

### Los números en tipo grueso dan las Dimensiones en 64 avos $^1/_{64}$ de pulg.

(*A* en pulgs cuad; *y* y *r* en pulgs. También véase ¶ y ||, y **nota** pag. 871).

(*N. del T.* — Por tratarse de unas tablas de fabricantes americanos de carriles, útiles para pedidos de los mismos tal como están, creemos más conducente dejarlas así. Los fabricantes que usan el sistema métrico usan también otros tipos. Para tener una idea de sus dimensiones en metros diremos que para tener los kg de carril por metro, se multiplican las lbs por yarda por 0.496. Para obtener centímetros cuad, se multiplican las pulgs cuadradas por 6.451; las dimensiones en $^1/_{64}$ de pulgada, se multiplican por 0.397 y dan milímetros; las pulgs lineales, por 25.4 y dan milímetros).

**94. Sección de carriles pesados, Manual de 1915 de la Ascn Am de Ing de F. C.**, pags 77-83. Vease fig, pag. siguiente.

**Los números en tipo grueso dan dimensiones lineales en 64 avos (1/64) de pulg.**

(Las areas en pulgs cuadradas. Vease tambien ¶ y ||. Vease *(N. del T.)* anterior.)

‖ *X* = módulo de la sección en pulgadas cuadradas. Vea pág 495.
§ Idéntico con el carril de 90 lbs, tipo A, p. 799 de la Ascn de Ferrocarriles.

**95. Secciones de carril, bridas y juntas.** Tabla, p. 873.

**Memorias de la Asociación Americana de Ferrocarriles.** Feb7, 1908, abril 22, 1908.

Las secciones de carriles propuestas por la Comisión de Secciones, Tipo de Carriles y Ruedas, « adoptadas como práctica recomendada ». Las bridas y juntas recomendadas por la Comision de Manufactureros representando las Cias de Acero de Maryland, Lackawanna, Illinois y Carnegie y el F. C. de Pennsylvania acordaron considerar las especificaciones y diseño de las bridas, y notificado por la Comisión de secciones, encuentran que los tipos de Carriles y Ruedas de la Asen Am de F. C. A y B presentan vistas divergentes.

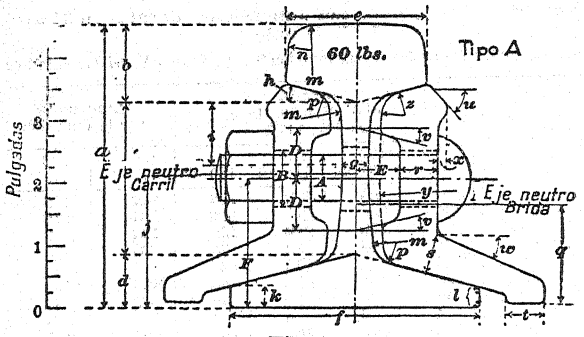

**Fig. 7a.**

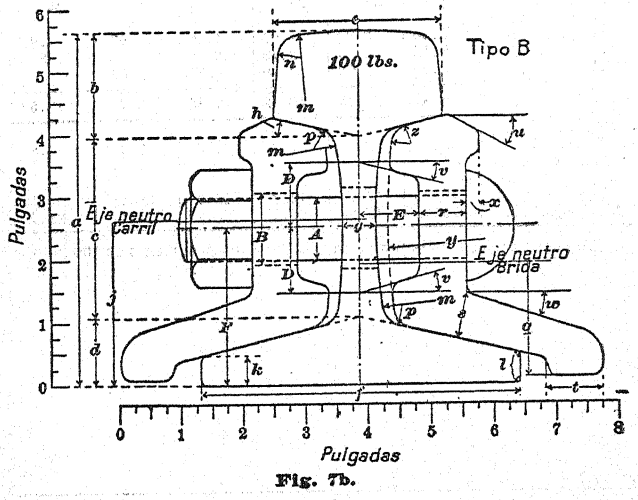

**Fig. 7b.**

*(N. del T.* : 60 lbs por yarda = 29,76 kg por m
100 — = 49.6 —

**Nota. Para evitar la impresión de fracciones,** las dimensiones lineales (excepto para *R*; véase nota al pie ††, abajo), están dadas en **tipo grueso,** y son en *sesenta y cuatro avos* ($^1/_{64}$) *de una pulg.* Las areas en pulgadas cuadradas.

Las letras *a, b, c,* etc. del caso abajo, refierense a dimensiones de *carril y brida.* Las dimensiones de bridas están anotadas en la brida del *lado derecho.* Las MAYUSCULAS se refieren a dimensiones de la **junta,** ó á la combinación del carril y la brida.

**Juntas de carril. Los números de tipo grueso dan la dimensión lineal en 64 avos de pulgada.**

(Véase para la conversión de estas unidades al sistema métrico la *N. del T.*: al principio pag 871.

### Clavos de ferrocarril.

**96.** Los clavos con cabeza de gancho *t*, comunmente usados para asegurar los carriles a las traviesas, varian dentro de los limites de la siguiente tabla; los mas ligeros, para carriles ligeros en ramales cortos locales; y los mas pesados para carril pesado en linea de primera clase. Los clavos se venden en cuñetes generalmente de 150 lbs (69 kg). Para saber el peso de clavos de dimensiones mayores podemos aproximarnos tomando el peso de una barra cuadrada del mismo largo. Lo que se economiza en la punta es suficiente para lo que se adiciona en la cabeza.

**Dimensiones**, etc.

| Tamaño en pulg. Largo. | Lado. | N.° por cuñete de 150 lbs. | N.° por 100 lbs. | Tamaño en pulgs. Largo. | Lado. | N.° por cuñete de 150 lbs. | N.° por 100 lbs. |

**97. Cantidad por milla y por kilometro.** Una milla de linea de una sola vía con carriles de 33 pies (10,06 m) y 18 traviesas por largo de carril, con 4 clavos en cada traviesa; tendra 160 tramos de carril, 2.880 traviesas, y 11.520 clavos, o cerca de 39 cuñetes de clavos de 5 ½ × 9/10" (14 × 1.4 cm) que pesan un poquito más de ½ lb por clavo.

(*N. del T.* — En un kilometro entran 99.4 tramos de carriles; 1.786 traviesas; 7.143 clavos o 24 cuñetes de clavos mas o menos.)

**98. Pero se debe dejar un margen** para guardacarriles en los cruceros, que podemos suponer sean de 33 pies (10,06 m) de ancho, o el largo de un carril. Estos se forman generalmente de 4 carriles extras para proteger la vía, y clavados a las 18 traviesas a las cuales estan sujetos los carriles de la vía. Por consiguiente, tal crucero requiere 18 × 8 = 144 clavos adicionales. Para desvíos, vías laterales, pérdidas, etc., podemos apreciar un promedio (dejando 1 milla de vía extra aproximadamente en la forma de desviaderos y vía lateral por cada 15 millas de camino) de 900 clavos mas por milla; arrojando por todo (asumiendo un crucero de carretera por milla) 11,520 + 144 + 900 = 12,564 clavos por milla o mas o menos 43 cuñetes de 150 lbs cada uno.

(*N. del T.* — Dejando 1 km por cada 15 resultan : 7.143 + 87 + 600 = 7.831 o 26 cuñetes de clavos.)

**99. Adhesion de los clavos.** El profesor **W.** R. Johnson encontró que con un clavo sencillo de 0.75, o de 3/4 de pulgs cuad (2.42 cm²) metido 3 3/4 de pulgada (8.5 cm) en pino de Jersey sazonado o castaño sin sazonar, se necesitó una fuerza como de 2.000 lbs (920 kg) para extraerlo; en roble blanco sazonado, cerca de 4.000 (1.840 kg); y con algarrobo bien sazonado cerca de 6.000 lbs (2.760 kg). Bevan encontró que una puntilla de 6 *penny nail* (medida inglesa de clavos) **6-penny**, metida una pulgada (25 mm) necesitaba para extraerlo : 667 lbs (307 kg) en haya sazonada, 557 (256 kg) en roble; 327 (150 kg) en olmo, 187 (86 kg) en pino.

**100.** En experimentos cuidadosos verificados en Hanover (Alemania), por el Ingeniero Funk, dió de 2.465 a 3.940 lbs (promedio de muchos experimentos 3.000 lbs) (1.380 kg), como la fuerza necesaria para extraer un clavo sencillo de hierro de ½ pulg cuadrado (12 mm) 6 pulgs largo (15 cm) y con la punta en forma de cuña de 1 pulgada largo (el doble del grueso del clavo), y metido 4 ½ pulgs (11.4 cm) en pino blanco o amarillo. Cuando se metió a 5 pulgs (12.7 cm) la fuerza necesaria fué cerca de 1/10 parte mayor. Clavos por el estilo de 9/10 en cuadro (14.3 mm) 7 pulgs largo (17.8 cm) metidos a 6 pulgs (15.2 cm) necesitaron de 3.700 a 6.745 lbs para extraerlos del pino, el promedio del resultado fué de 4.873 lbs (2.242 kg). En todos los casos *cerca del doble de esta fuerza fue necesaria para extraerlos del roble.* Todos los clavos fueron metidos al través del grano de la madera. La experiencia demuestra que cuando son metidos en **sentido** del grano, clavos o puntillas no aguantan ni la mitad de la fuerza.

**101.** Los clavos arponados o torcidos (como una barrena), o a los que se les haya aumentado o disminuido su sección cerca del medio de su longitud han resultado inferiores a los clavos cuadrados sencillos. Cuando el largo de la cuña de la punta se aumento a 4 veces el grueso del clavo, la resistencia para sacarlo resulta un poquito menor.

**102.** Cuando el largo del clavo es apropiado, probablemente no hay mejor forma que la de sección cuadrada sencilla, con una punta de cuña de largo doble al ancho del clavo.

**103. Resultado.** El clavo con cabeza de gancho con el tiempo se levanta por el movimiento ondulatorio del carril. Al meterse tritura la fibra de la madera; así

que (especialmente en maderas blandas) fallan al sostener la presión lateral del clavo. El agujero del clavo se agranda de este modo haciéndole perder al clavo su resistencia y el agua al penetrar en el hueco precipita su destrucción.

**104. Acero** *. El clavo no debe mostrar señales de fractura (a) cuando se dobla sobre si mismo a 180° y cerrado a martillazos, (b) cuando la cabeza se dobla hacia atras en frío, (c) cuando el cuerpo del clavo se tuerce en frio 1.5 vueltas *.

* Las variaciones máximas permitidas de las dimensiones expresadas, son : grueso $^1/_{32}$ de pulg (0,8 mm); largo bajo la cabeza o pulg menos, $^1/_4$ de pulg (6 mm) más; grueso de la cabeza, $^1/_{16}$ de pulg (1.5 mm); angulo del gancho, 1.° *.

**105. Agujeros.** Se barrenan a veces con $^1/_{16}$ de pulg (1.5 mm) menos en diámetro que el grueso del clavo, para recibir los clavos. De este modo se evita la trituracion de las fibras de la madera por el clavo, y asi aumenta la resistencia de clavo al tiro vertical y la de la madera al empuje lateral del clavo.

**106. Tarugos de traviesas.** Los tarugos de madera para traviesas, formados como el cuerpo del clavo, y metidos en los agujeros de los clavos cuando estos se aflojan, evitan la destrucción porque excluyen el agua. Si se mete un clavo después que se haya metido el tarugo en el mismo agujero, el tarugo aumenta el aguante en la traviesa. † La madera secada al aire; cortada longitudinalmente al grano; de lados opuestos paralelos; cortada a escuadra en el extremo que se mete; 4.5 pulgs largo (12 cm); $^{11}/_{16}$ pulg (17 mm) en cuadro; punta de cincel en 0.5 pulg (12 mm) en una punta. 1910 †.

## Tornillos tirafondos.

**107.** Los tirafondos son costosos y consumen tiempo (véase : Costos, ¶ ¶ 118, etc.) en su instalación, en renovaciones subsecuentes y otros cambios; pero prolongan la duracion útil de la traviesa quizás dos o tres veces más, y mantienen la vía en mejor estado y por mas tiempo, haciendo de este modo que las renovaciones sean menos frecuentes. Su uso por consiguiente reduce los gastos de instalacion **total** y mantenimiento **total.**

En el F. C. Lackwanna durante 5 años de uso no hubo necesidad de aumentar el número de hombres por milla.

**Resistencia.** En conjunto los tirafondos ofrecen de dos a tres veces la resistencia de los clavos ordinarios y mayor resistencia al empuje lateral, y mantienen estas resistencias mucho más tiempo. De este modo reducen la posibilidad del descarrilamiento y daños consiguientes.

**108. Corrosion.** Esta puede reducir el tamaño de la cabeza hasta hacer que estas no encaje bien en la llave de cubo y hacer difícil su cambio. Una cabeza cónica (fig. 8) evita esta dificultad hasta cierto punto; pero el atornillado a máquina (véase ¶ ¶ 130, etc.) produce agarraduras alternadas con resbalamientos de la llave que redondean las esquinas. Durante 5 años de uso en el F. C. Delaware Lackawanna & W'n no se encontró en las traviesas un tirafondo oxidado.

Cuando la cabeza se rompe se hace generalmente impracticable el cambio.

**109. Una letra en relieve** o marca en la parte de arriba de la cabeza excluye la posibilidad de usar mandarria al meterlos.

**110. Las variaciones en la sección del carril** aumentan la dificultad para usar los tirafondos.

**111. Resultados.** En general, el tirafondo al tener el carril y la traviesa en contacto, los obliga a descansar o moverse (segun sea el caso) juntos. Cuando se mueven juntos verticalmente, la traviesa puede, dañando el balasto, revolverlo o bien mejorándolo pisonarlo, segun las circunstancias. Algunos ferrocarriles prefieren aguantar en firme la plancha o la traviesa y dejar algun juego entre el carril y la plancha.

**112.** Como el agujero debe siempre barrenarse con anticipación, el tirafondo es menos propenso a rajar la traviesa que el clavo cortado metido en un agujero sin barrenar.

---

* Asen am Ings de F. C. † F. C. Pen ‡ F. C. U. Pacific. Véase también Especificaciones, pág 853

**113.** Debido a la compresión de la traviesa, lo junto que están y el aumento de contacto entre la traviesa, la plancha y el carril en servicio, los tirafondos metidos nuevos, *deben generalmente apretarse* una o dos veces a intervalos de algunos meses; pero desde ese momento sostienen su aguante con muy poca o ninguna atención.

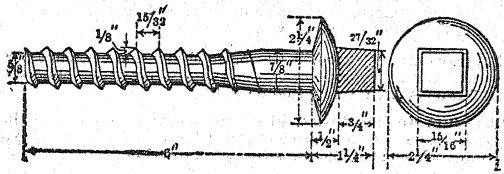

**Fig. 8.**

(*N. del T.* — 1/8 pulg = 3.16 mm; 15/32 pulg = 11.9 mm; 7/8 pulg = 22.12 mm; 2 1/4 pulg = 57 mm; 27/32 pulg = 22.8 mm; 15/16 pulg = 23.8 mm; 1 1/4 pulg = 32 mm; 3/4 pulg = 19 mm; 1/2 pulg = 12.7 mm; 5/8 = 16 mm.

**114. Dimensiones.** La fig. 8 representa el tirafondo tipo del F. C. D. L.[r] & —, 1915. Dimensiones en pulgadas. Otros diseños muestran la cabeza plana en el lado de abajo y sin cono. Véase ¶ 115.

**114a. El diseño,** una vez adoptado, no debe cambiarse, porque cualquier cambio aumentaría grandemente la dificultad de usar los tirafondos.

**115.** A fin de *proteger el tirafondo para que no se doble* bajo presiones laterales su cabeza, a cada lado debe estar bien soportada por medio de presillas adecuadas, o de tacones en la plancha de la traviesa, o ajustando la cabeza del clarvo a la pestaña de la base del carril.

**116. Espigas.** Se ponen tarugos o espigas de madera dura ó metal metidas ó enroscadas en agujeros preparados para ellos y con rosca interior para la rosca del tirafondo, y resultan ventajosos, especialmente en traviesas de madera blanda, cuando los tirafondos se meten nuevos o cuando el tirafondo ha empezado a aflojarse. Si son de madera, se tratan con preservativos antes de insertarse. El agujero que necesita la espiga es claro que debilita algo la traviesa. La espiga actúa como una columna y de este modo evita daños a la traviesa. Si es de madera, la fibra va vertical, y despues de metida, la parte de arriba de la espiga se corta parejo con la superficie superior de la traviesa. Las espigas se renuevan indefinidamente mientras dure la traviesa.

**117.** El muelle espiral de acero **The Thiollier** se ha usado como espiga en varios F. C. Americanos y en Francia. Resultan dificultosos para colocarlos y para quitarlos.

**117a.** En Francia se ha usado el buje o casquillo abierto de acero fundido **The Lakhovsky,** enroscado en la traviesa y que se expande a medida que el tirafondo se mete.

**118. Costos.** Los tirafondos cuestan de 2 a 3 cts cada uno, o, 2 o 3 veces más que los clavos cortados. Las espigas de madera dura, enroscadas por fuera y dentro, cuestan 1.5 ctvs cada una.

**119.** El costo de las varias **operaciones necesarias** varia mucho segun las condiciones. Ejemplo : *colocar* 2 traviesas, barrenar 4 agujeros y meter 4 tirafondos, costo 13,74 cts por traviesa cuando el trabajo se hizo *a mano*; 4,89 ctvs en *trabajo regado hecho con máquina* que tenia dos barrenas y herramienta para meter las piezas; y 2,9 ctvs en *trabajo continuo con máquina* que tiene dos barrenas y dos herramientas de meter las piezas.

**120. Barrenado.** Mr. J. W. Kendrick, en la Memoria de 1910 de la Asen de Ings Am de F. C. y mantenimiento de via, dice en la pag. 625, Part I, vol. 11 : Una máquina apropiada en la planta de tratar traviesas debe barrenar y enta-

rugar 600 traviesas con 8 tarugos cada una por dia de 10 horas a un costo de 3,5 ctvs por traviesa. » = 0,4375 cent por tarugo, pero al estimar el costo por milla, Mr Kendrick calcula para trabajo en el campo « barrenar traviesas y meter 24.000 espigas » (8 por traviesa) a 1 cent cada una.

**121. Uso.** Los tirafondos se han usado por mucho tiempo en Europa generalmente en lineas importantes, y se usan ahora en pocas lineas de los E. U. y notablemente en los F. C. Santa Fé y D. L. & W.

**122.** « Las traviesas deben protegerse contra el desgaste mecánico por medio de planchas y tirafondos. « Informe de la Comision de Traviesas. Memoria de 1915, vol. 16, pag. 522 de la Asen Am de Ings de F. C.

**123. Planchas de traviesas.** El uso de planchas de traviesas sin pestañas abajo (vease ¶ ¶ 135, etc.) se considera generalmente como esencial para dar un servicio satisfactorio con tirafondos. Vease ¶ ¶ 115 y 111.

**124.** La plancha de la traviesa se atornilla algunas veces a la traviesa y el carriles asegura por medio de clavos metidos al traves de ranuras en la plancha de la traviesa.

**125. Uniones o juntas.** Durante los 2 primeros años (1910-11) de uso de los tirafondos el F. C. D. L. & W. usó juntas de planchas de hierro maleable, y las barras angulares fueron ranuradas para clavos. Se usó un tirafondo en el exterior de la parte de fuera de la barra angular. Mas tarde, todas las planchas de union se hacen laminadas, y los tirafondos en barras angulares laminadas, con un tirafondo extra en el exterior de la barra angular.

**126. Metido.** Cualquiera *instrumento de meter* tirafondos debe estar dispuesto de modo que suelte su *agarre* sobre el tirafondo cuando este llegue a su lugar y asi se evita el forzar el tirafondo. Esto se arregla generalmente disponiendo un movimiento de friccion en la herramienta o instrumento.

**127. Metida a mano** : Aunque inseguro, y mucho mas costoso y gastándose mas tiempo que metido a máquina (véase ¶ ¶ 119, *etc.*), debe hacerse asi cuando son unos pocos los tirafondos que hay que meter, y en lineas de mucho tráfico (en las cuales no se pueda permitir un carro con maquinaria) a menos que no haya fuerza eléctrica o de aire comprimido para usar la herramienta.

**128.** Para el metido a mano, la herramienta *mas simple* es un husillo vertical con una mazorca abajo para sostener la llave, y un brazo horizontal, cruzado, o una chicharra en la cabeza.

**129.** Está descrita *una máquina de cigueña movida á mano para barrenar y meter material* montada sobre una trípode ajustable, y con un cigüeñal horizontal con engranes de angulo recto al husillo vertical, inventada por el Prof. A. L. Smith, del Instituto Politécnico de Worcester, Worcester, Mass., en el Boletin No. 50 del Negociado de Montes, pag. 53. Sometida a prueba esta máquina, metió dos tirafondos mientras se metieron 3 clavos. Puede ser movida por fuerza de vapor, etc.

**130.** *Máquinas movidas por vapor, etc.* Varian desde el pequeño aparato movido por electricidad o aire; a mano, ó por carros de gasolina que la cuadrilla puede levantar de la via, hasta la colección formidable de taladros y llaves, instalados en la planta de tratamientos o montados sobre carros para economizar la manipulacion de las traviesas y hacer mas fácil el cambiarlas de la via. Están generalmente provistas con sierras de carril, ruedas de esmeril, etc. Las máquinas grandes están provistas de contadores que llevan nota de las traviesas manipuladas y con un sistema de escape para sacar las virutas.

**131.** El carro motor Snow de gasolina tiene un motor que mueve un generador de corriente que por medio de un cable lleva a las herramientas de barrenar y llaves la corriente motriz; asi pueden estar aquellas a 300 m de distancia del carro. De este modo el carro puede quedarse en un desvio, fuera del tráfico de trenes. Pesa completo, 1.560 kgs, y lleva ademas del operador 10 hombres; generalmente mete de 2.000 a 2.500 tirafondos por dia. Puede ir a 50 millas por hora. Los fusibles se funden cuando se encuentra resistencia excesiva, de este modo se evita meter los tirafondos demasiado. Véase ¶ 126.

**132.** El « au-tra-kar » es un pequeño carro de gasolina; puede barrenar un agujero de tirafondo en roble en 5 a 10 segundos y meter un tirafondo en 20 segundos aproximadamente.

**133.** *Velocidad.* Un hombre con máquina puede barrenar 9 agujeros mientras se barrena 1 a mano, y puede meter 5 tirafondos mientras 2 hombres meten 1 con llave.

**134.** Una *máquina de hacer espigas*, usada por el F. C. de Santa Fé, tenia 4 herramientas; (1) para *barrenar* agujeros de espiga, (2) para hacer *rosca* a estos agujeros, (3) para insertar estas espigas, y (4) para recortar y enfrentar los extremos de las espigas que se proyectaban fuera de la traviesa. Podia entarugar traviesas para 1300 ms de via por dia, mientras que otra máquina metia los tirafondos necesarios para la misma distancia.

Una *barrena sola* barrenará 11000 agujeros, como 1500 agujeros entre cada dos afiladas.

El agujero debe de barrenarse *mas hondo que el largo del tirafondo.*

Si se barrena pasando la traviesa, *facilitará la salida de la viruta.*

## Planchas de traviesas, ó de asiento.

**135. Necesidad.** Donde los carriles descansan directamente sobre las traviesas la gran presion sobre la base estrecha del carril, las sacudidas del carril al pasar las ruedas y la friccion de las fibras de la madera, causarán el desgaste rápido de la traviesa debajo del carril.

**136. Economía.** Las planchas de traviesas aumentan grandemente su duración, en las curvas y puentes, la economia en gran número de casos, se ha estimado como en un 50 % del costo del material y de 60 a 75 % en jornales. Las planchas de traviesas han hecho a menudo innecesario el uso de pequeñas cuadrillas de hombres cuya mision era solamente reponer traviesas.

**137.** La plancha de traviesa se coloca en la traviesa debajo del carril. Aguantando la plancha y el carril en su lugar, se meten los clavos en la traviesa al traves de agujeros, en la plancha. Algunas formas de planchas tienen dos o mas filetes en la cara inferior. Estos filetes le dan rigidez a la plancha; y, al cortar estos filetes la superficie superior de la traviesa, resisten el resbalamiento de la plancha sobre ella. Los filetes algunas veces están al traves de las fibras de la traviesa y algunas veces paralelos. Algunas formas tienen un borde en la cara superior, para ayudar a los clavos a resistir y que se separen los carriles, actuando como mordaza del carril.

**138. Asiento.** Un asiento desigual bajo la plancha de la traviesa da lugar a que se abolle la plancha y la vía no quede a cartabón. Las traviesas deben estar provistas de sus planchas antes de ponerse en la vía. En traviesas labradas, los asientos para las planchas deben labrarse con hacha para tener los asientos del carril en el mismo plano.

**139. Costo.** El de las planchas de traviesas es de 5 a 15 cts cada una; y colocarlas cuesta de ½ a 1 ½ cts cada una.

**140. Materiales y pruebas.** * *Hierro dulce;* $<$ 3.150 kg por cm$^2$ de resistencia a la tensión; debe doblarse en frío a 90° al través de la fibra sin señal de fractura.

*Hierro maleable de horno.* La pieza de prueba debe doblarse y mostrar tenacidad. La fractura debe mostrar una franja de metal blanco en la superficie. La porción central obscura y sin fibra. 1915 *.

*Acero Bessemer o de Martin Siemens.* † El acero de Mart. Siemens se prefiere al Bessemer. Cortado y punzonado en frío. Piezas de prueba de 36 cm de largo de sección uniforme, area del extremo $<$ 3 cm$^2$ cortada del material terminado. Se requieren pruebas para cada orden y por cada fundición. Las planchas de traviesas de sección completa deben doblarse en frío en una dirección a angulo recto de la fibra, dobladas en plano sin señal de fractura. 1914 †. $\doteqdot$ (Bessemer o M. S.); carbón 0.2 % (0.05 % de variación en cualquier sentido), fósforo $>$ 0.1 %. 1905. $\doteqdot$ *Resistencia a la tensión,* kg por cm$^3$; 3867 *, 3796 a 4499 †. *Límite de elasticidad;* $<$ 0.5 ult * †. *Alargamiento;* en 5 cm $<$ 20 % * †. *Reducción de área;* $<$ 40 % * †.

**141. Dimensiones.** * *Ancho* $<$ 6 pulgs (15 cm).

$$Largo < \frac{\text{área del asiento de seguridad de la traviesa}}{\text{ancho de la plancha}}. \quad Borde < 12 \text{ mm alto.}$$

Distancia (uniforme) desde el canto de la base del carril al extremo de la plancha en el lado de afuera. $>$ proyección interior de la base del carril. *Filetes* (pocos en número) en la base, $>$ 6 mm de hondo. Con traviesas tratadas o con tirafondos, se prefieren planchas con *base plana*. 1915 *.

***Para embarques** : Las planchas van amarradas juntas con alambre en mazos y en numero fijo, pesando $>$ 100 lbs (46 kg). 1915. *

**Uso.**

**142.** † « Las planchas de traviesas deben usarse en todas las traviesas en vias de alta velocidad, en las curvas de 2º ó más; en todas las traviesas de via sujetas a servicio pesado; en todas las traviesas de chucho, y en traviesas de mesas giratorias, fosas de cenizas, puentes y pilas; en aguadas y vias con canal de agua y en todos los cruces de via y andenes. Las planchas para traviesas deben usarse en traviesas de madera blanda y en todas las traviesas que han sido tratadas. » †.

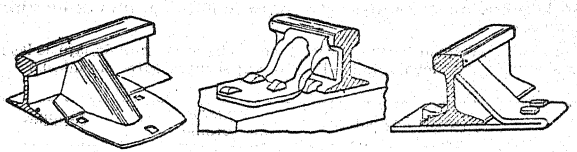
‡ A menos que no se indique otra cosa, las planchas para traviesa se aplicarán como sigue, siempre que se renuevan carriles o traviesas. (En « maderas blandas » incluyendo todas : las tratadas y no tratadas, excepto el roble);

* Asoc Am Ings F. C. † F. C. Pen. ‡ F. C. U. Pacific. Véase tambien Especificaciones, pág. 853.

En lineas nuevas : en todas las traviesas de madera blanda de la linea principal;
En lineas principales, en todas las traviesas de madera blanda;
En ramales; en todas las traviesas de madera dura en curvas de 3° y mas cerradas, y en todas las traviesas tratadas ya esten en curva ó en tangentes;
En los desvios; en todas las traviesas de desvios; en todas las curvas de 3° y mas fuertes y en todas las traviesas tratadas esten en curva ó en tangente ÷.

## Tacones o abrazaderas entre carriles.

**143.** Los tacones o abrazaderas de carriles se usan para evitar que se abra la carrilera, especialmente en las curvas. Para curvas de 5°, cinco abrazaderas por carril de (33) pies (10,06 m) es suficiconte Para curvas de 10° se usa una abrazadera en cada traviesa alternada.



Tacon *Alkins* de acero forjado | Tacon *Ajax* de acero. | Tacon y plancha *Edwards*, de traviesa.

**Fig. 10.**

**144.** La fig. 10 muestra tres tipos de abrazadera o tacones de carriles de uso corriente.

## Uniones (Bridas).

**145.** La tendencia de una via a ceder o rendirse en las bridas (mal llamadas eclisas. *N. del T.*) va en detrimento de la via y del material rodante.
El extremo de un carril sobre el cual se mueve una rueda cargada, se dobla mas que el extremo adyacente sin carga del proximo carril, y de este modo recibe un golpe fuerte de la rueda.

**146.** Cuando las traviesas están colocadas de modo inseguro, no se puede esperar que ninguna junta (brida) de carril haga buen servicio.

**147. Las bridas o uniones suspendidas** (aquellas donde los extremos del carril se encuentran entre dos traviesas) son generalmente preferidas a las bridas soportadas (que se encuentran directamente sobre una traviesa).

**148. El coeficiente de dilatacion**, en carriles de acero puede tomarse como (0.000 006 5 de pie) por grado Fahr. De aqui un carril de (33) pies (396 pulgs) bajo un aumento de 60° Fahr (33° C) en temperatura, se alargará en $(396 \times 60 \times 0.000\ 006\ 5) = (0.154)$ pulgs (ó sean 3,9 mm por 33° Cent). Los carriles se alargan ligeramente en sus extremos por el tráfico.

**149. Deslizamiento del carril** (Vease ¶ ¶ 163, etc.) Este ocasiona esfuerzo adicionales sobre las juntas. El deslizamiento ocurre en la direccion del tráfico mas pesado, y donde el tráfico es igual en ambas direcciones, el deslizamiento se hace en el sentido de la pendiente.

**150.** Si en las dos lineas de carril que forma la via, las juntas estan opuestas una a la otra « son juntas ó bridas parejas » y se llaman juntas « salteadas » cuando cada junta en una de las lineas de carril ocurre hacia el medio del carril de la otra linea. En este ultimo caso, el mas comun, la trepidacion al pasar de un carril a otro es menos fuerte que cuando las juntas son parejas, pero por supuesto de doble frecuencia.

**151.** Para disminuir esta trepidación, los carriles se cortan con extremos **biselados** de modo que el plano vertical formado por los extremos del carril haga un ángulo de 45° a 60° (y no angulo recto) con el plano vertical longitudinal del alma del carril.

**152. Las bridas angulares**, fig. 7, han reemplazado practicamente toda otra forma de brida. Sus pestañas horizontales le dan estabilidad lateral a la unión y llevan parte de la carga directamente a las traviesas, de este modo alivian a los extremos del carril, *de esa carga.*

**153. Las ranuras** en las pestañas del carril y de la barra o brida angular deben estar separadas de tal modo que los dos clavos, metidos en la traviesa, no deben quedar directamente opuestos unos a otros sino alternados o en « zig-zag », con el fin de evitar que se raje la traviesa.

**154. Dimensiones usuales, etc., para bridas angulares de uniones de carril.**

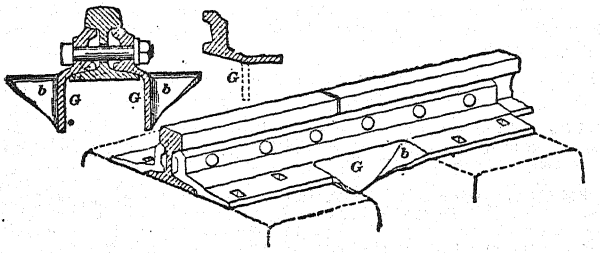

Fig. 11.

**155. Juntas en los puentes.** Fig. 11. En las juntas ó bridas en los puentes, la pestaña horizontal de la brida angular se lamina mas ancha que de ordinario y su porcion media se prensa hacia abajo con dados, formando una viga, G, que se extiende hacia abajo entre las dos traviesas en que cae la brida. Esto aumenta la resistencia vertical de la brida, y las pestañas extendidas aumentan la superficie de asiento de la carga y aumenta la resistencia lateral de la unión; pero las pestañas que se proyectan hacia abajo (que deben caer entre dos traviesas), restringen la libertad de colocar las bridas donde se quiera con respecto a las traviesas. Véase el final de ¶ 168. La fig. 11 representa las bridas del puente Bonzano.

**156. La fig. 12 representa otros tipos importantes de bridas angulares.**

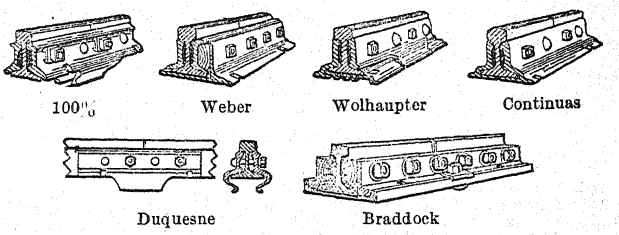

**Fig. 12.**

**157. Abbott.** En la brida Abbott de carril inventada por F. E. Abbott, Ingeniero Inspector de la Cia de Acero Lackawanna, el canto superior de cada barra angular está ligeramente hundido en el centro á fin de mantenerla separada de la parte baja de las cabezas del carril en la unión, evitandose con esto el efecto cortante y el desgaste de la parte superior de la barra angular por las cabezas del carril.

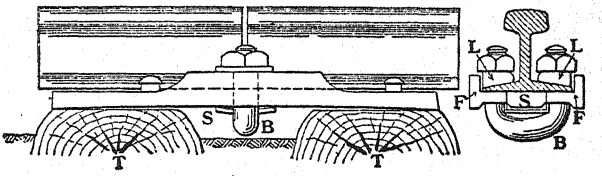

**Fig. 13.**

**158. Fisher.** Fig. 13. En la brida Fisher de carril (de la Fisher Rail Joint Works Trenton, N. J.) las *bases* de carril, en sus extremos, están soportadas por una placa *F* con pestañas, colocada bajo la base del carril y atornillada a él por medio de un tornillo *B*, en U, y grapas *L* como indica el diseño, en lugar de tener el soporte debajo de las *cabezas* del carril como sucede en las bridas de barras angulares, una muesca o entalladura y una pieza combada *S* de acero de resorte, colocada entre el tornillo *B*, y la placa con pestaña, *F*, y sostenida en su lugar por el tornillo en U que pasa al través de las muescas, le dan á la brida elasticidad, recibe y recoge los movimientos debidos á los desgastes, sirve de cojín á los esfuerzos en el tornillo, y mantiene la presión entre las roscas del tornillo y las tuercas, obrando como una tuerca de seguridad.

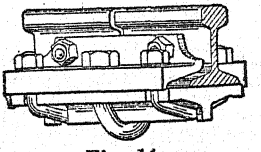

**Fig. 14.**

**159.** La junta « **triple fish** » (Fisher), fig. 14, tiene tambien una placa soporte bajo la base del carril. Es una junta corta con tres tornillos en U, como se indica en la fig. y formada de barras angulares especiales (« keepers ») « sostenedoras » atornilladas al través del alma del carril.

## Tornillos de Vía.

**160.** * El tornillo sin rosca debe doblarse en frío á 180° y aplastarse sin fractura afuera *.

*Rosca; Standard de los E. U. y de mayor diámetro, la parte de la rosca que el resto del tornillo, a menos que no se especifique de otro modo; cortada o laminada. $\lessdot 2 \gtrdot 5$ hilos en *dedo.* * (*N. del T.* — Un de do tiene $^5/_4$ pulg (19 mm). El pie tiene 16 dedos.)

* Para embarques, los tornillos deben aceitarse; y las tuercas en los tornillos metidas $\lessdot 2$ espiras. 1915. *

## Muelle espiral de tuercas de seguridad.

(Véase tambien pag. 1211.)

**161.** * Acero; fósforo $\gtrdot$ 0.05 5 %; sulfuro $\gtrdot$ 0.05 %.

La tuerca terminada (de un diámetro interno de ($^{13}/_{16}$ a 1 $^{5}/_{16}$ de pulg (20.64 a 33.34 mm) aguantada a plano una hora, debe recuperar $\lessdot$ $^2/_3$ de su altura o grueso si el grueso $<$ ancho; $\lessdot$ 0.5 del grueso si es cuadrada; $\lessdot$ ancho si la altura o grueso $>$ ancho.

No debe haber señales de fractura cuando se sujeta un extremo en un tornillo de banco, y el extremo opuesto se tuerce a 45°. 1915 *

## Partes de metal. Especificaciones.

## Deslizamientos.

**163.** El deslizamiento del carril es debido al movimento ondulatorio del carril producido por el movimiento de los trenes, y es mas marcado en los lechos de via faltos de firmeza, y en pendientes pronunciadas. Los carriles ondulan y se deslizan en la direccion en que se mueven los trenes; por consiguiente el deslizamiento da mas que hacer en lineas de via doble. Aumenta tambien con la dilatacion del carril en tiempo de calor, y disminuye en las heladas.

**164.** « **Amarre cruzado** », fig. 15. Se emplea con éxito para evitar el deslizamiento. Consiste simplemente en meter los clavos de afuera, como se ve en la fig. mas adelante que los clavos de adentro en la direccion en la cual el carril tiende a

* Ascn Am Ings F. C. † F. C. Pen. ‡ F. C. U. Pacific. Véase tambien Especificaciones, pág. 853.

deslizarse. Entonces si, por ejemplo, el carril *A* se desliza en la direccion indicada por la flecha, llevandose consigo el extremo de la traviesa, la traviesa es llevada hacia adelante en la posicion indicada por la linea de puntos; (1) aumentando las

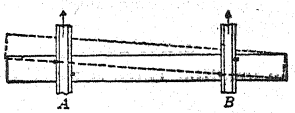

**Fig. 15.**

presiones laterales de sus dos clavos contra la pestaña; (2) aumentando el engrampe de la traviesa en el carril, y con esto (3) la resistencia al deslizamiento del carril en la traviesa. Y reciprocamente para el carril *B*.

**165. Las traviesas muy largas** (algunas veces hasta de 12 pies) (3,66 m) se han usado también para disminuir o evitar el deslizamiento.

**166. Ranuras para clavos** en las barras de brida son eficaces contra el deslizamiento, siempre que las traviesas de las juntas agarren en el balasto. Si no es asi, los carriles deben anclar en las traviesas intermedias con abrazaderas antideslizables, o las anclas pueden hacerse de barras de bridas desechadas cortadas al través en secciones, dejando un agujero de tornillo en cada sección, y haciendo una ranura de clavo en su pata horizontal. Entonces se barrena un agujero en el alma del carril, sobre la traviesa, y el ancla se atornilla al carril, clavado a la traviesa al través de la ranura. Se puede aumentar mas la resistencia al deslizamiento, ajustando bloques entre las traviesas delante de las traviesas ancladas.

**Otro** accesorio contra deslizamientos consiste en una grampa que muerda la base del carril sin atornillar, y lleva un tocón que descansa contra el costado de una traviesa.

Aunque a fin de evitar el deslizamiento del carril, las bridas algunas veces son ranuradas para clavos en las traviesas, ¶ 166, parece preferible emplear las anclas de carril o los otros medios; vease los anteriores ¶ ¶.

**167.** En el puente de St. Louis (arcos de acero) y en sus inmediaciones (vigas de planchas en columnas de hierro), los carriles se deslizan en la direccion del tráfico (un pie) 30 cm por dia aprox, en una pendiente de 1.5 % y con tal fuerza que ninguna de las varias sujeciones probadas han sido suficientes para evitar el deslizamiento del carril, y la vía ha sido ajustada diariamente. Vease el folleto del Prof. J. B. Johnson, Auxiliar de la Revista de la Sociedad de Ingenieria. Vol. IV, n.° 1, nov. 1884.

**168.** *Al reponer carriles*, cuando se hace necesario cambiar la posición de las bridas ha sido costumbre cambiar la separación de las traviesas para conformarlas con las nuevas posiciones; pero esta práctica se ha abandonado; el sitio de las traviesas y el balasto se dejan sin cambiar y parece que el resultado es satisfactorio.

Donde se usan bridas de barras angulares (tales como la junta Bonzano, ¶ 155) con pestañas verticales que se proyectan hacia abajo entre las traviesas, por supuesto que es inevitable mover las traviesas.

## Carriles continuos.

**169. Dilatación y contracción.** En los trabajos de lineas de ferrocarril en las calles, los carriles por lo regular van **soldados, fundidos** o remachados en sus extremos, formando practicamente carriles continuos; y una amplia experiencia ha demostrado que una linea larga de carril continuo no se dilata ni contrae considerablemente, considerada en conjunto, con los cambios de temperatura; la tendencia a expansionarse y contraerse es resistida con éxito por el terreno que actúa por medio de las traviesas y las sujeciones del carril. Por supuesto que el resultado es un aumento de esfuerzos longitudinales en los carriles, con el correspondiente cambio microscopico en sus areas de sección transversal.

**170.** Tomando el coeficiente de expansion lineal, $a$, del acero (o sea 0.000 006 5) o estiramiento por unidad de longitud $e$ (pp. 478-9) a 1° Fahr cambio de temperatura, y su módulo de elasticidad, E, como 29,000,000 lbs por pulg cuad (2.038.910 kg por cm cuad) tenemos la unidad de esfuerzo $= Ee =$ 188.5 lbs/pulg

cuad/grado Fahr (23,9 kg/cm cuad/grado C.). Tomando la variación de temperatura a 140° Fahr (60° C) y suponiendo que los carriles están puestos a temperatura media, estos estarian sujetos a un cambio máximo de temperatura de 70° (39° C) y una unidad máxima de esfuerzo de $70 \times 188.5 = 6$ sea 13,200 lbs/pulg cuad (928 kg por cm cuad), quedando comprendido dentro de la unidad del esfuerzo, permitido al carril de acero.

## Miscelánea.

**171. Diferencia en longitud entre el carril exterior y el interior** Fig. 16.

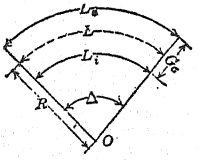

**Fig. 16.**

Sea

$R$ = radio de la linea del centro de la via;
$\Delta$ = abertura de la curva;
$G_c$ = ancho de via, medido entre los *centros* de carriles;
$L, L_o, L_i$ = largo del arco, en los arcos del centro de la curva, del carril exterior y del interior respectivamente.

En un circulo completo (360°) :

$$L_s = 2\pi(R + G_c/2) = 2\pi R + 2\pi G_c/2; = 2\pi R + \pi G_c;$$
$$L_i = 2\pi(R - G_c/2) = 2\pi R - 2\pi G_c/2; = 2\pi R - \pi G_c;$$

y, restando, $L_o - L_i = 2\pi G_c$.

**Por consiguiente, en un arco de** $\Delta^o$, tenemos :

$$L_o - L_i = 2\pi G_c \frac{\Delta^o}{360_i} = \frac{\pi G_c}{180}\Delta^o.$$

Con un ancho de via $G.$ = 4 pies 8.5 pulgs (1,435 m) tenemos $G_c$ = 4 pies 11 pulgs (1.499 m) aprox = 4.917 pies; y $L_o - L_i = 0.085818\ \Delta^o$.

(*N. del T.* — Empleando la medida métrica 1.499, resulta 0,02614.)

**En cualquier largo dado,** $L$, en la linea de centro, tenemos :

$$\Delta^o = 360^o \frac{L}{2\pi R} = \frac{180\,L}{\pi R}.$$

De donde $L_o - L_i = \frac{\pi G_c \Delta^o}{180} = \frac{\pi G_c}{180} \cdot \frac{180\,L}{\pi R} = \frac{G_c L}{R}$.

(*N. del T.* — Las mismas formulas se emplean para el sistema métrico.)

De otro modo : *para una abertura dada,* $\Delta$, la diferencia, $L_o - L_i$, es *independiente del radio ;* mientras que, *para un arco de longitud dada,* $L$, la diferencia *varía inversamente con el radio,* y es *independiente de la abertura.*

## Abertura de cartabón en curvas.

**172.** La necesidad y extensión de la abertura entre carriles, en las curvas, depende de muchos factores variables, tales como la longitud de la base rigida de la rueda (vease fig. 2 en Material rodante) el juego, S, o diferencia entre el ancho de via, $G$ (en tangentes), y el mismo entre *ruedas,* W, en ambos en ruedas nuevas y gastadas, etc. De aquí el que las opiniones y la práctica varien mucho.

**173. Práctica.** De 104 ferrocarriles preguntados por la Ascn de Ings Am de F. C., en 1897, 25 informaron que no debe haber aumento del ancho de via en las curvas. Los otros 79 ferrocarriles informaron tener prácticas variadas que en conjunto resumimos como sigue :

(*N. del T.* — Entre parentesis los ms equivalentes a los pies y los mm equivalentes a los $^1/_{16}$ de pulgs.)

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Aumento de ancho de via empezando con D = | 1° | 2° | 3° | 4° | 5° | 6° | 8° |
| Radio en pies | 5730 | 2865 | 1910 | 1433 | 1146 | 955 | 717 |
| — en metros | 1746. | 873 | 582 | 437 | 349 | 291 | 219 |
| Aumento máximo, en $^1/_{16}$ de pulg | 4 | 4 | 6 | 8 | 8 | 8 | 12 |
| Lo mismo en mm | 6 | 6 | 9 | 13 | 13 | 13 | 19 |
| Numero de respuestas | 18 | 5 | 15 | 10 | 16 | 7 | 3 |

| | | | | | | |
|---|---|---|---|---|---|---|
| Aumento de ancho de via empezando con D = | 9° | 10° | 12° | 13° | 20° | 21° |
| Radio en pies | 637 | 574 | 478 | 442 | 288 | 274 |
| — en metros | 194 | 175 | 146 | 135 | 88 | 84 |
| Aumento maximo en $^1/_{16}$ de pulg | 12 | 16 | 16 | 16 | 16 | 19 |
| Lo mismo en mm | 19 | 25 | 25 | 25 | 25 | 30 |
| Numero de respuestas | 1 | 2 | 0 | 1 | 0 | 1 |

**174. La Asoen Am de Ings de F. C. no recomienda** (Manual, 1915, p. 117) aumento en curvas de 8° ó más abiertas. En curvas cerradas, recomienda un aumento de ($^1/_8$) de pulg (3 mm) por cada 2° adicionales (ó fracción) de cierre, hasta un ancho de via máximo de (4 pies 9.25 pulgs) (1.454 m) para via ancha de (4 pies 8.5 pulgs) (1·435 m). El ancho de via incluyendo desgaste, en ningun caso excederá de (4 pies 9.5 pulgs) o (1.460 m).

**175. Los patrones de los maestros constructores de carros** (véase fig. 2 en « Material rodante ») se hacen :

$S\ (= G - W)$ = (4 pies 8.5 pulgs menos 4 pies 7 $^{11}/_{16}$ pulgs = $^{13}/_{16}$ pulgs) igual (20.637 mm).

Este juego es suficiente para evitar que los troles de 4 ruedas de los carros se tranquen en las lineas de tracción por vapor. Pero el caso es distinto con las bases rígidas largas en las voladoras (motrices) de las locomotoras.

**176. El F. C. Pennsylvania** empuja carros de carga en desviaderos de almacenes con 60 pies de radio (D = 113° aprox) : cartabón de via en tangentes, 4 pies 8.5 pulgs (1.435 m); en curvas donde sea necesario (4 pies 9 pulgs) o sean 1 m 448.

**177. Relaciones geométricas entre el sobreancho y la curvatura.**

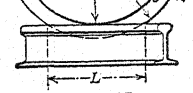

**Fig. 17**

Fig 17. Sea

$r$ = radio de la pestaña de la rueda;
$f$ = altura de la pestaña de la rueda;
$L$ = largo del contacto de la pestaña con el carril.

Tenemos

$$L = 2\sqrt{(r+f)^2 - r^2}.$$

**178.** Figs 18, 19, sea

$D$ = abertura de la curva;
$G$ = ancho de via en las tangentes;
$B$ = base rígida de la rueda;
$L$ = largo del contacto de la pestaña con el carril;
$R_1$ $R_2$ = radio de la curva;
$G_1$ $G_2$ = ancho de la via en las curvas que da un juego, $S$, igual al juego $G$ en las tangentes;
$S_1 = G_1 - G$ ; $S_2\ (= G_2 - G)$ = juego = aumento del ancho de via debido a las curvas.

Entonces, fig. 18, **para un trole de cuatro ruedas** :

**Juego**, $S_4 = G_4 - G = m\ n = (\text{aprox})\ m'\text{-}n'$

$$= L \operatorname{sen} n'\ E\ m'$$

$$= (\text{aprox})\ L \operatorname{sen} A\ O\ E = L \frac{B + L}{2\ (R_4 + G/2)\ *}$$

$$= \frac{L\ (B + L)}{2\ R_4 + G}$$

Bastante aproximado, $S_4 = \dfrac{L\ B}{2\ R_4} = \dfrac{L\ B\ D}{11{,}460}$.

(*N. del T.* — Aunque el autor nada explica para pasar de la fórmula $\dfrac{L\ B}{2\ R_4}$ a la $\dfrac{L\ B\ D}{11{,}460}$ se multiplican los dos términos del quebrado primero por $D$ y viene $\dfrac{L\ B\ D}{2\ R_4\ D}$ y en el párrafo 173 se toma como promedio la abertura de 5°, el Radio 1.146 y da para el denominador $2 \times 1.146 \times 5 = 11.460$. — Para usar el sistema métrico empléese la fórmula asi : $\dfrac{L\ B\ D.}{3{,}495}$ Entrando con $L$, $B$, $D$ en metros, el cuociente es metros.

Nos parece mucho mas práctico el procedimiento siguiente :

En vias anchas para radios de 1.000 ms o mas no se da sobreancho; para :

| Radios de..... | 850 | 600 | 400 | 250 | 150 metros. |
|---|---|---|---|---|---|
| Sobre anchos..... | 5 | 10 | 15 | 20 | 25 milimetros. |

En vias estrechas :

De 1 metro con radios de 80 a 250 metros. $S$ en mm $= 240 : \sqrt{R}$

De 0,75 — 50 a 150 — — $= 140 : \sqrt{R}$

De 0,60 — 30 a 100 — — $= 100 : \sqrt{R}$

(Tratado de ferrocarriles por S. Rahola, Madrid.)

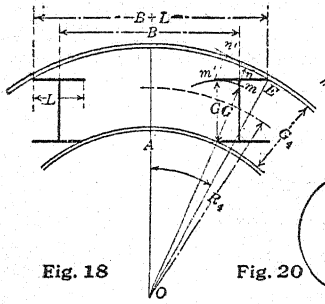

Fig. 18

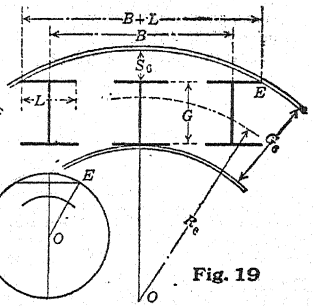

Fig. 19

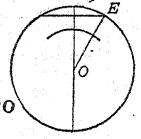

Fig. 20

Fig. 19. **Para un trole de seis ruedas** ; ejes igualmente separados, tenemos aprox (véase la pequeña escala fig. 20) :

$$S_6 = G_6 - G = \left(\frac{B + L}{2}\right)^2 \times \frac{1}{2\ R_6 + G} = \frac{(B + L)^2}{8\ R_6 + 4\ G\ *}$$

Bastante aproximado : $S_6 = \dfrac{B^2}{8\ R_6} = \dfrac{B^2\ D}{45.840}$.

(*N. del T.* — Poniendo la $B$ en metros úsese la fórmula $\dfrac{B^2\ D}{13{,}980}$ y el cuociente viene en metros.)

* Como una aproximación, $G$ se usa aqui para $G_4$ o $G_6$ (todavia sin conocerse). En la práctica, se puede prescindir de $G$.

Si, en un trole de seis ruedas, los ejes están **desigualmente** separados, o si hay **mas de tres ejes**, la ecuacion da para $S_0$ mas de lo necesario, pero aumentando la seguridad.

### Desgaste de los carriles en las curvas.

**179.** Fig. 21. Se han usado **carriles especiales** y otros accesorios para resistir o evitar las fuerzas laterales que se desarrollan en las curvas y el desgaste adicional debido a ellas.

**180.** Fig. 21a. En curvas estrechas, el F. C. de Lehigh Valley usa, en lugar de su carril normal de 100 lbs (49,6 kg p m) un carril de 110 lbs (54,57 kg por m) de la misma altura y ancho del patin, pero con un alma o nervio de $^1/_{32}$ de pulg (0,75 mm) mas grueso, y una cabeza de $^5/_{16}$ de pulg (7.5 mm) mas profunda, con una barra angular afuera de brida especial, que en el lado exterior, se proyecta hacia arriba, a lo largo de la cabeza para soportar esta. Se usa una junta escalonada o de « trancision » para efectuar el paso entre el carril normal y el especial.

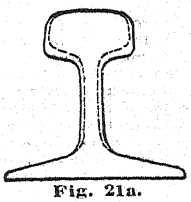

Fig. 21a.

**181.** Fig 21b. En el carril **Manning** usado en el F. C. Baltimore y Ohio, el grueso de la cabeza no es simétrico, el mayor grueso está en el lado sujeto al desgaste. Cuando este se ha gastado suficientemente, el carril se corre lateralmente hacia el centro de la curva a fin de cobrar el desgaste y de este modo restablecer el ancho de via.

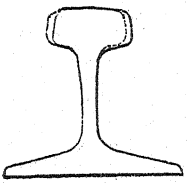

Fig. 21b.

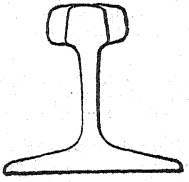

Fig. 21c.

**182.** Fig 21c. A fin de reducir el resbalamiento de las ruedas interiores cuando se pasan curvas, el F. C. Southern Pacific usa, en el lado interior de las curvas un carril con una cabeza 25 % mas estrecha que el del carril tipo. El carril especial es cerca de 8 % mas alto que el carril normal. Se usa un carril especial adelgazado para facilitar el pase del carril normal al especial.

**Peralte.** Véase ¶ ¶ 172 a 193, en « Curvas ».

### Colocacion y Mantenimiento.

**183.** La operacion completa de colocar la via se ejecuta generalmente en dos etapas (1). Colocando la via sobre el terreno lo bastante bien para permitir al tren de construccion pasar por ella, y (2). Balastrado y terminacion general del trabajo.

**184. Generalidades.** Una parte importante del trabajo es el de trasportar las traviesas, carriles y accesorios desde el lugar de abastecimiento hasta los lugares donde se van a colocar. Las traviesas algunas veces se mandan adelante en carretones, especialmente en las praderas, o donde haya un camino cerca. Los carriles suelen llevarse en *carros planchas* en el tren de construccion, que va empujándose adelante sobre la linea nueva a medida que va haciendose. Los carriles, y las traviesas, cuando se llevan en el tren, deben todavia llevarse desde los carros a puntos mas allá de donde llega la via, donde se echan, clavan y atornillan, lo suficiente para permitir que pase el tren de construccion.

**185. Tren de construccion.** La formación de un tren de construccion dependerá del adelanto de la via, distancia de la base de aprovisionamiento, pendiente y fuerza propulsora, y facilidades para la situacion de los desvios. Si los carros que van a utilizarse como vivienda se colocan a la cabeza del tren, los materiales

se deben trasportar por delante de ellos; si se dejan en un desvio mientras progresa el trabajo puede ocasionar atrazos serios en llevarlos y traerlos a la cuadrilla de construccion para las comidas y para dormir. Frecuentemente se colocan al frente del tren y se dejan ahi. El orden de colocacion de los carros en el tren es generalmente como sigue, empezando con el carro que esta mas adelante.

Carro « Avanzada »; con oficina y posiblemente taller y herramientas;
Carro almacen, con provisiones para vivir en él, etc.;
Carro o carros dormitorios y comedores, combinados o separados;
Carro cocina;
Carros cama y de comer adicionales, si es necesario;
Carro de herramientas, o de viveres y agua;
Carros de carriles; los necesarios para el dia, o que se puedan manejar sobre las cuestas y curvas de acuerdo con la fuerza de traccion o propulsora disponible;
Carro con accesorios de via; barras, bridas, tornillos, tuercas, etc;
Carros de traviesas; como se necesiten;
Carros con accesorios de linea telegráfica (si hace falta);
Carro con combustible (si el ténder no es de suficiente capacidad para un dia de servicio o si no hay puntos de aprovisionamiento disponible);
Locomotora; algunas veces varias.

**186. Entrega de Materiales.** De noche o cuando sea necesario volver por mas material de via, los carros-camas y de cocina se dejan en la parte mas avanzada de la via en construccion ó en un desvio, y la locomotora regresa con los carros de carriles y traviesas (y el carro de combustible si lo hay) a la base de aprovisionamiento, probablemente un patio. Los carriles y otros accesorios se cargan en el tren de construccion. Los carriles rectos y curvos de diversos largos, y las traviesas duras y blandas deben cargarse por separado. De otro modo se puede perder mucho tiempo en su manipulacion y en su busca cuando se necesitan. Por la mañana, esta parte del tren regresa al sitio de operaciones y conecta con el resto.

**187. El afirmado de la via** debe nivelarse bien, antes de recibir las traviesas y carriles; porque una superficie irregular puede forzar y doblar los carriles en mala forma cuando pase el tren de construccion y aumentar los descarrilamientos.

**188. Entongue de traviesas.** Cuando las traviesas se depositan cerca de la via, se requieren las siguiente condiciones. (Vease tambien « Sazonado » en « Traviesas », ¶ 53.) * Entongado $\lessdot$ (4 m) del carril mas cerca (0,90 m) de espacio entre las tongas *. † En terreno no mas bajo que el declive del F. C. pónganse sobre una fundacion de piedra o de traviesas de desecho. † * Tongas de 25 o 50 traviesas *. † Tongas $\gtrdot$ 12 camadas de alto. † * Cada tonga marcada con el nombre del propietario y fecha de entongue * † y el número de traviesas de cada clase de madera en la tonga. † * Las traviesas aserradas y labradas entongadas separadamente *. † Las de castaño entongadas separadamente. † * Las traviesas tratadas con cloruro de zinc u otra solución deben apilarse en tongas juntas en terrenos bien desaguados *.

**189. Reparto de traviesas.** Las traviesas son llevadas por parejas de animales ó á mano, ó con la « maquina de colocar via» (vease ¶ 199). Hasta donde sea posible, las traviesas de madera dura se reservan para las curvas. Las traviesas pueden tirarse, y colocarse en su lugar, poniendose en linea y graduando su separacion por una cuerda o liston graduado o por otros medios.

**190. Reparto de carriles.** Los carriles pueden correrse desde los carros hacia el suelo lateralmente sobre un par de carriles inclinados; pero en general no debe dejarse que se golpeen unos con otros, o dejarlos caer sobre un terreno irregular. † Deben distribuirse con la base hacia abajo, en una superficie uniforme de asiento sobre el afirmado de la via †. Deben llevarse hacia adelante con hombres, o arrastrados por caballos, o entregados por la « maquina de colocar via « (vease ¶ 199), como parezca mas expedito; y entonces se ponen sobre las traviesas.

† Carriles puestos uno a un tiempo. Los extremos puestos juntos a escuadra teniendo en cuenta la expansion †.

---

* Ascn Am Ingo F. C. † F. C. Pen. ‡ F. C. U. Pacific. Vèase tambien Especificaciones, p. 853.

**191. Doblado de carriles en las curvas.** La necesidad de doblar los carriles de modo permanente, antes de ponerlos en las curvas, aumenta con el peso de los carriles y con la estrechez de la curva; y disminuye a medida que el largo de carril aumenta y segun se aguante el carril en la curva con el tráfico.

**192.** *En curvas medianas se colocan generalmente* los carriles sin doblarlos previamente, se obligan a encurvarse y se aguantan con los clavos, etc. Para curvas mas cerradas que 10°, y para ramales; los carriles se doblan en su sitio, por medio de un dobla-carril de mano, a un costo de $28 á $36 o mas, por kilometro (Camp). Para trazados especiales, algunas veces se doblan (en frio) en la fábrica, con máquinas adecuadas.

**193.** *En los ramales*, los « carriles de arranque deben encurvarse antes de ponerlos; de otro modo es difícil evitar que se doblen las abrazaderas cuando se trate de forzar una curva » (Camp).

## Ordenada media *m* ó flecha para doblar los carriles en las curvas.

C = longitud de la cuerda tomada como unidad;

D = grado de curvatura = ángulo central subtendido por la cuerda, C;

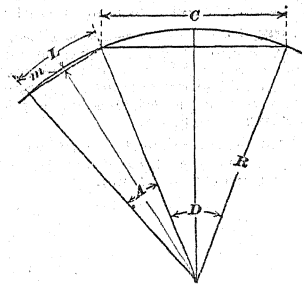
$R = \frac{C}{2 \operatorname{sen} \frac{1}{2} D}$ = radio de la curva, en metros;

L = longitud del carril;

$A = \frac{L}{R}$ = ángulo central subtendido por el carril, en radiales (véase *N. del T.* pág. 103, § 2);

A° = 57.2958 A;
log 57.2958 = 1.758 1226;
(1 radial = 57°.2958);

$m = R\left(1 - \cos\frac{A}{2}\right)$, en metros, tomando el R en metros.



(*N. del T.*— La que sigue es la tabla del autor convertida al sistema métrico. Para cualquier radio que no esté en la tabla, se encuentra la flecha por una simple proporción.)

| R metros | Largo L del carril en metros. | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 9.14 | 8.53 | 7.92 | 7.32 | 6.70 | 6.40 | 5.49 | 4.88 | 4.27 | 3.66 | 3.05 | 2.44 | 1.83 |

**194. Expansión y contracción. Suplementos de expansión.** Los hay de muchos tipos, desde cuñas graduadas especiales hasta clavos de alambre; pero deben ser de hierro o acero, no de madera, y deben tener estampada las temperaturas a que deben usarse; se colocan provisionalmente entre los extremos del carril y así sirven para separar las juntas del carril, dejando el juego para la expansión y contracción. Despues se quitan.

**195. Espacios para la expansión.** (Carriles de 33 pies, 10,065 m.) Temperaturas. Fahr, tomadas en el carril al tiempo de ponerse.
(*N. del T.* — Al lado de las pulgs van los milimetros y debajo de los grados Fahr van los Centig).

| | | | |
|---|---|---|---|
| Espacio, en pulgs, entre los ext del carril..... | $^{5}/_{16}$ (8 mm) | $^{1}/_{4}$ (6 mm) | $^{3}/_{16}$ (4.5 mm) |
| Ascn Am Ingo F. C..... | — 20 a 0° | 0° a + 25° | 25° a 50° |

† En juntas aisladas, ½ pulg (12 mm) sin considerar la temperatura.†

**196. Las juntas** son las que siguen. Las barras de brida se ponen en su lugar, algunos si no todos los tornillos se pasan por los agujeros, y las tuercas se aprietan. Entonces los suplementos de expansión pueden quitarse. † *En las tangentes* cada junta debe caer frente al medio del carril opuesto de la misma via. *En las curvas*, una variacion de ⩾ 18 pulgs. † (45 cm).

**197. El clavado** de los carriles a las traviesas sigue ahora. La traviesa se sujeta contra el carril empleando un hombre con una « pata de cabra », (una palanca que se para por arriba del carril y agarra debajo de la traviesa), y dos hombres meten los clavos, uno a cada lado del carril, golpeando alternativamente. Cada clavo debe meterse verticalmente y debe empezarse de modo que el lado de la punta toque el canto de la base del carril, y que fuerce el carril. Cuando se usan *tirafondos* la operacion es por supuesto diferente. Véase en « tirafondos », ¶ ¶ 107, etc. Por supuesto que se tiene cuidado de que el cartabón esté bien puesto cuando los clavos se esten poniendo en el otro extremo de la traviesa.

**198. Especificaciones.** † Cuando no se usen planchas de traviesas, los clavos interiores deben meterse cerca del canto este ó sur de la traviesa; los clavos exteriores deben meterse cerca del lado oeste ó norte de la traviesa; ⩽ 2″ (5 cm) del canto de la traviesa. 1909. †

† Clavos por traviesa en cada carril; —

| | |
|---|---|
| En tangentes sin plancha de asiento..... | 1 dentro, 1 afuera |
| En tangentes con planchas de asiento planas o con nervios..... | 2 dentro, 1 afuera |
| En curvas con planchas de asiento planas o con nervios..... | 2 dentro, 2 afuera.† |

* Los clavos no deben enderezarse mientras se meten. Los clavos exteriores de ambos carriles, deben estar en un lado de la traviesa; ambos clavos interiores en el lado opuesto. Los clavos ordinariamente a (2.5 pulgs) (7 cm) de la parte exterior de la traviesa. Los agujeros de clavos viejos deben entarugarse. *

---

* Ascn Am Ingo F. C. † F. C. Pen. ‡ F. C. U. Pacific. Véase tambien Especificaciones, p. 853.
§ Puesto junto, sin golpear.

**199.** «**Maquinas de colocar vias**». Asi se las llama, pero no colocan en verdad la linea. Simplemente facilitan la entrega de los carriles y las traviesas de los carros a los puntos avanzados donde se necesitan, consisten en cierta forma de rolletes ó via montada en el tren de construcción, a lo largo de uno ó de ambos lados, ó sobre la parte superior. En algunas máquinas la corredera está colocada en pendiente y el material rueda por gravedad; mientras que en otras es llevada en plataformas ó correas conductoras a otros accesorios movidos por una máquina especial fija. Estas máquinas rara vez aumentan la cantidad de trabajo en un tiempo dado, pero lo abaratan reduciendo el número de trabajadores necesarios.

**200. Velocidad** de colocación, segun Camp, en condiciones medias; cerca de una milla (1 609 m) en 10 horas sin apurarse, empleando 64 trabajadores, 3 capataces y 2 parejas de caballos.

**Balastado.**

**201. Entrega del balasto.** En carros o planchas corrientes, sin tablas de costado, cargados con paleadoras de vapor, con capacidad de (7.6 $m^3$) cada uno. Con costados, (2 pies 8 pulgs (80 cm) alto), un carro de 12 m. de largo llevará cerca de (32 yardas cubicas) 25 $m^3$. Las tablas de costado estan dispuestas como una serie de puertas, embisagradas arriba.

**202.** Los carros planchas se descargan economicamente con una pala que se arrastra por arriba de los carros planchas, por medio de un cable de alambre conectado la locomotora o al tambor de una máquina situada en un carro al extremo del tren. Con una locomotora el tren se estaciona, y cada carro deposita su carga completa en una distancia igual a su propia longitud; pero, con máquina y tambor, la distribución del material se puede hacer teniendo el tren en movimiento.

**203.** *Pala central*, esta distribuye el balasto a ambos lados de la via. Y se guia por estacas provisionalmente colocadas en las estaqueras laterales para este efecto, o por rolletes que descansan en el costado del carro. La punta de la pala central es movible para un lado ú otro : asi que, si se desea, se puede descargar mas de un lado que de otro en la via.

**204.** *Palas laterales.* Estas descargan a un lado solamente, están guiadas por estaqueras laterales. La descarga lateral con pala central o lateral significa el gasto de volver a tirar el balasto sobre la via. Vease tambien carros de volteo, (mas adelante) en Material Rodante (¶ 80).

**205.** Para evitar que el balasto caiga en la via entre los extremos de los carros se embisagra una plancha horizontal de caldera en una cabeza de cada carro; de modo que cubra el espacio donde se enganchan entre carro y carro.

**206. Nivelación.** Cuando el balasto se descarga (entre los carriles) por carros tolva, se nivela ó empareja por medio de un carro pala que lo extiende; este carro va conectado a la cola del tren, o por medio de nua traviesa atravesada y asegurada delante de las ruedas del tren, atrás del carro que descarga. Se necesitan algunos hombres con barretas ó palas en el carro, para empujar el material hacia abajo en las tolvas.

**207. Apisonado.** *Balasto de tierra o arcilla.* Equipo de pala con mango de hierro para apisonar : barretas de punta ancha para apisonar. * Apisónese cada traviesa la una distancia de (18 pulgs) (45 cm); (15 pulgs (38 cm) con arcilla quemada) desde el interior del carril al extremo de la traviesa con el mango de la pala ó con la barreta de apisonar. Si es posible apisónese primero el extremo de la traviesa y déjese pasar el tren antes de apisonar el interior del carril; désele especial atención al apisonado debajo del carril : apisónese el centro de las traviesas flojamente con la punta de la pala. La tierra ó arcilla entre las traviesas debe colocarse en camadas y bien prensada con los pies ó de otro modo, de manera que deje correr el agua facilmente; la tierra no se debe dejar amontonada mas arriba del fondo de las cabezas de las traviesas; el relleno entre las traviesas no debe tocar al carril y debe estar tan alto ó mas que la parte superior de las traviesas en el medio de la via. Con **piedra picada** ó **escorias de horno**, no se apisona el centro de las traviesas; arrímese balasto cerca del extremo de las traviesas a nivel con la parte superior de ellas. *

---

* Asen Am Ingo F. C. † F. C. Pen. ÷ F. C. U. Pacific. Véase tambien Especificaciones, p. 853.

**208. Costos**; Balasto, ctvs por metro cúb.

| | |
|---|---|
| Piedra triturada a máquina en la cantera | 58 a 97 |
| Colocarla en la via abajo y apisonarla | 20 a 33 |
| En la via, completamente balastrada, alineada y emparejada | 97 a 162 |
| Cascajo, en via terminada | 26 a 39 |
| Incluyendo costo de jornal para colcarlo en la via apisonado y emparejado | 13 a 20 |
| Descargado, con pala y cable, incluyendo jornales para manejar el cable y el uso del equipo | 0.7 |

El aceite para el afirmado de la via de 2 a 3 1/2 cts por galón.

**209. Aceitado del Balasto.** *En afirmados de vias polvorientas* se puede evitar la mortificacion al pasaje, y el daño a las traviesas y muñones, rociando el balasto con aceite que penetre a una profundidad de varias pulgadas, disminuyendo no solo el polvo actual sino el que pueda asentarse mas tarde. Se evapora tan lentamente que una aplicacion por cada estacion del año es bastante.

**210.** « El aceite para el afirmado de la via « es un producto de la destilacion del petroleo con una densidad de cerca de 0.89. Es practicamente incombustible en las condiciones en que se usa, y se dice que se queman menos traviesas en via aceitadas que en las que no lo estan.

**211.** La capa de aceite retarda el crecimiento de la yerba en el balasto; y como lo hace no absorbente reduce el levantamiento de la via en las heladas. Se cree que conserva las traviesas porque excluye la humedad.

**212.** Los aparatos de regar o rociar se instalan por lo regular en un carro plancha, con enchufes para conectarse al carro-tanque de aceite. En tiempo de calor el aceite corre libremente por gravedad. En tiempo frio se puede ayudar a correr por medio de vapor, o con presion de aire tomado de la locomotora. El aceite se aplica al borde del afirmado de la via, y si es necesario al talud en excavaciones y terraplenes.

**213.** El tren de riego puede cubrir cerca de (4 millas) (6.400 m) por hora gastando de 1.200 a 1.500 gals de aceite por kilometro de via sencilla sin aceitar. En los riegos subsecuentes se necesita menos aceite. La penetracion aumenta en cada regada hasta que llega a cerca de (8 pulgs) 20 cm que es suficiente para evitar que el balasto seco y polvoriento se levante durante las renovaciones y el apisonado.

## Conservación de la Via.

**214. Emparejado.** Consiste en levantar las depresiones en la via (sobre todo en las juntas) a un nivel parejo. No es necesario mantener la via en las marcas que se pusieron cuando se hizo nueva mientras se mantenga bastante pareja.

**215. El emparejado completo** (consiste en emparejar la via en conjunto); es necesario cada cierto numero de años.

**216.** El *costo* de emparejar varia desde $60 a $120 kilometro por año, dependiendo del tráfico, y de los materiales de que esta construida la via.

**217. Balasto.** *Renovación.* Antes de distribuir el balasto nuevo sobre la via, el balasto viejo debe quitarse de entre las traviesas hasta el fondo de ellas para anchar el borde del afirmado de la via. Véase tambien « Embalastado ». ¶ ¶ 201, etc.

**218.** *Limpia* del balasto. * Intervalos de años entre las limpiezas; en las estaciones terminales, 1 a 3; en lineas de tráfico pesado, de carbon y coke, 3 a 5; en tráfico ligero, 5 a 8 *.

* En condiciones usuales, limpiese solamente la piedra y escoria dura. Úsese pala de balasto. Limpiese (a) el borde, hacia abajo ;(b) entre traviesas hasta el fondo de las traviesas; (c) centro de la zanja de doble via hacia abajo. Vuélvase a poner el balasto limpio *.

* Cascajo de orilla (Los promedios se refieren al volumen *original*).

| Clase de via. | Para lavarse o cernirse cuando contiene >. | El cascajo lavado ó cernido debe contener: |
|---|---|---|
| A. | 2 % de polvo ó 40 % arena | < 25 % > 35 % arena. |
| B. | 3 % — ó 60 % — | < 25 % > 50 % — * |

* Ascn Am Ingo F. C. † F. C. Pen. ÷ F. C. U. Pacific. Véase tambien Especificaciones, p. 853.

**219. Traviesas.** La persona que inspeccione las traviesas, con el propósito de renovarlas, las puede marcar con pintura blanca. El método usual de poner traviesas nuevas es excavar una zanja al lado de la traviesa vieja un poco mas honda que la traviesa; entonces se empuja de costado en la zanja, y se saca. Si la traviesa nueva es mas gruesa, o si la traviesa vieja estaba cortada por la base del carril, es necesario recorrer el asiento de la traviesa.

En balasto de roca, las traviesas se pueden renovar a razón de 8 o 10/dia/hombre; en cascajo, de 14 a 18.

**220.** *Gasto para Renovar traviesas.*

| | |
|---|---|
| En balasto de piedra..... | cerca de 20 ctos cada una. |
| En cascajo flojo..... | 6 a 10 ctos cada una. |
| En cascajo que fragua..... | 10 a 20 ctos cada una. |
| En escoria dura..... | 9 a 15 ctos cada una. |

**221. Carriles.** Para ponerse los carriles nuevos se colocan sobre las traviesas en la parte de afuera de los carriles viejos, se atornillan unos a otros en tramos que puedan manejarse. Los clavos en el interior del carril se sacan, el carril se levanta hacia afuera sin aflojar las juntas (excepto en el extremo de las secciones o tramo), y el carril nuevo se coloca en su lugar y se clava.

**222.** *En curvas*, se trasponen a menudo los carriles, el carril exterior gastado se pone al interior de la via, y el menos gastado interiormente va al exterior; los clavos interiores se sacan, los carriles se trasponen, y los clavos se reponen.

**223.** La via mas difícil de conservar es la de curvas estrechas para servicio rápido de pasajeros, y por la que corren trenes de carga cuya velocidad sea limitada, por las condiciones de las cuestas y declives.

**224. Carros registradores de via.** Los hay de muchos tipos, no hay aparentemente ninguno que prive. Casi todos llevan una larga tira de papel, movido por un mecanismo de relojería o por engranes de las ruedas, de modo, que por medio de lápices o plumas, se hacen trazados en los cuales la abcisa puede representar tiempo o distancia, como se desee. A fin de identificar, diferentes partes del registro, es costumbre dedicar una o dos plumas a registrar el tiempo por medio de un reloj impulsado por un electro-magneto que obra sobre una pluma; o registrar la distancia, automáticamente, por engranes desde las ruedas, ó por impulsos dados con un boton de contacto por un observador que vigile los postes kilométricos u otras marcas. Estas marcas son identificadas, haciendolas con cierta caracteristicas como dandoles, por ejemplo, doble ó triple longitud ó por otro operador registrando el nombre a la mano y frente a la marca.

**225.** Varios son los elementos que se registran, y de diferentes modos. Las desigualdades laterales o verticales de la via son registradas por pendulos (libres, ó contrapesados por « cojinetes »), por el movimiento relativo del trole (carretilla) y cuerpo del carro, o por los de una rueda loca ó un par de ruedas. Algunos carros estan dispuestos para manchar automaticamente con pintura el costado del carril, donde quiera que haya desigualdades en la via.

**Carros dinamómetros.** Véase Resistencia de trenes, ¶ ¶ 56, etc. (masadelante).

# DESVIOS Y CRUCEROS

## PARTE I. PRÁCTICA

### DESVÍOS

Para el estudio geométrico de los desvios, véase Part II, Pag 923, etc.

#### Generalidades.

**1. Elementos.** Figs 1. Un desvio se compone esencialmente de un chucho (1), dos carriles de « arranque », $L$ y $L_t$ *, una rana, y dos guarda carriles, $g$ y $g_t$.

**2. Enfrentado y Arrastre.** Figs 1. Cuando un tren entra en un desvio en la direccion de la flecha (pasando el chucho antes de llegar á la rana), se dice que « enfrenta » el chucho. Cuando se aproxima (viniendo de la linea principal, $M'$, ó del desvio $T$) en la direccion opuesta (pasando la rana antes de llegar al chucho) se dice que « arrastra » (trail) el chucho.

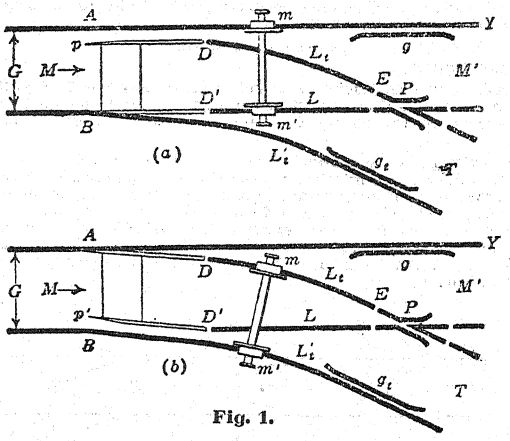

**Fig. 1.**

**3. Via doble;** Fig. 2; Los trenes se mantienen a la derecha, como se indica por las flechas. Aqui, para el tráfico normal, $X$ é $Y$ estan enfrentando los chuchos; mientras que $V$ y $W$ estan arrastrando los chuchos. Cuando se deja la via principal por arrastre de un chucho (por ej. : *enfrentando* un *chucho* de *arrastre*) un tren debe moverse en la direccion, contraria a la propia, a dicha via. No obstante la superior seguridad de los chuchos de arrastre justifica su uso.

**4.** Fig. 2. Un desvio es **derecho** o **izquierdo**, segun mande un tren que *enfrente* a la derecha o a la izquierda de la linea principal. Asi, $V$ y $W$ son desvios *derecho*, mientras $X$ e $Y$ son *izquierdo*.

**5. La posicion del chucho** (Figs 1), determina cual de las dos vias, $M'$ o $T$, seguira un tren que los enfrente. El carril principal de arranque o carril principal de cierre, $L$, y el carril de desvio de arranque o carril de desvio de cierre, $L_t$ *, conduce desde el chucho a la rana, y las ranuras de la rana para las pestañas permite a dichas pestañas de las ruedas en cualquiera de los dos carriles, $L$ y $L_t$, * pasar al otro (vease párrafo 68).

---

* Algunos escritores llaman a los dos carriles encorvados, $Lt$ y $Lt'$, carriles de arranque. Vease Webb, construction de Ferrocarriles, pp. 265 y 272.

(1) (*N. del T.* — Asi se llama en Cuba el conjunto *movible* de las agujas. A veces comprende tambien todo el desvio. Lo hemos adoptado.)

Los dos guarda carriles, $g$ y $g_1$, mantienen dichas ruedas en sus propias vias dirigiendo las pestañas de sus compañeras mientras están pasando la rana.

**6. El avance** (algunas veces llamado la **distancia de la rana**), es la distancia $B\,P$, Figs 1, donde $P$, es el vértice teórico de la rana (¶42) y $B$ es la posicion del punto teórico del chucho (¶ 79) hacia el lado del desvio de la linea principal, $M\,M'$, cuando el chucho (1) esta puesto para la linea principal, como en la **Fig 1 a.**

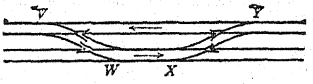

**Fig. 2.**

**7. La curva de arranque, o curva de desvio**, $D\,E$, Figs 1, es generalmente (por lo menos en teoría) una curva simple o circular. Fig 13. Las lineas de cartabon, $a\,y$ y $b\,z$, de la rana son generalmente rectas en todo su curso, o desde el principio hasta el fin de la rana; como tambien lo son los carriles del chucho en toda su longitud. Pero véase ¶ 77.

## Tipos de Desvios.

### Desvios dobles.

**8.** Figs 3. En un desvio doble (a menudo llamado desvio de **tres vias**) las dos vias laterales dejan la linea principal en el mismo punto. Comparándolos con dos desvios vecinos economiza, espacio, material, trabajo y tiempo, y facilitan su manejo.

**9. Curvatura.** La *linea principal* puede ser *recta o en curva* y las *vias laterales* pueden dejar la via principal *en la misma o en opuestas direcciones.* Cuando dejan o arrancan de lados opuestos, su agudeza (curvas ¶ 11) puede ser igual o diferente. Aunque las vias laterales se distinguen por su objeto ó funciones.

Es conveniente con frecuencia descartar esta distinción, y considerar las tres vias con referencia solamente a sus *posiciones* relativas, o como via *exterior* o del *medio.* Vease ¶ 11. Asi, $T$ o $T'$ puede ser una via principal en curva; en cuyo caso, $M'$ es un desvio recto.

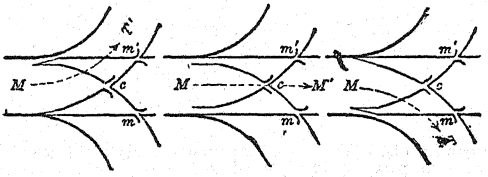

**Fig. 3.**

**10. Elementos.** Figs 3. Un desvio doble requiere *un chucho de 3 tiros* o tendidos, dos ranas principales, $m$, $m'$, una rana central $c$, y seis guarda carriles (dos para cada una de las tres ranas), a menos, que como en la Figs 3 los dos ángulos de la rana principal (vease Part II, ¶ 32) sean iguales, y las dos ranas principales sean por consiguiente opuestas : en este caso una pata de carril (vease ¶ 41) de cada rana principal actúa como guarda carril para la otra rana principal, y solamente se necesitan cuatro guarda carriles (véase figura) propiamente dichos. Cuando las dos ranas principales, $m$ y $m'$, son de poca diferencia en sus angulos, y por consiguiente casi opuestas, es impracticable colocar y mantener los dos guarda carriles adicionales de suficiente largo. En la Figs 3, los dos carriles de cada chucho de tres-tiros estan indicados por líneas finas, que muestran el chucho puesto para las vias $T'$, $M'$ y $T$, respectivamente, como se indica por las flechas. Cuando la curvatura del desvio es fuerte, las patas de la rana central estan encorvadas para que se adapten a la curvatura.

(1) Véase *N. del T.* ¶ 1.

**Vias principales, apartaderos y enlaces.**

**11.** De las dos vias, conectadas por un desvio, es generalmente fácil distinguir una, como la via *principal*, y la otra como el desvio. La linea o via entre la rana de la via principal y el desviadero se llama enlace : y la expresion « enlace « se aplica tambien a una via de alguna longitud que une dos vias, ninguna de las cuales es un desvio de la otra.

**12. Un chucho** (1) **muerto** es una via (generalmente corta), hecha con algun propósito especial, como para una cantera vecina, apartadero, foso o almacen, que no vuelve a enlazar con la linea principal.

**12 a. Una transferencia** conecta dos vias no-adyacentes, y el termino se usa especialmente cuando estas se encuentran a diferente nivel.

**12 b. Una maestra** es una via que cruza diagonalmente, y conecta una serie de vias paralelas o concéntricas.

**12 c. Un entronque** (vease parte II, ¶ 57) conecta una via principal con vias de patio adyacentes.

**Fig. 4 a.**

**Fig. 4 b.**

**Enlaces (Gauntlet) adheridos y (Intervolvd) envueltos.**

**13.** Fig. 4. En ciertos casos especiales, como en el caso de dos vias paralelas o concéntricas que deban pasar por un espacio demasiado estrecho para doble via como en un puente de via sencilla o túnel, puede usarse la disposicion que se indica. Donde el tráfico, en las dos vias, sea en direcciones opuestas se llama enlace *adherido*; cuando es en la misma direccion, se dice que las vias estan **envueltas**. Se necesitan dos ranas sin chuchos. Las dos vias se tiran sobre las mismas traviesas.

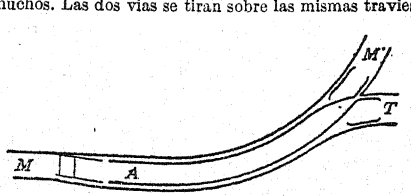

**Fig. 5.**

**14. Mejora en el Replanteo de Chucho.** Fig. 5. Para evitar la colocacion de un chucho en el exterior de una curva puede colocarse en la tangente, detras del punto *A* de la curva, y llevar el tráfico por una via envuelta concentrica, a la rana donde el desvio, *T*, deja la curva de la via principal, *A M'*. Esta disposicion requiere el uso de un chucho y una rana.

**15.** Un sistema de vias envueltas se usa algunas veces en las básculas o romanas **de via** para el material de tráfico que no se pesa. La via que lleve dicho trafico descansa en estribos independientes de la plataforma de la báscula. Esta disposicion exige el uso de dos chuchos, sin rana. Véase Patios y Estaciones, ¶ 60.

(1) Véase *N. del T.* ¶ 1.

**Desvio diamante o equilátero.**

**16.** Donde una via lateral paralela o concéntrica deje una via principal recta o curva, la linea principal ordinariamente continua su curso sin afectarse por el desvio; la deflexion de la via se concreta enteramente a el desvio.

**17.** No obstante, si la desviacion se divide igualmente entre la linea principal y la lateral, tenemos un desvio « diamante » o « equilátero ». Esto permite el uso de una rana de mayor angulo (numero bajo) sin estrechar la curvatura. Véase Part II, ¶ 52.

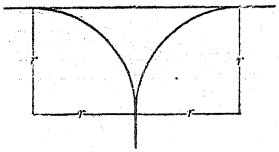

Fig. 6.

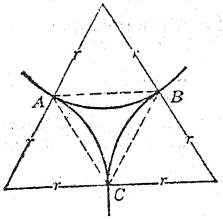

Fig. 7.

**Triángulos (desvios en Y).**

**18.** El triángulo, Figs 6 y 7, se usa para virar locomotoras (cambio de cabeza) de este modo sustituye a la mesa giratoria. Tambien se viran trenes enteros, si no son demasiado largos para el triángulo.

El sostenimiento del triángulo debe costar menos que el de la mesa giratoria : y puede costar menos su instalacion, segun sea el costo del terreno.

**19.** Fig. 7. En igualdad de condiciones, el triangulo *ocupa el mínimo de terreno* cuando las tres vias o « patas » son curvas de radios iguales, y de igual largo. Los tres chuchos caen entonces en los vértices de un triangulo equilátero, *A B C*, y cada lado es igual al radio comun, *r*.

**Descarrilamientos.**

**20. Generalidades.** Los carros dejados en los desvios, pueden moverse, por gravedad por el viento, descuidos, etc., a posiciones lo bastante cerca de la linea principal para hacer peligrar el tráfico por un choque. Los carros pueden arrancar solos por gravedad, sobre una pendiente de cerca de 0.4 por ciento (21 pies por milla); o (por la accion del viento) en pendientes mas planas o en vias a nivel. Es inseguro fiarse de los frenos.

**21.** Generalmente se considera segura una distancia de (12 pies) 3.66 m entre centros de via o sea un espacio de (6.5 a 7 pies) 2 a 2.15 m de espacio entre las cabezas de los carriles. El ferrocarril de Pennsylvania exige ∢ (16 pies) 4.90 m desde el centro de la via lateral al centro de la via principal (18 pies (5.50 m) donde sea viable); excepto en apartaderos paralelos a la via principal se encurvarán hacía afuera.

**22.** El punto, donde las dos vias se acercan mas de lo permitido, se indica con un **poste cartabón** de madera o de metal. Si se pone entre vias, tales postes son peligrosos de noche para los vigilantes. Por consiguiente, se colocan con preferencia 1,50 m a un lado de cualquier via. Algunas veces el punto de cartabón está indicado por una traviesa en forma de mediacaña pintada de blanco, puesta entre las dos vias.

**23.** Se usa en la via principal **un aparato de descarrilar** o apartaderos donde el descarrilamiento sea preferible antes que el carro llegue al punto de peligro, como un chucho (1), o un crucero, etc.

**24.** Figs 8 *a*, 8 *b*. *El extremo de empalme* de las agujas de chucho están indicados por tildes pequeños en el interior de la via.

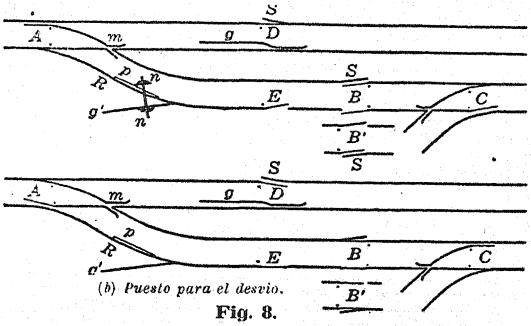
**25.** *Un carril solo de chucho de descarrilar*, como se muestra en *D* ó *E*, es suficiente para un descarrilo; pero un par de carriles de chucho, como se muestra en *B*, facilita el volver a la via los carros descarrilados. En posicion para descarrilar, el carril de chucho esta generalmente soportado por dos o tres mordazas de via. Véase Via, ¶ 143.

**26.** Es preferible que los chuchos de descarrilar, vayan *conectados con el chucho de la via principal A*, de modo que el aparato de descarrilar esté siempre en posicion adecuada con el chucho principal (compárense Figs 8 *a* y 8 *b*). De otro modo debe ponerse una señal o cartel, para recordarle al chuchero que los disponga para descarrilar.

**27. En las disposiciones para descarrilar de via principal**, como se muestra en *D*, el carril principal se dobla hacia afuera : y un carril de chucho de descarrilar simple se usa comunmente, con el empalme hacia la rana de la via principal *m*, y que abra hacia adentro, Fig. 8 *b*.

**28. En apartaderos**, basta un simple carril de chucho de descarrilar, *E*, fig. 8*a*, colocado en el carril exterior, con el empalme hacia la rana *m* de la via principal, y que obra hacia adentro.

*(a) Puesto para la Via principal.*



*(b) Puesto para el desvio.*

**Fig. 8.**

**29.** Fig. 8 *a*. Un carro, que descarrile en un desviadero, como en *E*, puede no obstante obstruir la via principal (como cuando el *descarrilamiento sea cerca de chucho de la via principal*, y la pendiente del apartadero sea considerable), y puede usarse un guardacarril largo *g'*, para mantener las ruedas *n*, mas lejos, fuera de la linea principal, y un tablon, *p*, para llevar las ruedas mas cercanas *n'*, sobre el carril del apartadero adyacente, *R*. Tambien puede usarse un *desviadero* de descarrilar, *C*.

**30.** Fig. 8 *b*. Descarrilado un carro en la linea principal, en *D*, se mantiene cerca de su propio curso por un largo guardacarril, *g*, colocado como a (20 cm) del carril que está opuesto al chucho de descarrilar. Este guardacarril puede continuarse hacia atrás, y doblarse, como se muestra, estrechando la abertura de la pestaña opuesta al aparato de descarrilar, de este modo se protege la punta o aguja del aparato de descarrilar cuando este esté puesto para la linea principal, como se muestra en la Fig. 8 *a*.

**31.** Figs. 8 *a*, 8 *b*. **En via doble**, si se usa un chucho de carril de descarrilar simple, *D* o *E*, se coloca generalmente en un carril *exterior*, con el objeto de evitar obstruir la otra via con los carros descarrilados.

**32. Direccion de Salida.** Figs. 8 *a*, 8 *b*. Donde se use un par de chuchos de descarrilar, *E* o *B'* en un apartadero, pueden como se indica en *B* huir de la rana, *m*, de la via principal, *separándose de* la via principal; o, como se muestra en *B'*, pueden huir *hacia* la rana de la via principal acercándose a la via principal; en cualquiera de os dos casos guiando el carro descarrilado *fuera* de la via principal.

(1) Véase *N. del T.*, ¶ 1.

**33. Desvio Wharton.** Se usa una forma especial de desvio corto Warton (vease ¶ ¶ 119, etc) para descarrilamientos en linea principal. Los carriles del desvio de descarrilar se dirigen *contra* los carriles de la linea principal para *descarrilar*, y *fuera* de ellos para el tráfico de la *linea principal*. Esta disposicion deja la linea principal entera sin interrupcion, y su ancho curso evita el peligro de un indebido e imperfecto descarrilamiento cuando esté puesto para la via principal.

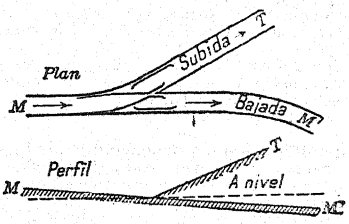


**Fig. 9.**

**Desvios de ataje.**

**34.** Fig. 9. A menudo, con el objeto de detener y desviar carros corridos en las pendientes, especialmente cuando se acercan a las curvas se usan los desvios de ataje. Estos desvios se extienden por una corta distancia hacia arriba al lado de la pendiente; y el chucho* se sujeta por medio de un muelle en posición para el desvio. De modo que el carro corrido se desvia de la principal al desviadero, donde se para por su propio peso. Entonces retrocede por gravedad al chucho pasando a la via principal y subiendo la pendiente. De este modo oscila hasta detenerse finalmente en el chucho. En operacion normal, el chuchero pone el chucho para la via principal, contra el muelle, el cual lo retiene asi hasta que el carro o tren haya pasado el chucho.

**Para Topes de via**, vease Señales, ¶ 47, pag. 1066.

**Enlaces.**

**35.** Figs 10 *a*, 10 *b*. Un enlace conecta dos vias paralelas o concéntricas. Consiste en dos desvios (enfrentados en direcciones opuestas) y una via que conecta, que puede ser una tangente o una curva invertida.

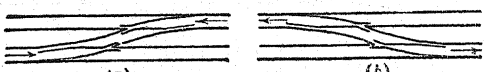

**Fig. 10.**

**36. Derecha e Izquierda.** Con tráfico que lleve su direccion a la derecha como se indica en las Figs. 10 *a* y 10 *b*, los dos desvios son ambos del lado *izquierdo*, si van de *frente*, como en la Fig. 10 *a*; y ambos del lado *derecho*, si *arrastran* o *siguen*, como en la Fig. 10 *b*.

**37. Desvios Doble.** Figs. 11 *a*, 11 *b*. Se usa un doble desvio en las lineas de via sencilla, con el objeto de que dos trenes que se encuentran, esperando para dar

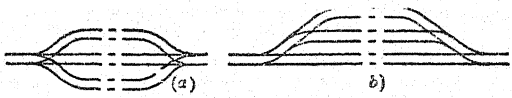

**Fig. 11.**

paso a un tercer tren puedan seguir entonces simultaneamente y sin retroceder, o estorbarse. Las vias laterales pueden ser una a cada lado de la via principal, Fig. 11 *a*, o ambas al mismo lado, Fig. 11 *b*.

* Véase *N. del T.*, ¶ 1.

**38. Desvios de doble enlace** (lap siding). Como se indica en la Fig. 12, tienen la ventaja de que la oficina de telégrafo puede colocarse en los enlaces del medio, y por consiguiente de modo conveniente para las máquinas de los dos trenes parados facilitando así las operaciones. Como se ve, el desvío de doble enlace, es en realidad una doble vía, de largo *A B*, con enlaces a la mitad de su tramo o largo.

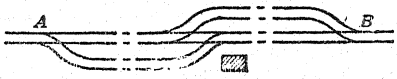

**Fig. 12.**

## Entrevía.

**39.** Algunos ferrocarriles mantienen la entrevía tipo en los desvíos. Otros la aumentan de (6 a 12 mm) entre la aguja del desvío y el extremo de la rana, fuera de cuyos puntos aquella se estrecha gradualmente hasta el ancho tipo en una distancia como de (9 m) a cada lado; mientras que en los ferrocarriles Europeos, con frecuencia se estrecha la vía en el desvío (6 mm) a fin de evitar el juego lateral de las ruedas, y dar estabilidad a los vehículos mientras están en el desvío. El desvío Wharton, vease ¶ ¶ 119, etc., requiere en el desvío una vía (12 mm) mas ancha que el tipo establecido.

## Ranas.

### Ranas rígidas.

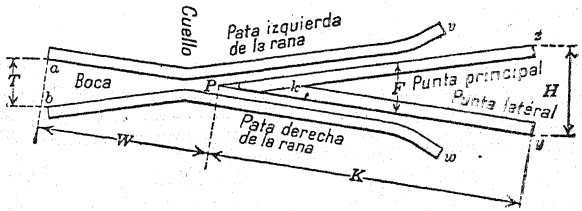

**Fig. 13.**

**40. Canales.** Fig. 13. Para la descripcion geométrica de la rana, véase Part II, ¶ 2, etc. A fin de que las pestañas de las ruedas, en el carril *a y*, puedan pasar en cualquiera direccion, del carril *b z* (o *vice* versa), la rana esta provista de « canales » al traves de los carriles *b z* y *a y*, respectivamente.

**41. Elementos.** Fig. 13. La rana se compone esencialmente de cuatro piezas de carril, así :

*a v*, la pata del carril lado izquierdo (pata izquierda de rana);
*b w*, la pata del carril lado derecho (pata derecha de rana);
*P z*, la punta principal o lengueta larga;
*k y*, la punta lateral o lengueta corta.

**42. Las lineas de la via**, a lo largo de la rana, son *a y* y *b z*. Fig. 13. A las *partes restantes* y *dimensiones* de la rana se le dan nombres como sigue : —

Abertura de la cabeza, $T$, $= a\ b$, medida entre las patas de la rana en las cabezas del carril;

Abertura de las patas de la rana, $H$, $= z\ y$; medida entre las cabezas de los carriles;

Cuello de la rana al punto de menor distancia entre las patas de rana;

Bocaa l espacio trapezoidal entre las patas, el cuello y la cabeza $T$;

Vertice de la rana el punto $P$; de la interseccion de las lineas de via $a\ y\ y\ b\ z$;
Lengueta, el triángulo entre $P$ y $k$;
Canales, los dos canales entre la punta y las patas;
Angulo de la rana, $F, = z\ P\ y = a\ P\ b$.

**43. El número de la rana**, $N$, es el cociente, $l/i$, donde $l$ (no se indica) = al largo de cualquier porcion de la rana, y $i$ (no se indica) = al aumento del ancho de la rana (medido entre los carriles de via y perpendicular al eje de la rana) en esa porcion. Algunos ingenieros miden $l$ a lo largo de la linea central de la rana; otros, a lo largo de los carriles de via; y el número dado de una misma rana varia segun el caso. Vease Parte II, ¶ 6, etc.

**44. Ranas derechas o izquierdas :** Fig 13. Una rana se llama *derecha* o *izquierda* si una persona dandole el frente a la rana, ve el *lado* de la punta principal ó lengueta larga $P\ z$ al lado derecho ó izquierdo.

**45. Bloques o Entre-dos.** Las dos puntas de carril van remachadas juntas y un bloque o entredos de acero va insertado entre la punta y cada pata de la rana. Los dos bloques algunas veces se llevan mas alla de la punta, y unidos alli forman un bloque.

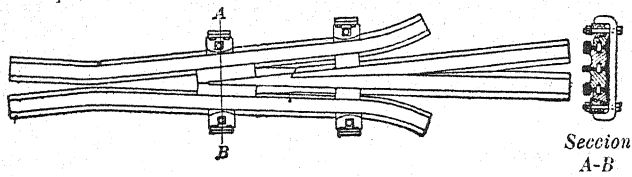

**Fig. 14a.**

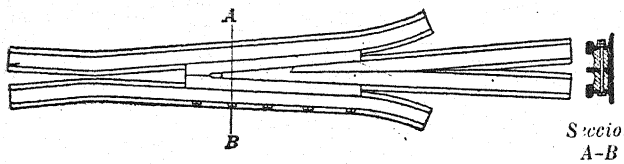

**Fig. 14b.**

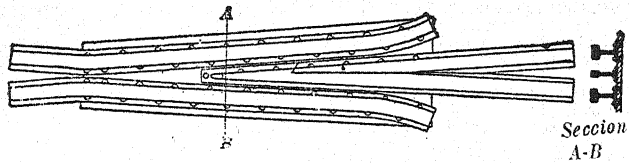

**Fig. 14c.**

**46. Amarres.** Las patas de los carriles y la punta, se aseguran, en sus posiciones relativas generalmente ó
(1) por grampas y cuñas, Fig. 14*a*;
(2) por tornillos, Fig. 14*b*;
(3) por remaches a una placa, Fig. 14*c*;
(4) por tornillos y placa [combinacion de (2) y (3)] ; o
(5) por remaches a las placas de asiento de las traviesas.

**47.** La práctica, respecto a la elección entre estos métodos, esta indicada por el resultado de dos investigaciones sobre los ferrocarriles que usan cada método.

| | (1) Grampa. | (2) Tornillo. | (3) Platina. | (4) Tornillo y Platina. | Total. |
|---|---|---|---|---|---|
| Asociación de Maestros de via, 1897..... | 7 | 29 | 9 | ..... | 45 |
| Revista Engineering News. Jun 4 1908..... | 7 | 32 | 15 | 10 | 64 |

Las ranas van conectadas con los carriles ordinarios de la via por los métodos usuales. Véase Via, ¶ ¶ 145, etc.

**48.** Aunque un lado de la rana esté en la curva del desvio, y el otro lado en la curva de la linea principal por lo corto de los lados deben hacerce rectos, excepto en desvios muy agudos y en casos especiales.

**49. Largo.** El largo de una rana debe ser tal, que los extremos del carril en la cabeza y las patas, esten separados lo necesario para dar lugar a las juntas del carril sin estorbarse. Aumentando el largo se hace mas fuerte la rana; pero tambien aumenta el desperdicio cuando hay que renovar las ranas, porque los carriles próximos duran mas que las ranas. La adopción de una rana, tipo fijo de ranas, reduce el corte de carriles cuando hay que cambiarlas, vease ¶ 70.

**50. Detalles.** El carril pata de rana en el lado del desvio se hace algunas veces ligeramente mas larga en la cabeza, que en la otra parte, con el objeto de que el carril principal y el del arranque del desvio (¶ 5) puedan ser del mismo largo, y dejar opuestos los extremos de las agujas o carriles del desvio.

## Desgaste, Refuerzo, etc.

**51. Acero Especial.** Aquellas partes de las ranas que están sujetas a un desgaste fuerte se hacen frecuentemente de manganeso especial u otro acero de alta resistencia para el desgaste, y construido en el cuerpo de la rana. Las ranas hechas de este modo cuestan cerca del doble de las ordinarias; pero su uso, es no obstante, económico en tráficos pesados.

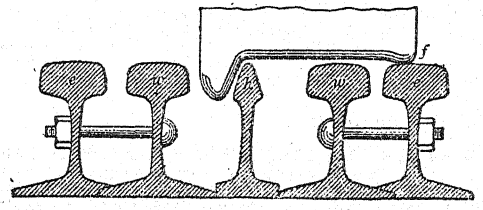

**Fig. 15.**

**52. Carriles de alivio ó de defensa.** Fig. 15. Se forman pestañas exteriores o falsas, *f*, por el desgaste de la llanta de la rueda. Un carril de alivio o de defensa corto, *e*, atornillado afuera del carril de las ancas de la rana (*w*), y formando, con *w*, un pata de dos cabezas, levanta la rueda suficientemente para mantener la llanta gastada fuera de contacto con la lengueta o punta de carril, *h*.

**53. Bloque en las patas de la rana.** Fig. 16. La pestaña falsa, *f*, de una rueda que arrastre, al caer entre las lenguetas de carril, *M* y *S*, tiende a separarlas. Para evitar esto se atornilla un bloque de patas *R*, entre las dos lenguetas de carril. El bloque tiene pendiente hacia la culata de la rana, como se muestra en la seccion con objeto de levantar ó bajar las ruedas gradualmente. Puede ser una pieza sólida de acero fundido, o un pedazo de carril invertido. Tambien sirve como guardapatas. Vease ¶ 75. Si no está bien asegurado, la pestaña puede forzarlo hacia adelante y actuar entonces como una cuña destructiva.

**54.** En la rana rígida (hasta ahora descrita) todas las partes son inmovibles y ambas canales están siempre abiertas. Las patas, Fig. 13, soportando la parte exterior de la llanta de la rueda, protege la relativa delgadez de la punta de la rana, que de otro modo se maltrataria con el paso de las ruedas; y las canales por donde pasan las pestañas de las ruedas, se hacen lo mas estrecha posibles, con el objeto de disminuir la intensidad de los golpes que dan las ruedas al pasar. No obstante, estos golpes son de consideración dado el volumen del tráfico.

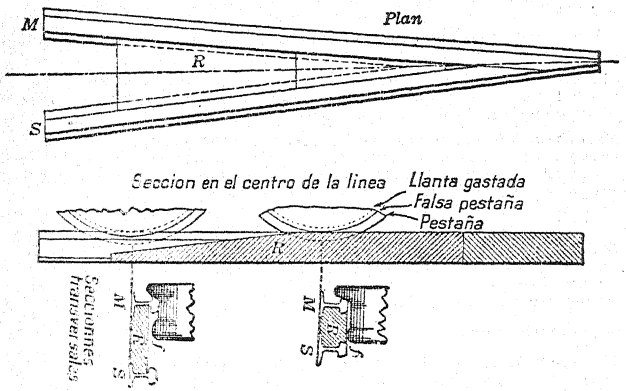

Fig. 16.

**55. Canales de Pestañas altas.** Al principio, con objeto de eliminar esta dificultad, las canales eran poco profundas de modo que las ruedas al atravesarlas, corrian sobre las pestañas, de este modo se levantaba la llanta de la rueda y no tenia contacto con la cabeza del carril; pero las pestañas pronto formaban ranuras, que hacian bajar las ruedas hasta que las llantas de las ruedas volvian a descansar sobre las cabezas del carril, dando golpes como antes.

## Ranas con Carril de muelles.

**56. Funcionamiento.** Figs 17 y 18. En la rana con carril de muelle la pata de la rana del desvio, *b s w* (que es el carril de muelle), aunque empalmado al carril de la via en su extremo, *b*, está clavado en su longitud solamente del lado de la via, y por consiguiente puede separarse del contacto con la punta, *P y*, contra la cual se apoya por muelles, como el de *h*. Cualquiera rueda de la via principal, *m'* (ó su compañera, *m*) tiene asi siempre un asiento completo en toda la rana. El carril con muelle se desliza sobre grandes placas fijas, que se extienden bajo todos los carriles de la rana.

De 59 ferrocarriles interrogados 58 usaron ranas con carril de muelle. Véase la revista Engineering News, de junio 4, 1908.

**57.** Las ruedas, *n'*, *o'*, yendo para o viniendo del *desvio*, al atravesar la rana, deben cruzar el canal de la pestaña entre la punta del carril, *P z*, y la pata de la rana *P v*. Para tener canal para la pestaña, entre el carril de resorte, *s w*, y *P y*, la pestaña de una rueda de *arrastre*, *o'*, empuja simplemente al entrar entre los dos; mientras que una rueda de *frente*, *n* (al estar separada de la rana por el guardacarril, *gt*), necesariamente guia su rueda compañera, *n'*, tambien en esa dirección y asi fuerza el carril de muelle, *s w*, fuera de, *P y*, y abre un canal para pestaña para la rueda *n'*. En cualquier caso, el muelle, *h*, vuelve al carril de muelle, *s w*, a su posicion normal, en contacto con *P y*, después que pasa cada rueda.

**58. Caja de guia.** Figs 17, 18. Para evitar que el extremo libre *w*, del carril de muelle, *b w*, se levante, cuando una carga se concentra en, o cerca de su otro extremo, *b*, se asegura al alma del carril de muelle, cerca de *w*, una pieza forjada, cuya lengua horizontal se desliza en una caja de guia, *c*, remachada a una plancha de corredera fija, extendida bajo todos los carriles de la rana en ese punto. La caja-guia obra tambien como retención para que el extremo libre, *w*, del carril de muelle no se salga demasiado.

**59.** Para evitar que la cabeza del carril de muelle pueda quedarse pegado al carril de lengueta de la punta de rana, su *patin o aleta debe cortarse* del lado próximo a la punta. El carril de muelle asi debilitado, se *refuerza* generalmente con una tira remachada o atornillada a su alma.

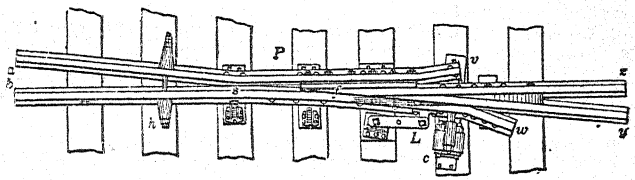

Fig. 17.

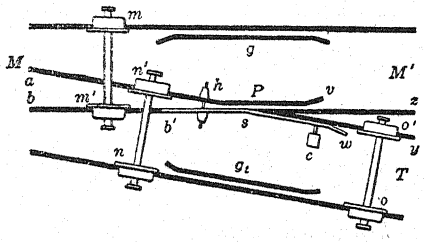

Fig. 18.

**60. Prevision contra las pestañas falsas.** Fig 18. Si el asiento entre la cabeza del carril de muelle, *s w*, y el de la punta del carril *P y*, es demasiado corto, una pestaña falsa (¶ 52) del canto exterior de la llanta de una rueda de arrastre de *m'* de la linea principal, pasando de *M'* hacia *M*, pudiera golpear la abertura, *w*, del carril de muelle, y de este modo acuñar el carril de muelle separándolo del punto, *P*. Para evitar esto al carril de muelle, *s w*, se le da un asiento o descanso mas amplio contra el carril de punta, *P y*, de lo que, sin esto seria necesario. Por una razon análoga, la cabeza del carril de muelle, donde se hace el contacto con la punta de la rana, se cepilla hasta formar una ranura paralela con la orilla de los carriles de la linea principal, como se indica por la sombra en la fig. 17 dando asi un paso a las pestañas falsas.

**61. Para Via Principal solamente.** Como las ranas corrientes con carril de muelle presentan un asiento completo a la llanta de las ruedas, *m'*, en la via *principal* solamente, fig. 18, y no a las ruedas *n'* y *o'*, que vienen por el desvio, son por consiguiente mas útiles donde la mayor parte del tráfico usa la linea principal y son pocos los trenes que usan el desvio. Vease ¶ ¶ 66, 67.

**62. Lado Derecho e Izquierdo.** Las ranas rígidas (exceptuando aquellas con patas de carril desiguales, ¶ 50) pueden usarse para desvíos del lado derecho o izquierdo; pero, las ranas con carril de muelle deben hacerse expresamente para el lado derecho o izquierdo.

**63. Resbalamiento.** Fig. 17. Para evitar que el carril de muelle se deslize o resbale; sin restringir su movimiento lateral, se usa el eslabón, *L*, que está puesto de tal modo que la tendencia a deslizarse forzaria el muelle de carril *contra* la lengueta, sin dejarlo *separarse* de ella.

**64.** *En la rana con carril de muelle embisagrado* (trazada para evitar la necesidad de emplear medios contra el deslizamiento del carril de muelle) este último se divide en *s*, fig. 17; y la parte *b s* se fija en su posición, mientras que la parte, *s a*, va embisagrada en *w*, en lugar de estarlo en *s*, donde se deja libre para girar hacia afuera contra un muelle, que lo hace volver a su puesto en contacto con la punta, despues que pasa cada rueda.

**65. En curvas.** Figs. 17, 18. Cuando una rana de carril de muelle se usa en la parte exterior de una curva en la via principal, la fuerza centrífuga de un tren en la via principal, empujando contra el carril de muelle, entre *b* y *s*, tiende a abrirlo. Esta tendencia se resiste solamente con el guarda carril, *g*, fig. 18, opuesto, pero se alivia abriendo ligeramente el carril de muelle fuera de contacto con la lengueta cerca de la punta.

**66. Rana con carril de Muelle Doble.** En la rana de carril de muelle doble, las dos patas de carril están equipadas como carril de muelle, y cada una se mueve independientemente de la otra. Ambas canales de las pestañas permanecen cerradas cuando no pasan ruedas. Estas ranas se adaptan en los desvíos donde el tráfico en la linea principal y en el desvío, es casi igual. Véase ¶ 61.

**67. Rana de carril de patas Corredizo.** En estas, los dos carriles de patas están conectadas rigidamente, a una distancia fija; pero libres para deslizarse juntos, de modo que cualquiera de las dos pueda descansar contra la lengueta fija, dejando una canal para las pestañas de las ruedas entre el otro y la lengueta. Las ruedas que entren de frente o arrastrando, abren la canal de pestaña (si no está ya abierta) por haberse deslizado los carriles (las ruedas que entran de frente lo efectuan por medio del guarda carril opuesto). Los carriles dichos permanecen entonces en la nueva posición para las ruedas que siguen. Estos carriles deben deslizarse, bajo alta presión, mientras uno de ellos soporta la carga de la primera rueda; una obstrucción alojada entre una pata del carril y la lengueta, puede trancar las patas del carril, y ocasionar un descarrilamiento. Como la rana de carril de doble muelle, ¶ 66, la rana de carriles de patas, corredizo esta dibujada, trazada, para casos donde el tráfico en la linea principal y en el desvío, es casi igual. Vease ¶ 61.

### Ranas de Carril Principal contínuo.

**68.** Para dejar siempre el carril de la via principal sin interrupción, enterizo, algunas ranas tienen el carril del desvío elevado de tal modo, que las ruedas en el desvío pasan por *encima* (en lugar de al través) del carril principal, las llantas quedan sostenidas por carriles cortos de apoyo que giran provisionalmente con este objeto, y que despues vuelven a girar hacia un lado, en direcciones opuestas, del carril principal, al despejar la linea principal. El chucho (1) se pone simultaneamente con la rana.

### Especificaciones, Uso, etc.

**69. Requisitos.** Al pedirse ranas, especifíquese tipo y detalles de construcción; sección y peso del carril; número de la rana o ángulo; largo total; largo desde la punta de la lengueta a la pata; reparto o espacio de los agujeros de las juntas de carril; grueso y dimensiones de la platina o placa usada; y, en el caso de una rana de carril de muelle, u otra rana con patas desiguales, decir si es lado derecho o izquierdo. A fin de que las partes sean cambiables, especifíquese tambien que todas las ranas de una clase deben hacerse iguales con respecto al barrenado de agujeros, de tornillos y remaches. Los carriles de las patas (que se gastan mas rapidamente que las lengüetas) pueden entonces reponerse con facilidad.

(1) Véase *N. del T.*, ¶ 1.

**70. Dimensiones. Assen Am Ings F. C.** Manual, 1915, pags 168-170. **Tamaños o números.** (Vease tambien el final de este parrafo para otros que no son de la Assen Am Ings F. C.) « Las ranas nos. 8, 11 y 16 se recomiendan como las que reunen todos los requisitos para patios, desvios de via principal y desviaderos o enlaces. Los trabajos nuevos deben hacerse hasta donde sea practicable, con estas ranas, con objeto de efectuar una eliminacion gradual de otros números, disminuyendo el costo de manufactura, y la cantidad que hay que tener en existencia. »

(*N. del T.* — Entre parentesis las medidas métricas correspondientes a pies y pulg y tambien los kg por metro de los carriles.)

*Ranas rigidas fig.* 13.

| No. de la rana. | *W* | *K* | *W* + *K* | *T* | *H* |

*Para Ranas de Carril de Muelle,* Fig. 17.

*Los extremos de los carriles de las patas achaflanados* a 45° con la vertical.

*La rana de muelle n.º* 11 *tiene* cinco bloques de tope de $^{3}/_{8}$ (9 mm) con extremo abierto de acero prensado.

**Tamaños o Nos.** *Para linea principal* con desvios para *poca velocidad* se usan Ranas del n.º 8, 9 a 12; *para alta velocidad,* como en los extremos de via doble, se usan los n.os 15 o 16 á 20. *En patios,* se usan los n.os 6 ó 7 á 9; en *patios industriales* congestionados para locomotoras de cortas bases de ruedas, se usan los n.os 4 a 6.

**71. Canales para Pestañas.** Una investigacion en 59 ferrocarriles demostró que 38 usaban en las ranas canales de 1 $^{3}/_{4}$ (44 mm) de ancho; 18 usaban de 1 $^{7}/_{8}$ (47 mm) y 3 usaban de 2 pulgs (51 mm).

**Guarda-Carriles.**

**72.** Fig. 1. Cada rueda al pasar por la rana, se mantiene en su propio curso por medio del guarda-carril, *g, g1,* que sostiene sobre su rueda compañera.

**73. Detalles.** El patín del guarda carril que va pegado al carril de la via se corta (o el guarda carril se fabrica con el alma inclinada hacia el carril de la via) con el objeto de dejar espacio, para poder clavar en la canal estrecha de la pestaña. Se han usado como guarda-carriles en lugar de carriles arreglados de este modo ó deformados, angulares de acero pesados. El ancho tipo para canales de pestaña se lleva uno o dos pies (30 ó 60 cm) desde un punto opuesto a la punta de la rana. Los extremos del guarda carril se cepillan formando un bisel largo, para evitar que objetos arrastrados accidentalmente se engarcen : o tambien el alma, próxima al extremo se corta, y la cabeza del carril se dobla hacia abajo con la pendiente necesaria. En la via principal, los guarda carriles son de 15 a 18 pies (4,5 a 5,50 m) de largo.

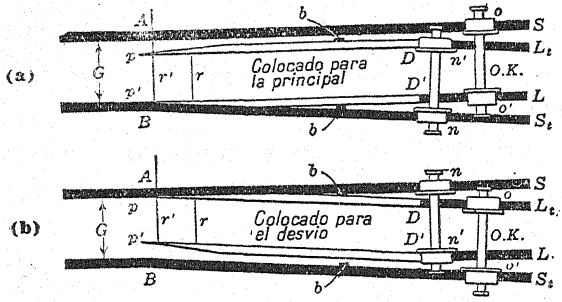
**74. Amarres.** Los guarda carriles (algunas veces debilitados por habérsele quitado el patín de un lado, ¶ 73) tienen que soportar presiones laterales fuertes; y por consiguiente están soportados por abrazaderas de carril aseguradas a las traviesas en el lado opuesto al carril de la via. Tambien planchas de asiento extendidas bajo el guarda carril y carril principal suelen usarse; o el guarda carril puede atornillarse al carril de la via, y quedar separado de él por bloques, que, cerca de os extremos actúan como guarda-pies. Véase ¶ 75.

**75. Guarda Pies.** Cuando el espacio libre, entre carriles adyacentes tiene entre 2 ½ y 5 pulgs (63 y 126 mm), hay peligro de que las personas se cojan los pies en el momento que avance un tren. Tales puntos se encuentran en los extremos de los guarda carriles, en la garganta y patas de las ranas, en la abertura de las patas de rana, y en los chuchos. Los guarda-pies se ponen para evitar tales accidentes. En ciertos estados los exige la ley. Están formados de piezas de tablón cortados para ajustarse a los espacios y clavados a las traviesas; o de bloques de madera o hierro con la forma necesaria o de tiras de acero, atornilladas al alma del carril; o si estan hechos de barras de acero, van doblados en una serie de angulos, y colocadas de canto.

## Chuchos (1).

**La Aguja de Chucho.**

Para el chucho de aguja de tope, véase ¶ ¶ 96-99.
Para el chucho Wharton, vease ¶ ¶ 119-126.



**Figs. 19.**

**76. Generalidades.** Figs 19 *a* y 19 *b*. Estas figs representan en lineas generales lo esencial del chucho de aguja, practicamente de uso universal. Para mas sencillez, los patines o bases del carril se han omitido en las figs, y solamente se muestran las cabezas del carril. En cada fig., se muestra el chucho puesto para las ruedas marcadas « O. K. ». Está mal colocado para las otras. Los carriles de arranque, $L_t$ y $L$ (vease ¶ 1, Fig. 1), y los carriles maestros, $S$ y $S_t$, están clavados de fijo a las traviesas. $S$, es el carril principal maestro (o carril continuo), y $S_t$ es el carril maestro del desvio (o carril articulado). En $B$, el carril articulado, $S_t$, está doblado formando un ángulo agudo = al angulo de chucho, $s$ (Fig. 21), y algunas veces doblado en este punto para recibir o alojar la punta de la aguja del carril, $p'$ $D'$, cuando esta puesto para la linea principal, como se indica en la fig. 19 *a*.

**Fig. 20.**

**77. Las agujas de chucho**, $p$ $D$, $p'$ $D'$, Figs 19, están formadas de carriles de via corrientes, asi cepillados, Fig. 20 (para afinar la punta), de modo que deje la via principal recta; estos carriles afilados se dejan rectos (excepto en los desvios muy agudos, donde algunas veces se encurvan). Permanecen rectos mientras se ponen para el desvio; girando en las juntas, $D$ $D'$, Figs 19.

(1) Véase *N. del T.*, ¶ 1.

**78. Largo de la Aguja.** En desvios corrientes, en lineas donde se usan carriles de (30 o 33 pies) 9,15 a 10,06 m en la via principal, el largo del carril de chucho (1) (por economia al cortar el carril) es usualmente (15′, ó 16′ − 6″), es decir la mitad del largo del carril; para altas velocidades, no obstante, como al final de una doble via, se usan largos de chucho de (20 y 30 pies), 6,10 y 9,15 ms; para patios y ramales, (10 o 11 pies) 3,05 ó 3,35 m. En cualquier caso, el largo del chucho debe ser cuando menos tal, que las juntas de carril en sus extremos, *D* y *D′*, Figs 19, no queden muy pegadas a los carriles maestros.

Véase la tabla, Part 2, ¶ 47.

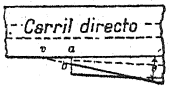


**Fig. 21.**

**79. El ángulo del chucho** (1) es el ángulo, *s*, Figs 20, 21, entre los lados de la via del chucho y el carril maestro (via principal). Debido al grueso, *a b*, Fig. 21, de la punta real, el punto teórico, o el vertice, *v*, de este ángulo está a una distancia, = *v a*, de dicha punta real. (Vease tabla de chuchos de aguja, ¶ 94.) El grueso de la punta de la aguja del chucho, *a b*, = *v a* tang *s*.

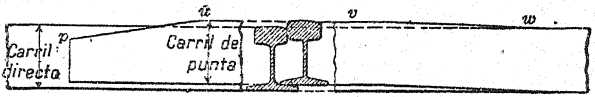

**Fig. 22.**

**80. Detalles.** Fig. 22. Para proteger la porcion delgada de cada aguja de carril, cerca de la punta, la parte superior de esa porción se rebaja cerca de (12 mm) la parte superior del carril maestro adyacente, en *p;* pero, desde *p*, la parte superior de la aguja del carril se levanta uniformemente en una distancia variable, *p u* (vease la tabla ¶ 94), hasta, digamos en *u*, donde la parte superior de la aguja del carril es cerca de (6 mm) *mas alta* que la del carril maestro adyacente, esto es con el objeto de que la falsa pestaña de una rueda que este acanalada, Fig. 23, no pueda chocar con el carril maestro, o separar los dos carriles cayendo en el espacio estrecho que hay entre ellos. Desde *u*, Fig. 22, la parte superior de la aguja del chucho mantiene esta sobreelevacion por algunos metros como se ve en *v*, y entonces declina hasta que las dos partes superiores de los dos carriles quedan a un mismo nivel, como en *w*. Algunas veces (con el mismo objeto) en lugar de *levantar la aguja del carril*, en *u*, el carril *maestro* se cepilla *rebajándolo* para dejar su parte superior por debajo del de la aguja de chucho.

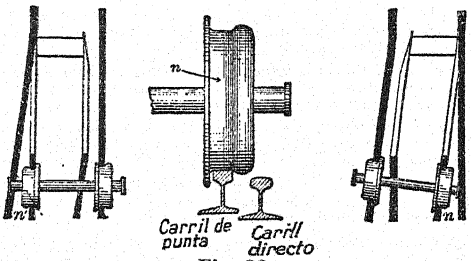

**Fig. 23.**

**81. Proteccion y Refuerzo.** Para evitar el riesgo de chocar o golpear la puntas abiertas, el empalme, en *p*, Fig. 19*a*; *p′* Fig. 19*b*, se hace mayor de lo que

(1) Véase *N del T.*, ¶ 1.

es necesario para que pasen las pestañas de las ruedas. La Asen Am de Ingos de F. C., (vease ¶ 94, abajo) especifica (12,5 cm).

**82.** Excepto en patios y para tráfico lento, las « agujas » son reforzadas, cuando menos en todo el largo de la parte cepillada, por un par de piezas de planchuela, de (6 a 15 mm) de grueso, y suficientemente anchas para llenar el espacio entre la cabeza y la pestaña, remachando o atornillando una a cada lado del alma del carril. Una barra angular o de canal sustituye a veces a una de las planchuelas.

**83.** En el *desvio de « canal »*, se atornilla una pieza ligera de carril en forma de T, de largo apropiado, a lo largo del carril de punta, del cual se mantiene como (15 cm) distante, por dos o tres separadores colocados a intervalos. La rigidez que resulta tiende a evitar que cierren el chucho (1) por equivocación cuando una obstrucción accidental separa los dos carriles, que deben traerse juntos. Vease ¶ 48, en señales.

**84.** Figs 19 *Bloques de tope, b.* Son bloques cortos de metal atornillados al alma del carril de aguja (Fig. 19*a*) o al alma del carril maestro (Fig. 19*b*) a intervalos convenientes, en puntos donde los dos carriles mismos nunca vienen en contacto. Su grueso es tal que presenta un asiento o sostén entre cada aguja de carril y el carril maestro adyacente, cuando estos están lo mas cerca. De este modo ellos apoyan la aguja del carril contra el carril maestro, permitiendole resistir mejor la presion lateral de las ruedas al pasar, que es fuerte sobre todo en las curvas debido a la fuerza centrifuga. Generalmente uno, dos o tres de estos bloques se colocan a cada lado de cada chucho (1).

**85. Platinas de corredera de acero.** Son de (12 a 15 cm) de ancho, y clavadas a las traviesas, extendidas bajo la aguja del carril y el carril maestro, entre la junta del chucho y el punto donde las pestañas de la aguja del carril y el carril maestro se separan. Hay generalmente de 6 a 8 platinas en cada lado del chucho. Sirven al doble propósito de guiar la aguja del carril a su asiento en la base del carril maestro, y (por medio de un asiento levantado en el cual la aguja del carril descansa y se desliza) de elevar la aguja del carril sobre el carril maestro, como se indica en el ¶ 80. Generalmente están hechas para recibir abrazaderas de carril para reforzar el carril maestro en el exterior.

**86. Platina de entrevia.** Se usa a veces una platina larga sencilla extendida enteramente al traves de la via, llamada platina de entrevia, en lugar de las dos platinas de correderas que se ponen en la junta del chucho. No solamente actúa como platina de corredera, sino tambien para retener los carriles maestros a cartabón, por medio de orejas o tacones adheridos a esta platina.

**87. Barras Tirante, Barras de desvio, Planchuela de Tirante Barras de Brida.** Figs 19. Las dos agujas de carril van conectadas, como se indica, por medio de barras tirante (barras de chucho, planchuelas de tirante, barras de brida), *r, r'* con preferencia sujetas al alma de las agujas de carril generalmente por conecciones embisagradas, para facilitar el cambio de angulo necesario al mover el chucho (1).

**88.** Las barras tirantes se hacen algunas veces amplias *en su largo* con objeto de rectificar el desgaste y para poder cambiarlas.

**89.** *Cantidad usada.* En linea principal, las barras tirantes son generalmente de 2 a 5. Su presencia estorba el apisonado; pero cuando se usan pocas barras, es necesario reforzar adicionalmente las agujas de carril.

**90.** *Situacion.* Las barras tirantes se colocan bajo el nivel de la parte superior de las traviesas para evitar que sean golpeadas por las ruedas de los carros, o que las arrastre alguna parte del material rodante que por un accidente se desprenda.

**91.** *Sección transversal.* En los chuchos de aguja, las barras tirantes son generalmente planas, y se colocan ó verticalmente de canto (en cuya posicion resisten el ladeo de las puntas del carril), u horizontalmente.

**92.** Figs 19. La barra tirante, *r'*, mas cerca de la junta del carril se llama *barra de cabeza* o barra *N.*° 1. A cada extremo se extiende bajo el carril maestro, con el propósito de evitar que el extremo de la junta del carril se levante fuera de su lugar. En uno de sus extremos esta unida a la barra de conección generalmente de 3 a 4 cm redonda o cuadrada.

(1) Véase *N. del T.*, ¶ 1.

**93. Requisitos en las Especificaciones.** Al pedirse chuchos (1) de aguja, especifíquese el ancho de la via; largo de las agujas de carril; carrera del chucho medido en la barra de cabeza; seccion del carril; barrenado para las juntas de carril, ángulo del chucho; y abertura.

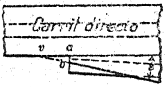

**Fig. 21 (Repetida.)**

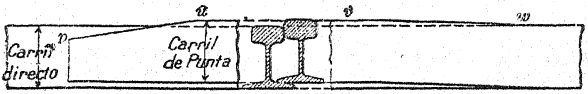

**Fig. 22 (Repetida.)**

**94. Especificación de Chuchos, Asen Am Ings F. C.,** Manual de 1915, paginas 178–9.

| $>$ 14 | 16 | 33 pies 0 pulg (10.058 m) | 12 pies (3.658 m) | 16.50 pulgs (0.406 m) |

*Barras de refuerzo,* $^3/_8$ (10 mm) grueso; altura para llenar el espacio entre la cabeza y la pestaña; largo lo mas que puedan permitir las conecciones en la junta.

Dos barras de chucho no ajustables, $^3/_4 \times 2\ ^1/_2$ (19 × 62 mm); colocadas horizontalmente; separadas (20″) 50 cm de centro a centro. El centro de la barra de cabeza a (12″) 30 cm mas atras de la punta de la aguja.

En cada traviesa, *dos placas de corredera* ($^7/_8$″ × 7″) 22 × 178 mm cepilladas para recibir el carril maestro y las abrazaderas.

**95. Un chucho de via triple,** Fig. 3 consiste virtualmente en dos chucho, de aguja separados; y asi estan dispuestos algunas veces, las puntas de dos pares de agujas de carril se colocan a veces separados cerca de un largo de carril de agujas o unos detras de los otros, en « *tandem* ».

**Chuchos de Aguja de Tope.**

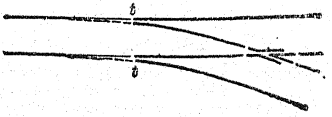

**Fig. 24.**

**96.** Fig. 24. El chucho de aguja de tope (todavia usado en localidades inferiores, como en desvios de lineas de ramales) es simple en construcción, y barato en su

(1) Véase *N. del T.*, ¶91.

primer costo, pero caro en su operación y mantenimiento. Para evitar la posibilidad de que se tranque con el calor, se debe dejar un gran espacio entre los topes o talones *tt*, y los extremos de los carriles adyacentes de la vía, y esto produce serios golpes con las ruedas al pasar por los extremos de los carriles. Tales golpes son perjudiciales a ambos : a los extremos de los carriles y al material rodante.

**97. Peligro.** La corrida de la punta del carril del chucho (1) o del extremo del carril adyacente causa un reborde, llamado « bemba », que puede hacerse peligroso. Pero la objeción mas seria del chucho de aguja de tope sin proteccion, es el inevitable descarrilamiento de los carros de arrastre cuando el chucho esta mal colocado.

**98. Largo.** Los carriles del chucho de aguja de tope son generalmente del largo completo de los carriles de vía, (30 o 33 pies) (9.15 a 10.06 mm) de largo. De este largo, (1.20 ó 1.50 m), próximo a la junta estan clavados a las traviesas, dejando el resto libre para encurvarlos cuando se ponen para el desvío.

**99. El curso** o distancia a que se mueve la punta del carril del chucho, debe ser cuando menos igual al ancho de la cabeza del carril (generalmente de 5 a 7 cm) mas un ancho (4 a 6 cm), lo suficiente para que pasen las pestañas de las ruedas. Generalmente la carrera ó juego, se hace de 12 a 14 cm.

**Pedestales de chucho.**

**100.** La palanca, por medio de la cual (ayudado por la barra de conexión) el chucho es puesto, se aloja en el « pedestal «. La forma o disposición varia mucho. La palanca puede girar en un plano vertical u horizontal. Si en plano vertical, este plano puede ser perpendicular, o paralelo a la vía; el movimiento de la palanca en este ultimo caso, se trasmite a la barra de coneccion por medio de un engrane o cigueña.

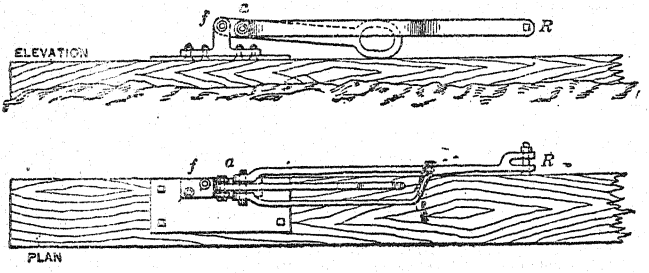

Fig 25.

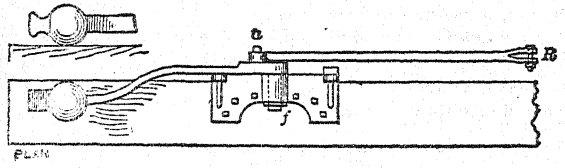

Fig. 26.

**101. Chucho de Palanca de Tumba.** Figs 25 y 26 muestran el pedestal de « palanca de tumba ». En la Fig. 25, la palanca se mueve en un arco de mas de 180°, en un plano vertical, perpendicular, o paralelo a la vía; de modo que cuando la palanca esta descansando, su unión, *a*, con la barra de conexión, está un poco mas abajo del fulcro, *f*, sobre el cual gira la palanca, o por debajo de su centro muerto; de modo que el chucho no puede ponerse o cambiarse porque lo empuje la presion lateral de las ruedas. En la Fig. 26, el extremo libre de la palanca

(1) Véase *N. del T.*, ¶ 1.

está contrapesado, y la junta, *a*, cuando la palanca, está descansada, queda por *arriba* del centro muerto. Esto permite reponer automáticamente un chucho (1) mal colocado por las ruedas de arrastre. Vease ¶ 57.

**102. Pedestal Giratorio.** La fig. 27 enseña una de las muchas formas de pedestal giratorio. La palanca generalmente embisagrada, de modo que cuelgue verticalmente, y fuera del paso (como se ve), cuando no está en uso para poner el chucho. Las escotaduras en *a*, *b* y *d*, lo retienen en sus tres posiciones, respectivamente. La cigueña, *c*, está generalmente construida como se indica, doblando el eje, *s*; y el pasador, *p*, al cual está unida la barra de conección, está formado doblando (para arriba o para abajo) el extremo de la cigueña.

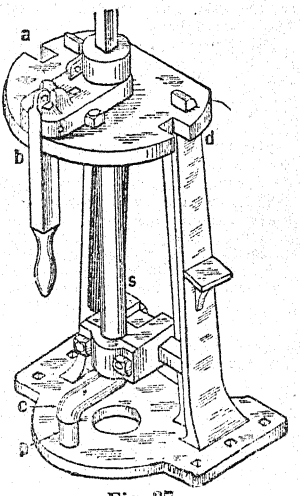

Fig. 27.

**103.** Fig. 28 *a*. Si en un pedestal giratorio el pasador de la cigueña se mueve 90° de *a* a *b* o *vice versa*, el movimiento lateral ( $= a'\,b' = b'\,a'$) del carril del chucho, es mayor que el que ( $= b'\,c'$) ocurre cuando el pasador de la cigueña se mueve 90° de *b* a *c* o viceversa. Esto puede rectificarse colocando el pedestal ligeramente sesgado o corrido, como se indica por las lineas de punto; porque esto corre materialmente $b'$ sobre $a'$, mientras que $a'$ y $c'$ cambian muy poco. O, como en la fig. 28 *b* el pedestal puede estar puesto de tal modo que la linea *o d*, normal a la barra del chucho, divida el curso de 90° de la cigueña, pero esta disposición no pone a la cigüeña en centro muerto en cualquiera posición. Para un juego dado de carril de chucho, y un ángulo dado de juego de cigüeña, fig. 28 *a* se requiere una cigueña mayor que la que se necesita en la Fig. 28 *b*.

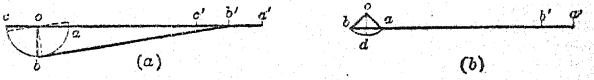

Fig. 28.

**104. Cerraderos.** Para evitar que se ande con el chucho, la palanca esta provista de un candado y argollas; pero se han usado pedestales con cerraderos complicados que forman cuerpo con aquellos. Véase tambien el final de ¶ 58, en señales.

**105. Una placa de señal,** en la parte superior de un eje vertical, que opera simultaneamente con el chucho, indica como está puesto el chucho. La placa de señal puede ser un disco sencillo, mostrando por su posición como está puesto el chucho (de plano o de canto a un tren que llega); o puede tener dos discos colocados a angulo recto, y diferenciándose en su forma, en su color o en ambos. Véase tambien señales, ¶ 14.

**106. Pedestales, Bajos, Intermedios,** o **Altos, son aquellos** en que la parte superior de la placa de señal está $>$ 60 cm, de (60 a 120 cm) de (180 a 240 cm o cerca de 540 cm) sobre el terreno respectivamente. Los pedestales intermedios son de uso corriente; los bajos se usan entre carrileras vecinas, y los altos donde la placa de señal de un pedestal bajo queda escondida por objetos que se atraviesan.

**107. Faroles.** Para chuchos que se tienen que usar de noche, el pedestal lleva tambien un farol, mostrando colores correspondientes a los que se usen con la placa de señal. Vease señales. Los faroles que usan *kerosene* están mas generalizados; pero, en patios grandes, a menudo se usan luces eléctricas incandescentes.

(1) Véase *N. del T.*, ¶ 1.

## Chuchos Automáticos.

**108.** Los chuchos (1) automáticos son aquellos en que las conexiones con el pedestal son tales que permiten el pasaje de un carro de arrastre cuando el chucho está mal puesto.

**109.** Figs 19 *a*, 19 *b*. La pestaña de una rueda de arrastre, *n*, en el carril maestro, se aprieta en el espacio estrecho entre él y el carril de chucho adyacente, y empujará a esta última (si no se evita) fuera del carril maestro, proporcionando así una canal para la pestaña, entre esos dos carriles; el otro carril de chucho simultaneamente se arroja contra el carril maestro opuesto, o en una posición apropiada para la rueda compañera, *n'*.

**110. El chucho automático « set-over »** es aquel en que las puntas del carril cuando se mueven automáticamente, como en ¶ 109, se llevan la palanca de chucho, y quedan en la nueva posición.

**111. En el chucho automático « fly-back »**, la palanca de chucho no se mueve cuando un carro de arrastre pasa un chucho mal puesto. Los carriles del chucho son separados temporalmente a un lado, y, despues del paso de cada par de ruedas, vuelven a sus posiciones anteriores por medio de un muelle en la barra de conexión, en la barra del chucho, o en el pedestal del chucho. El curso o carrera del pedestal se hace un poquito mayor que el curso del chucho, con el propósito de recoger el movimiento perdido.

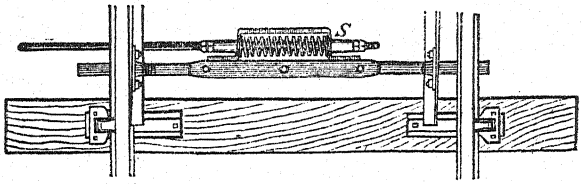

**Fig. 29.**

**112. Objeciones.** Ambas formas se prestan a la objeción de que al moverse el chucho parte de la carga que se mueve descansa sobre uno de los carriles de chucho relativamente delgados, que deben por consiguiente deslizarse mientras estan cargados.

**113. Muelle Lorenz.** La Fig. 29 enseña en principio, el muelle Lorenz, muy usado en los chuchos automáticos « fly back ». El muelle *S*, se coloca algunas veces fuera de la via.

**114.** Los *golpes repetidos* de las agujas de chucho contra el carril maestro en los chuchos automáticos es perjudicial, especialmente para las agujas delgadas; y la compresion permanente del muelle, como resultado del largo servicio, pudiera dejar una aguja de chucho (despues que la palanca haya sido cambiada) indebidamente fuera de contacto con su carril maestro, peligrando las ruedas que vengan de frente.

**115.** *El muelle* tambien pudiera permitir que la palanca sea forzada en su lugar, con la nieve o una piedra pequeña, u otra obstruccion alojada entre el carril maestro y la aguja impidiendo cambiar completamente el chucho.

**116. Automático y No-Automático.** Frecuentemente la barra pasando al traves del muelle espiral, está provista de dos bujes ajustables, por cuyo medio el chucho puede arreglarse como se quiera, de varios modos. Segun esta disposición (*a*, *b*, *c*, etc.), un carro de arrastre, entrando en un chucho mal puesto pudiera pasar libremente si viene.

(*a*) de la linea principal;
(*b*) del desvio;
(*c*) de la linea principal o del desvio;

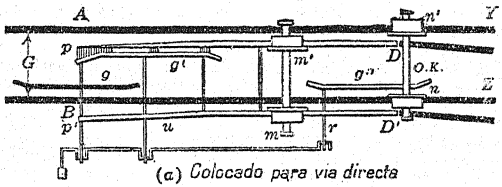
ó los bujes pueden estar ajustado de tal modo que eviten que el muelle actúe; de este modo el chucho se habilita no-automático, de manera que un carro de arrastre viniendo de la linea principal o del desvio, no puede pasar libremente el chucho si este último esta mal cambiado.

(1) Véase *N. del T.*, ¶ 1.

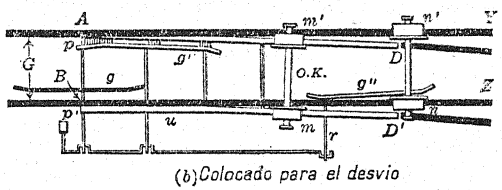
**117.** El *uso de* pedestales *automáticos* y *no-automáticos* («rigidos») de chucho (1), se compara como sigue : —

En 1900, 24 ferrocarriles usaban automáticos, y 23 usaban pedestales rigidos; en 1908, 23 ferrocarriles usaban automático y 29 usaban pedestales rigidos. Véase la Revista Eng News de junio 4, 1908.

**118. Especificaciones requeridas.** Al pedir pedestales de chucho, especifíquese el curso o carrera en el punto de conexion, tamaño de la barra de cabeza y si es vertical u horizontal, diámetro del agujero en la barra de cabeza largo y diámetro de la barra de conexion, estilo de la placa de señal y su altura sobre las traviesas, y dimensión del encaje de la linterna en la punta del eje.



(a) Colocado para via directa



(b) Colocado para el desvio

**Figs. 30.**

**Chucho** (1) **Wharton.**

**119.** Figs 30*a* y *b*. Omitimos las pestañas de carril, mostrando solamente las cabezas del carril. Los carriles *movibles* se indican en *blanco*. Las ruedas, para las cuales el chucho está propiamente puesto, están marcadas « O. K. ». La Fig. 30*a* muestra el chucho puesto para la linea principal. La Fig. 30*b* el chucho puesto para el desvio.

**120.** *A Y* y *B Z* son los carriles de la principal. Son continuos (excepto, por supuesto, que *B Z* está cortado en la *rana*, mas allá de la Fig.), y están clavados a las traviesas a todo lo largo. Estos no se mueven ni se interrumpen al operar el chucho. *p D* y *p' D'* son las agujas .

**121. La aguja de chucho,** *p' D'* (el « carril elevado »), termina en punta roma. En su extremo, *p'*, su parte superior está a nivel con el de *B Z;* pero, en *u*, 1,20 ó 1,50 m mas atrás de su extremo *p'*, su parte superior está unos 5 cm mas alto que en *B Z*. Esto permite que la pestaña *m*, al pasar viniendo o entrando en el desvio. Fig. 30*b*, deje libre el carril principal, *B Z*, *p' D'* conserva esta elevación desde *u* hasta su extremo, *D'*. Mas alla de *D'*, el carril del desvio a continuación de *p' D'*, desciende hasta que su parte superior queda al nivel normal. La « *aguja* » *p D*, se alza tambien, para evitar el balanceo lateral del material rodante que de otro modo resultaria de la elevacion de *p' D'*.

**122. El refuerzo de guardacarril,** *g'*, está atornillado y separado de la aguja del carril, *p D*, y se mueve con él. Se le deja canal para las pestañas de las ruedas entre sus cabezas. En la Fig. 30*b*, confinando la pestaña de la rueda *m'*, *g'* sostiene la pestaña de la rueda *m* libre de la cabeza del carril *B Z*, al bajar la inclinacion, *u p'*.

(1) Véase *N. del T.*, ¶ 1.

**123.** En la Fig. 30*b* el punto, *p*, se pega contra la cabeza del carril principal, *A Y*; de modo que la pestaña de la rueda *m'*, moviendose en cualquier dirección, deja libre el punto, *p*; y el guardacarril fijo, *g*, encerrando la pestaña de *m*, sostiene a *m'* fuera de *A Y*, dando de este modo protección adicional al punto, *p*.

**124. En los primitivos modelos** se ideaban accesorios especiales proyectados para recibir, del desvio un carro de arrastre cuando el chucho estaba puesto para la linea principal, y guiarlo con seguridad a la linea principal; pero estos accesorios se han abandonado por su costo y complicación.

**125. Arrastre.** Fig. 30*b*. Si un carro de arrastre se mueve a lo largo de la linea principal mientras el chucho (1) está puesto para el desvio, la pestaña de la primera rueda, *n*, empuja a *g''* a un lado (compárese la Fig. 30*a*) y esta empujando la barra, *r*, cambia el chucho a la posicion adecuada para la linea principal, como en la Fig. 30*a*.

**126. Entrevia.** Para la adecuada manipulación del chucho Wharton, al ancho de la via principal en el chucho, se le da media pulgada mas que al de la via normal.

### Cálculos.

**127.** Muchas de las aproximaciones permitidas al calcular desvios de pequeño ángulo, que son usuales en lineas de tracción por vapor, son inadmisibles en desvios y cruceros en lineas de tranvias, donde los trazados son frecuentemente muy complejos. De aqui que el diseño de tal trabajo se confia con preferencia a manufactureros especializados en ellos.

### Traviesas.

**128. Las traviesas de Desvios**, para via ancha tipo, varia en largo, entre la de una traviesa ordinaria, digamos de 2,60 y 7,4 m. Una o dos traviesas, de 3,6 a 4,80 m de largo (segun el estilo del pedestal del chucho), se usan en los extremos de los chuchos de aguja o de tope, como asiento del pedestal, y se llaman **cabezales.** El juego de traviesas debe extenderse mas allá de la rana, en un punto donde los extremos de las traviesas de las dos vias no se estorben. Las traviesas de (7 × 9 pulgs) 18 × 23 cm son las que se usan comunmente, excepto bajo la rana donde se usan traviesas de (7 × 10 pulgs) 18 × 25 cm para tener mayor area de asiento, y de resistencia a los choques de las ruedas que pasan sobre la rana. Generalmente se piden en largos que varian en (6 pulgs) 15 cm. Para traviesas en general, véase Via, pag 857,

**Traviesas de chuchos** (1).

**129. Recopilación de las Especificaciones de la Asen Am de Ing de F. C.** a continuación de la p 176. Manual de 1915.

Todos de 7″ × 9″ (18 × 23 cm).

Largos para traviesas de via de 8′ — 6″ (2.60 m). Para traviesas de 8′ — 0″ (2,44 m) los largos son en general 6 pulgs (15 cm) menos que los dados aqui.

* Traviesas de rana (7″ × 10″). 18 × 25 cm. Otras traviesas (7″ × 9″) 18 × 23 cm.)

(1) Véase *N. del T.*, ¶ 1.

### Tendido.

**133. Tiempo necesario.** Cuando no hay muchas interrupciones por el paso de trenes, « un buen capataz y seis peones de vias regulares pueden poner un chucho de tope o de aguja para desviadero en un dia de diez horas, incluyendo quitar las traviesas viejas y poner las traviesas de chucho ». Camp, en Notas de Via, p. 298.

### Miscelánea.

**134. Para evitar el deslizamiento** de las puntas de los carriles se clavan en ranuras las cuatro juntas de carril en los extremos de la rana, las del amarre de las agujas, y las juntas intermedias de los carriles de arranque de la rana. El anclado o afirmado de las agujas de carril en sus extremos a los carriles maestros próximos, ha sido motivo de dificultades por apiñarse las juntas fuera de linea.

### Remoción del Hielo y la Nieve.

**135. Calefacción de vapor.** Cuando muchos chuchos están próximos pueden tenerse económicamente libres del hielo y nieve con tubos de vapor, alimentados de alguna planta central, y tendidos entre varios pares de traviesas, cerca del punto. Se quita primero el balasto. Los tubos se proveen con trampas automáticas que permiten al vapor condensado salir, y asi evitar su congelacion en los tubos. Véase la Revista « Railway Age Gazette », p. 1199, mayo 13, 1910.

**136. Fluido abrasador.** Los desviaderos se han mantenido con facilidad y sin gran costo libres (y despejados) de hielo y nieve, por medio de un fluido hidrocarbónico (un derivado de las plantas que producen el gaz Pintsch), aplicado donde se necesita por medio de una lata distribuidora de seguridad, que se enciende. El fluido arde a pesar del viento y de la nieve, derritiendo y finalmente evaporando la nieve. La temperatura de la llama no es lo bastante para afectar los carriles. El fluido cuesta de 3 a 5 ctvs por galon. Donde haya que atender varios chuchos vecinos, el liquido se almacena en estanques, y se distribuye por gravedad, o por aire comprimido, al traves de una tuberia.

Vease la Revista « Engineering-Contracting », p. 151, sep. 2, 1903.

**137. Protección de las barras de chucho** (1). Para evitar que se doblen o se rompan en caso de descarrilamientos se puede colocar una traviesa aserrada a cada lado de cada barra, dejando (2,5") (8 cm) de espacio libre, entre las traviesas para la barra. En tiempo frio las barras dobladas deben calentarse antes de tratar de enderezarlas, el balasto debe mantenerse separado de las barras, y bien desaguadas alrededor, especialmente en tiempo frio.

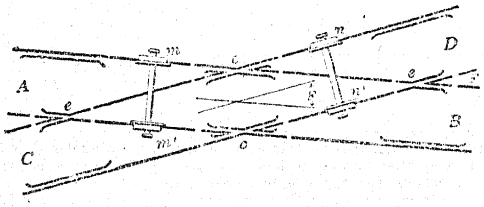

Fig. 31.

## CRUCEROS

**138.** Fig. 31. Un crucero consiste esencialmente en cuatro ranas, *e*, *e*, *c* y *c*, y lo guardarranas necesarios.

**139. El ángulo del crucero,** es el ángulo, *F*, entre las lineas de centro de as dos vias rectas que se cruzan.

**140. Cuando F = 90°,** las cuatro ranas son todas iguales. En la Fig. 31 las dos ranas de cabeza aguda, *e*, son iguales y parecidas a las ranas de desvio. Las dos ranas agudas del « medio », *c*, son iguales también. La presencia de guardacarriles, en las ranas del medio, da la apariencia de un segundo punto, opuesto al punto, *c*, propio; por consiguiente las ranas del medio se llaman con frecuencia de « punta doble », aunque por las « puntas » interiores formadas por los ángulos en los guardacarriles, no pasen ruedas.

(1) Véase *N. del T.*, ¶ 1.

**141. Donde una via o ambas estén en curva** todas las ranas tienen ángulos diferentes; y están encurvadas. Es mejor evitar cruceros de vias en curvas. Los problemas relacionados con ellas se resuelven mas facilmente por medio de trazados en escala mayor.

**142. Crucero de Doble-carril.** Fig. 31. Si los guardacarriles del medio estan extendidos, a ambos lados, hasta que encuentren los extremos opuestos de las ranas, y estan propiamente rellenados, atornillados y conectados, la resistencia y durabilidad del crucero aumenta grandemente, y se llama crucero de « doble-carril ». En este caso, las ranas de cabeza, *e*, (como tambien las ranas del medio, *c*) son de « doble punta » (¶ 140).

**143. Un carril de descanso** (¶ 52). Para que pasen « falsas pestañas » se atornilla algunas veces al exterior del carril que carga las ruedas.

**144. Cuando F excede de 35°**, las almas de ambos : del carril principal y de descanso de una de las dos vias, pasan algunas veces al traves del crucero sin cortarse; las canales para las ruedas en la otra via se cortan solamente al traves de las cabezas de estos carriles.

**145. Cuando F está entre 15° y 40°**, las cuatro ranas generalmente se encuentran directamente : pero en cruces, de pequeño ángulo, para evitar el manejo de ranas largas, se tienden pedazos de carril entre los extremos de los carriles de las ranas, como en la Fig. 31. Por conveniencia en los embarques y en su manejo, los cruceros se hacen con el menor número de uniones posible.

**146. Cuando F es menor de 10°**, Fig. 31, las puntas de las ranas del medio estan casi opuestas una a la otra en cualquiera de las dos vias, y no pueden protegerse bien. De este modo las ruedas *m* y *m'* pudieran salirse de su via propia, *A B*, en las ranas del medio, y tomar la via *C D* ; o las ruedas *n* y *n'* pudieran salirse de la via *D C*, y tomar la via *B A*.

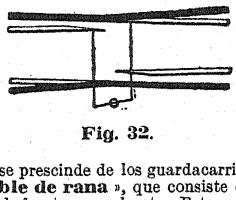

**Fig. 32.**

En tales casos (Fig. 32) se prescinde de los guardacarriles del medio, y se usa una « **punta central movible de rana** », que consiste en dos pares de agujas de carril de chucho (1) cortas, de frente una a la otra. Estos chuchos como requisito van asentados contra uno de los dos carriles maestros doblados, como se indica. Pueden operarse por un pedestal de chucho automático, de modo que si un tren se acerca a un crucero mal puesto, las primeras ruedas obligan a abrir las agujas de carril de arrastre del chucho, y automáticamente ponen las agujas de carril de frente en la buena posición.

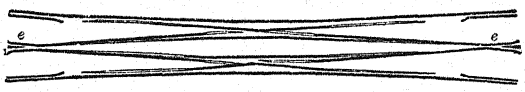

**Fig. 33.**

**147. Chucho-Corredizo o Crucero de combinación.** Fig. 33. En un crucero de pequeño ángulo, el tráfico puede intencionalmente llevarse de una carrilera a la otra, por medio de un chucho-corredizo o « crucero de combinación », que consiste en una disposicion de chucho y carriles de conección ademas de un crucero corriente, todo colocado entre las dos ranas de cabeza, *e*. La Fig. 33 muestra un chucho-corredizo doble. En el chucho-corredizo sencillo, los chuchos y carriles de conexión están puestos en un lado solamente.

(1) Véase *N. del T.*, ¶ 1.

**148.** El chucho (1) corredizo es especialmente útil para conectar un *enlace* (véase ¶ 12 *b*) con las vías paralelas con que se cruza. Tal combinación economiza mucho espacio, a lo largo, y da una línea recta si se compara con una serie de cruces separados.

**149.** *La punta central movible de rana* puede usarse, como en la Fig. 33, en chuchos-corredizos; pero en su lugar se usan *ranas corrientes rígidas en el medio*, ambas con chuchos-corredizos dobles y sencillos. Excepto donde el ángulo es tan pequeño que las patas de las ranas estorben a los carriles encorvados que conectan con las agujas del chucho.

**150.** *Palancas de chucho.* Estos cruceros pueden operarse por un pedestal de chucho corriente para cada par de agujas de carril y uno para la punta central movible de la rana; o todos los chuchos pueden conectarse por un sistema de barras y cigueñas, y operarse desde un pedestal sencillo, mientras que las puntas movibles de rana se manejan desde otro pedestal. O las agujas de chucho y los puntos movibles de rana se disponen de tal modo que puedan operarse juntas.

**151. Cruceros de Carril continuo.** En cruceros de ángulo muy grande, las ruedas al cruzar las canales, caen en ellas dando golpes fuertes al material rodante y a la vía; y se han construido sistemas que permiten carriles continuos en tales cruceros, por medio de un tramo corto de carril, o un equivalente, que por medio de un sistema entrelazado, puede colocarse provisionalmente en línea con el carril que se va a usar.

**152. Traviesas.** Las traviesas de cruceros, extendidos bajo ambas vías, son tendidas generalmente a ángulo recto, con la diagonal larga del rombo formado por los carriles que se cruzan; algunas veces se tienden a ángulo recto con la vía que tiene mas tráfico pesado; y algunas veces se usan traviesas de largo corriente, tendidos a ángulo recto con cada vía. Para traviesas, vease ¶ 128.

**153. Especificaciones requeridas.** Al pedir cruceros, especifíquese tipo de construcción; angulo del crucero, *F*, Fig. 31; ancho de vía; distancia de centro a centro, entre vías paralelas si es mas de una; sección del carril; largos de los brazos de las ranas; y separación de los agujeros de tornillo que se necesitan en los extremos para que ajusten con las juntas de carril en uso.

---

(1) Véase *N. del* T., ¶ 1.

# DESVÍOS Y CRUCEROS

## PARTE II. TEORÍA

### Geometria de los Desvíos.

Para la Construccion de los Desvios, véase Parte I, pag 897.

**1. Exactitud.** No es necesaria una exactitud escrupulosa en las medidas de los desvios. Una variación de unos pocos tantos por ciento en el largo del arranque o en el radio de un desvio, del valor teórico será rara vez notado. El ojo educado de un experto de via o un dibujo en escala mayor, puede dar tan buenos resultados como el cálculo mas cuidadoso. No obstante el ingeniero debe conocer bien el trazado de los desvios. Por consiguiente damos a continuación, ecuaciones (exactas y aproximadas) que tratan los casos mas simples.

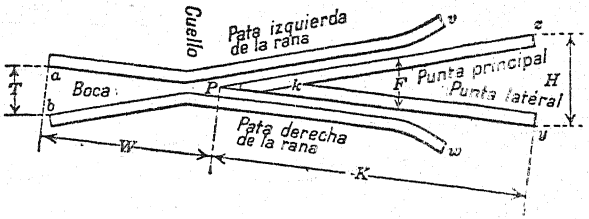

**Fig. 1.**

### Ángulo y número de la rana

Para descripcion de la rana, véase Parte I, ¶ 40, etc.

**2. Angulo de la Rana.** Figs 1 y 2. El punto teórico de la rana, $P$, es la intersección de las lineas de via que determinan la punta o lengueta de la rana. El ángulo, $F$, de la rana, es el ángulo, en el punto teórico, de la rana entre las dos lineas de via.

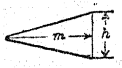
**3.** *Como se determina.* Figs 1 y 2. El ángulo, $F$, de la rana depende de la diferencia de agudeza (¶ 29) entre la curva del desvio y la curva de la linea principal (si la hay) y del ancho de la via.

**4.** *Como se expresa.* Fig. 2. El ángulo de la rana se expresa generalmente por medio de la relacion, $k/i$, entre el largo, $k$ (no se indica), de cualquier parte la rana, y el aumento, $i$ (no se indica), del ancho de la rana comprendida en dicha parte. Este es también la relación entre cualquier parte dada ($m$ ó $s$, empezando en $P$, vease abajo) del largo de la rana, y la correspondiente abertura, $h$. Esta relación es lo que llaman número de la rana, $N$.

**5. Número de la Rana.** *N se determina* de dos modos distintos, a saber:

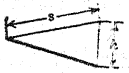
$$N = \frac{m}{h} = \frac{\cot (F/2)}{2}$$

$$2\,N = \cot (F/2)$$



$$N = \frac{s}{h} = \frac{1}{2 \operatorname{sen} (F/2)}$$

$$2\,N = \operatorname{cosec} (F/2)$$



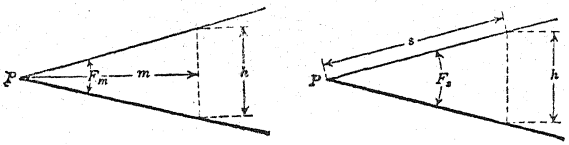
Ec (1)

**6.** La Asen Am de Ingo de F. C. hace $N = m/h = \frac{1}{2} \cot (F/2)$, como en la Fig. 2 *a* (véanse los valores de $F$, en la tabla, Manual de 1915, p 184); pero las

compañías de ferrocarril y los manufactureros están divididos en cuanto a sus prácticas a este respecto; muchos prefieren la segunda formula, $N = s/h$, Fig. 2 *b*, porque el largo de la rana se mide generalmente a lo largo de la via, *s*, mejor que a lo largo de la linea central *m*. Por otra parte, el largo asi medido, se da generalmente en numeros redondos de pies y pulgadas; y de aqui el que se encuentre facilmente la boca o abertura dividiendo mentalmente dicho largo por el numero de la rana.

**7. Comparación de los ángulos de rana, $F\,m$ y $F\,s$.**

| $N$ | $F\,m$ cot $(F\,m/2) = 2\,N$ Fig. 2 *a*. | $F\,s$ cosec $(F\,s/2) = 2\,N$ Fig. 2 *b*. | $F\,s - F\,m$ segundos. | $\frac{F\,m}{F\,s - F\,m}$ |
|---|---|---|---|---|
| 4 | 14° 15′ 00″ | 14° 21′ 41″ | 401 | 128 |
| 8 | 7° 9′ 10″ | 7° 10′ 00″ | 50 | 515 |
| 11 | 5° 12′ 18″ | 5° 12′ 38″ | 20 | 937 |
| 16 | 3° 34′ 47″ | 3° 34′ 54″ | 7 | 1841 |
| 24 | 2° 23′ 13″ | 2° 23′ 15″ | 1.87 | 4606 |



*Para* $h = 1$, $N = m$ (*a*)

*Para* $h = 1$, $N = s$ (*b*)

**Fig. 2.**

**8. Funciones del ángulo de la rana**, $F$, entrando el número $N$ de la rana. Vease p. 106, ¶ 16, y p. 107, ¶ 19.

Ec (2)

**9. Para determinar el número** de una rana dada, Fig. 3; búsquese cualquier parte de la rana, donde la distancia, $h$ o $t$ entre *líneas de la vía* (¶ 2) sea una unidad (esto es 1 pie ó metro, o el largo de un lapiz o cuchilla de bolsillo). Entonces $N$ = distancia, $h$ $P$ o $t$ $P$ de esa parte al vértice teórico de la rana, $P$ (vease ¶ 2) medido, con la misma unidad a lo largo de la linea central $M$, o a lo largo de la vía, $S$, segun la definicion de $N$ adoptada (vease ¶ 6). O (si el vértice teórico, $P$, de la rana no se determina facilmente) mídase *ambas* aberturas, $h$ y $t$ (entre las *líneas de la vía*), en *dos* puntos convenientes en direcciones opuestas del vertice de la rana y la distancia, $M$ ó $S$, entre dichos puntos. Entonces,

$$N = \frac{M}{h+t} \text{ o } \frac{S}{h+t}.$$ Vease ¶ 5.

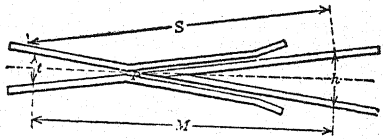

**Fig. 3.**

**10. Vértice de una rana dada.** Fig. 1. En la práctica, la lengüeta o vértice de ella termina en el « vértice real de la rana » (o « punto de media pulgada de ancho ») donde la lengueta tiene cerca de ½" de ancho; dejando un pequeño triángulo isoceles entre el punto real y el teórico. (Vease ¶ 2). El largo de este triángulo, o la distancia entre el punto teórico y el real de la rana, es el producto del ancho del punto real de la rana por el número de la rana, $N$.

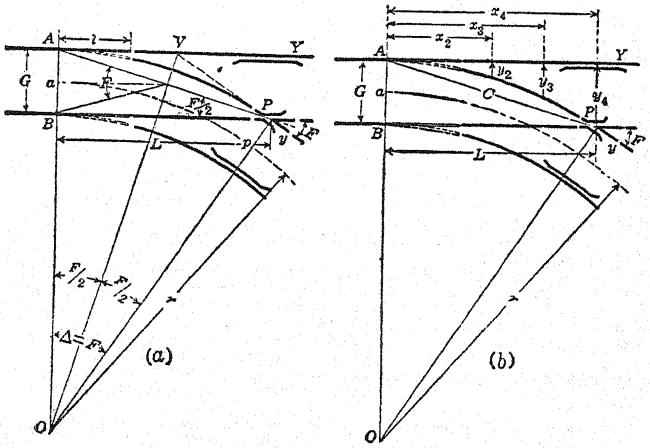

**Fig. 4.**

**11. Cuando el ángulo es pequeño.** Asi como un ángulo, $A$, se acerca a cero como límite, los valores de $A \times \cot A$ ( $= A/\text{tang } A$) y de $A \times \text{cosec } A$, ( $= A/\text{sen } A$) se acercan a la unidad, $A$ va expresado en radiantes o radiales de 57.295 779°. (¶ 2, pag. 103). Por tanto, los mismos valores expresados en

grados, se acercan, como límite, 57.295 779* (log = 1.758 1226); y para pequeños ángulos, tenemos approx.:

Para $A$ en grados, $A^o = 57.3^o/\cot A = 57.3 \text{ sen } A$;
$F = 2 \times 57.3/\cot (F/2) = 2 \times 57.3 \text{ sen } (F/2) = 57.3/N$.
Para $A$ en minutos, $A' = 3438'/\cot A = 3438 \text{ sen } A$.. (3)

## CHUCHOS (1) DE TOPE

(*N. del T.* — En las fórmulas que vienen inmediatamente y en las sucesivas, así como en muchas de las tablas, el Autor supone (como es costumbre entre los ingenieros ingleses y americanos) que los trazados de líneas, de desvíos, de chuchos, etc. se hacen teniendo como base, como unidad, la cuerda de 100 pies. Los ingenieros que usamos el sistema métrico, empleamos siempre la cuerda de 20 metros. Están tan mezcladas en este capítulo y en varios mas adelante así como en muchas tablas las fórmulas de estructura puramente trigonométrica, aplicables al Sistema Métrico y al Sistema Ingles indiferentemente, con las fórmulas y con muchos coeficientes y números que, presuponen el uso *de medidas en pies y el empleo de cuerdas de 100 pies*, que, despues de haber comenzado, a convertir muchas de estas al sistema métrico, nos resulta un embrollo que compromete la claridad y los datos tan prácticos y utiles, en esta parte de la obra y hemos resuelto dejarla como está recomendando como mas fácil y eficaz que los ingenieros usen la cuerda fija de 30,48 m que equivale a cien pies y las medidas que tomen en metros sobre el terreno, para entrar a las fórmulas y tablas las multipliquem por 3,28 para tenerlas en pies ó bien usar una cinta en pies y pulgs ingleses).

### Curva circular de desvío en una tangente.

**Generalidades.**

**12.** Fig. 4. Supongamos que la curva de arranque $A\,P$, del desvío (carril exterior) sea una curva circular simple desde su comienzo $A$ hasta el vertice teórico $P$ de la rana; dicha curva es tangente a $A\,Y$ y a $P\,y$ en $A$ y en $P$ respectivamente. Esta condicion rara vez se verifica con toda exactitud en la práctica; pero aproximadamente aun en chuchos de aguja ¶ 35, y da ecuaciones que, debido a su sencillez no solamente se usan algunas veces en chuchos de tope de desvío, sino tambien (por ser suficientemente aproximadas) en chuchos de aguja para desvío. Por consiguiente estas ecuaciones se dan a continuacion, aunque el chucho de tope se usa ahora en lugares de secundaria importancia.

**13. Ecuaciones.** Fig. 4. Chucho (1) de tope de desvío tangencial. Tenemos:

$G$ = $A\,B$..... = ancho de vía;
$r$ = $O\,a = O\,A - G/2$.
= $O\,B + G/2$..... = radio de la línea de centro del desvío;
$D$ ..... = agudeza de la curva del desvío;
$\Delta$ ..... = extencion del desvío, desde la union del chucho, $A$, al vértice $P$ de la rana;

$F$ = $\Delta = B\,P\,V$.
= $Y\,V\,P = A\,O\,P$..... = ángulo de la rana;
$N$ = $m/h$, Fig. 2.
= ½ cot $(F/2)$ (Vease ¶ 5)..... = número de la rana;
$L$ = $B\,P$..... = arranque = distancia de la rana;
$C$ = $A\,P$..... = cuerda del carril exterior del desvío;
$M$ ..... = ordenada media para $C$;
$Q$ ..... = ordenada de cuarto punto (¼ de la cuerda) para $C$;
$y_1$ (no se muestra), $y_2$, $y_3$, $y_4$..... = ordenadas perpendiculares de la tangente a los cuartos puntos del arco, $A\,P$;
$x_1$ (no se muestra), $x_2$, $x_3$, $x_4$..... = abscisa para las ordenadas, $y$;
$s$ (Fig. 10)..... = ángulo del chucho (1);
$l$ ..... = largo del chucho;
$t$ ..... = curso ó juego del chucho;

---

* Este es también el número de grados en el ángulo (= 1 radial) cuyo arco = el radio y es tambien el largo del radio de una curva en que un ángulo de 1° esté cubierta por un arco cuyo largo es la unidad.

(1) En Cuba se llama *chucho*, al conjunto movible de las agujas del desvío, y, por extensión a veces al desvío. — Lo hemos adoptado. (*N. del T.*).

**14. Ángulo de la Rana, F,** = extensión del desvío, $\Delta$.
Funciones de $F$ y de $(F/2)$.

$$\text{Sen } F = \frac{L}{r + (G/2)}\ ;\ \tan F = \frac{L}{r - (G/2)}\ ;$$

$$\text{Cos } F = \frac{\text{sen } F}{\tan F} = \frac{r - (G/2)}{r + (G/2)}$$

$$\text{Senoverso } F = \frac{G}{r + (G/2)}\ .\ F = \text{aprox } D\ L/100 \ldots \quad (4)$$

(*Vease N. del T.* — ¶ 11 pag 926.)
Para los valores de $F$ en función de $N$, vease ¶ 8.
Cot $(F/2) = L/G = 2\ N = r/G\ N$.
Tan $(F/2) = G/L = 1/(2\ N) = G\ N/r$.

**15. Número N de la rana.**

$$N = \frac{\cot (F/2)}{2} = \frac{L}{2\ G} = \frac{r}{L} = \sqrt{\frac{r}{2\ G}} = \frac{r \tan (F/2).}{G}$$

$$= \text{aprox } l/(2\sqrt{G\ t}) = \text{aprox } 5730^{o}/D^{o}L \ldots\ldots\ldots\ldots\ldots\ldots \quad (6)$$

**16. Radio de la linea central del desvio de radio, r.**

$r = L/\text{sen } F - G/2 = L/\text{tang } F + G/2 = G/\text{seno vers } F - G/2.$

$$= G\ \frac{\cot^2 (F/2)}{2} = G\ N \cot (F/2) = \frac{G\ N}{\text{tang } (F/2)}$$

$$= 2\ N^2\ G = L^2/2\ G = N\ L = \text{aprox } l^2/2\ t \ldots\ldots\ldots\ldots\ldots\ldots \quad (7)$$

**17. Agudeza D de la curva central del desvio.**

$$\text{sen } (D/2) = 50/r = 25/N^2\ G.$$

$$D = \frac{100\ F}{\text{arc; } a\ p,\ \text{en pies}} = \text{aprox } \frac{100\ F}{L,\ (\text{pies})} = \text{aprox } \frac{57.3^{o}}{N} \cdot \frac{100}{2\ N\ G.}$$

$$= \text{aprox } \frac{2865^{o}}{N^2\ G} = \text{aprox } \frac{608^{o}}{N^2} \quad \text{para } G = 4 \text{ pies } 8.5 \text{ pulgs } (1.435 \text{ ms}).$$

$$= \text{aprox } \frac{5730^{o}}{r,\ (\text{pies})} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

**18. Ancho de via, G.**

$$G = \frac{L}{\cot (F/2)} = \frac{L}{2\ N} = \frac{r}{2\ N^2} = \frac{L^2}{2\ r.}$$

$$= 2\ \left(\frac{L}{\text{sen } F} - r\right) = 2\left(r - \frac{L}{\text{tang } F}\right)$$

$$= \text{aprox } \frac{l^2}{4\ N^2\ t} = \text{aprox } \frac{L^2\ t}{l^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (9)$$

**19. Arrangue o distancia de là rana, L** = $B\ P$, Fig. 4.

$L = [r + (G/2)]$ sen $F = [r - (G/2)]$ tan $F = G$ cot $(F/2)$.

$$= 2\ G\ N = r/N = \sqrt{2\ r\ G} = 2\ r \tan (F/2).$$

$$= (\text{aprox, en pies})\ 100\ F/D \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (10)$$

(1) Véase *N. del T.* (1) pag. 926.

**20. Cuerda larga, C** ( $= A\,P$), del carril exterior de arranque. $C = 2\,[r + (G/2)]$ sen $(F/2) = \sqrt{G^2 + L^2}$.

$$= G\sqrt{1 + 4\,N^2} = \text{aprox } 2\,r \text{ sen } (F/2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (11)$$

**21. Ordenadas, y**, desde el carril exterior de la linea principal hasta el carril exterior del arranque del desvio.

| *A*. Valores exactos de $y$. | *B*. Valores aproximados de $y$. | *A*/*B*. Cuando $F = 12^o$ $(N = 4.76)$ * |
|---|---|---|
| $y_1 = [r + (G/2)]$ senoverso $(F/4)$ = | $G/16$ ..... | 1.0034 |
| $y_2 = [r + (G/2)]$ » $(F/2)$ = | $G/4$ ..... | 1.0027 |
| $y_3 = [r + (G/2)]$ » $(3\,F/4)$ = | $9\,G/16$ ..... | 1.0016 |
| $y_4 = [r + (G/2)]$ » $F = G$ ..... | | (12) |

**22. Ordenadas** de la cuerda larga, $C$ ( $= A\,P$) hacia el carril exterior de la via.

**22 a.** *Ordenada Media*, M.

$M = [r + (G/2)]$ senover $(F/2)$

= aprox $G/4$ = aprox 14 $^1/_8$ pulgs (35,9 cm) cuando $G = 4$ pies 8.5 pulgs (1,435 m).

| Cuando $N =$ | 4 | 8 | 16 | |
|---|---|---|---|---|
| encontramos $M/(G/4) =$ | 1.0039 | 1.0010 | 1.000244 ..... | (13) |

**22 b.** Ordenada de cuarto-punto, $Q$.

$$Q = \sqrt{[r + (G/2)]^2 - (C/4)^2} + M - (G/2) - r \ldots\ldots\ldots\ldots\ldots\ldots \quad (14)$$

$$\text{Donde } C/4 = \frac{[r + (G/2)] \text{ sen } (F/2)}{2}.$$

$Q$ = aprox $3\,G/16$ = aprox $0.1875\,G$.

= aprox 10.6 pulgs (26,6 cm) cuando $G = 4$ pies 8.5 pulgs (1.435 m)... (15

Cuando $F = 12^o$, $(N = 4.76)$,

$$\frac{Q}{3\,G/16} = 1.0035.$$

Con pequeños valores de $F$ (mayores valores de $N$) la aproximación es mayor.

**23.** En desvios de tope, las ordenadas medias y de cuarto-punto son casi independientes del ángulo de la rana, $F$. Cuando $N = 4$. $N = 16$, y el ancho de via = 4 pies 8,5 pulgs (1,435) las ordenadas medias, al carril exterior de la via se comparan como sigue :

$$\frac{\text{Ord med, } N = 4}{\text{Ord med, } N = 16} = \frac{1.18165 \text{ pies}}{1.17737 \text{ pies}} = 1.00363.$$

Pero vease ¶ 38.

**24. Ángulo del desvio, s, largo, l, y curso, t.** Para la relación entre estos elementos podemos tomar :

$$t = l \text{ sen } s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (16)$$

---

* Con pequeños valores de $F$ (mayores valores de $N$) la aproximación para $y_1$, $y_2$ y $y_3$, es mayor.

**25. Dimensiones.** Desvio circular de la tangente. Fig. 4.

Cartabón 4 pies 8.5 pulgs (1,435 m) = 4.70833..... pies.
Curso del chucho (1) = 5.5 pulgs (0,14 m) = 0.45833..... —

$N$ = numero de la rana; $C = A\ P$ = cuerda;
$F$ = ángulo de la rana; $L = B\ P$ = arranque;
$r$ = radio de la linea central del desvio; $l$ = largo del carril del chucho;
$D$ = agudeza del desvio; $t$ = juego de la aguja.

*N. del T.* Cuando se quiera usar el sistema métrico, recuérdese que los metros se convierten en pies, mult por 3,28 y los piés en ms mult. por 0,305).

| $N$ | $F$ | $r$ | log $r$ | $D$ | $C$ | $L$ | $l = 2N\sqrt{Gt}$ |

(1) Véase *N. del T*, ¶ 11, pág. 926.

## Desvios que arrancan de una curva.

**26 a.** Para desvios de tope en tangentes las fig. 5 *b*, y el ¶ 25 dan la agudeza $D$ de la curva, el radio, $r$, y el arranque, $L$, = $B\,P$, para numeros de ranas del 4 al 16. La ordenada media,

$M = \left(r + \frac{G}{2}\right) \text{senover} \frac{F}{2}$, de la cuerda $A\,P$ al carril de la rana del lado del carril exterior es practicamente el mismo para todos los números de las ranas. Véase ¶ 23.

**26 b.** Pero, figs 5 *a* y 5 *c*, cuando un número dado de rana se usa en un desvio de una linea o via principal *en curva*, todos estos valores (incluyendo las ordenadas) se afectan; y sus valores dependen no solamente de la agudeza, $Dm$, de la curva de la linea o via principal, sino tambien de si la curva del desvio va en la misma dirección de la curva de la via principal, fig. 5 *a*, o en dirección opuesta. Fig. 5 *c*.

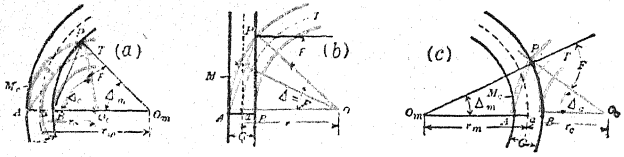

Fig. 5.

**27. Símbolos.** Figs 5. Supongamos :

$G$ = ancho de via; $F$ = ángulo de la rana; $N = \frac{\cot (F/2)}{2}$ = número de la rana y que otros símbolos denoten como sigue :

| | Para via principal en curva. Figs 5 *a*, *c*. | Para desvios. | |
|---|---|---|---|
| | | De tangentes Fig. 5 *b*. | De curvas. Figs 5 *a*, *c*. |
| Centro | $O^m$ | $O$ | $O_c$ |
| Radio de linea de centro | $r^m$ | $r$ | $r_c$ |
| Agudeza | $D^m$ | $D$ | $D_c$ |
| Longitud desde el comienzo, $a$, del desvio, al punto de la rana $P$ | $\Delta^m$ | $\Delta$ | $\Delta_c$ |
| Ordenadas, desde la cuerda larga, $A\,P$, hasta el carril de la rana del lado del carril exterior de la via. | | | |
| Ordenada media | ... | $M$ | $M_c$ |
| Ordenada de cuarto punto | ... | $Q$ | $Q_c$ |
| Arranque $B\,P$ | ... | $L$ | $L_c$ |

**28. Relaciones.** Entonces, para un ángulo dado $F$ de la rana :

Fig. 5 *a*, cuando las dos curvas están en la *misma* dirección :

$$D_c > D; \quad r_c < r; \quad L_c < L; \quad M_c > M.$$

Fig. 5 *c*, cuando las dos curvas están en direcciones *opuestas* :

$$D_c < D; \quad r_c > r; \quad L_c > L; \quad M_c < M.$$

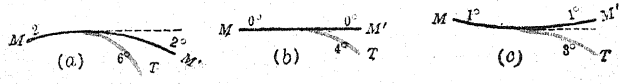

Fig. 6.

**29. Diferencia de Agudeza.** Fig. 6. Supongamos que la agudeza de la curva de la via principal, $M\,M'$, sea $D\,m$, y que la curva del desvío, $T$, sea $D_c$. (En fig. 6 *b*, $D\,m = 0$.)

Entonces para la diferencia de su agudeza, $D_d$ tenemos : —

$D_d = D_c \pm D^m$; mas para la Fig. 6 *c* ; menos para la Fig. 6 *a* ;

ó bien :

$D_c = D_d \pm D^m$ ; más para la Fig. 6 *d* ; menos para la Fig. 6 *c*. (17).

Si (Fig. 7*c*) la via principal tiene la curva *mas aguda*, o $D_m > D_c$, tenemos; $D_d$ $(= D_c - D_m)$ negativo, y $D_c = D_m - D_d$.

Las ecuaciones (17) de arriba, son exactas, cuando $D$ = extensión por unidad de *arco*. Vease curvas pag 954, ¶ 20.

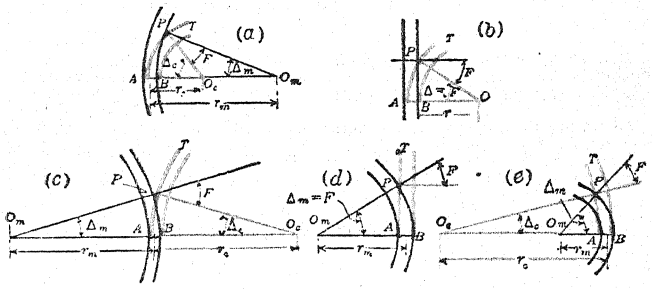

**Fig. 7.**

**30 a. Disposiciones.** Dejemos que las Figs 7 representen una serie de desvios, $T$ (que estan en rojo) cada uno dejando la via principal (esta, en negro) a la derecha con ángulo de la rana $F$ constante; y, comenzando con Fig. 7 *a*, dejemos que la via principal se separe progresivamente hacia la izquierda. Entonces tenemos : —

| | Fig. | | | | |
|---|---|---|---|---|---|
| | 7 *a*. | 7 *b*. $r_m = \infty$; $\Delta = F$ | 7 *c*. $r^m = r_c$. | 7 *d*. $r_c = \infty$; $\Delta_m = F$ | 7 *e*. |
| Centro (y separación de la tangente en nuestras Figs)..... | | | | | |
| Principal..., $O_m$ | Derecha. | 0 | Izquierda. | | |
| Desvio ...., $O_c$ | Derecha. | | | 0 | Izquierda. |
| El desvio deja la via principal en. | Interior. | | Exterior. | | |
| Carril de rana.. | | | | | |
| Principal ..., $B\,P$ | Dentro. | | Fuera. | | |
| Desvio ...., $A\,P$. | Fuera. | | | | Dentro. |
| Radio..... | | | | | |
| Mayor..... | Principal. | | | Desvio. | |
| Principal..., $r_m$.. | Aumento. | $\infty$ | Disminución. | | |
| Desvio ..., $r_c$.... | Aumento. | | | $\infty$ | Disminución. |
| Extension..... | | | | | |
| Principal....., $\Delta_m$ | Disminución. | 0 | Aumento. | | |
| Desvio....., $\Delta_c$... | Disminucion. | | | 0 | Aumento. |

**30 b.** Vemos, por consiguiente, que un desvio puede ser una tangente, Fig. 7 *d*, o una curva en cualquiera dirección; y que, una curva, puede dejar:

Fig. 7 *b*, una tangente de la linea principal, como en nuestros articulos anteriores;

Fig. 7 *c*, una linea principal encurvandose en la dirección *opuesta* (con centros en lados *opuestos* de la via);

Fig. 7 *a*, *e*, una linea principal encurvándose en la *misma* dirección (con centros hacia el *mismo* lado de la via).

**30 c. Cuando el desvio es una tangente** (Fig. 7 *d*), necesariamente deja el *exterior* de la curva de la via principal; y el ángulo de la rana, $F$, entonces el mismo (= extension del desvio, $\Delta_m$) que para un desvio (Fig. 7 *b*) de radio $r = r_m$, Fig. 7 *d*, dejando una tangente de la via principal.

**30 d. Cuando las dos curvas están en direcciónes opuestas** (Fig. 7 *c*), (centros, $O_m$ y $O_c$, en lados opuestos de la via), la curva del desvio necesariamente tambien deja el exterior de la curva de la linea principal.

**30 e. Cuando las dos curvas están en la misma direcciún** (Figs 7 *a*, *e*) (centros, $O_m$ y $O_c$, en el mismo lado de la via) el desvio puede dejar el interior o el exterior de la curva de la via principal, pero suponemos (Fig. 7 *a*) que, en este caso, a menos que no se especifique de otro modo, la curva del desvio tiene el radio mas corto, de modo que deja el *interior* de la curva de la via principal.

**31 a. Ecuaciones** para curvas de desvios. Para símbolos, vease ¶ 27.

Para ecuaciones aproximadas, vease ¶ 31 *b*.

$$\pm \Delta_m = F \pm \Delta_c\dagger; \qquad \pm \Delta_c = F \pm \Delta_m\dagger; \ldots\ldots\ldots\

| | En desvio de tangente. | En desvio de la curva. Exacto. | Aprox. |
|---|---|---|---|
| Radio de la linea de centro de la linea principal..... | $r_m$ ( $= \infty$ ) | $r_m$ | ... |
| del desvio..... | $r$ | $r_c$ | $r_{ca}$ |
| Agudeza de la linea principal..... | $D_m$ ( $= 0$) | $D_m$ | ... |
| del desvio..... | $D$ | $D_c$ | $D_{ca}$ |
| Diferencia de agudeza..... | $D_d$ ( $= D$) | $D_d$ ( $= D_c \pm D_m$)* | $D_{da}$ |

* Más para curvas en direcciones opuestas; menos para curvas en la misma direccion.

† Más para curvas en la misma direccion; menos para curvas en direcciones opuestas.

‡ Con $Dm = 8°$, $N$ 16, el desvio, del exterior de la curva de la linea principal; curvas en la misma direccion, vease fig, 7*e*; *i. e.*, los dos centros están en el mismo lado de la via. Vease ¶ 30 *e*.

## Doble Desvio de la Tangente.

### De lados opuestos.

**32.** Fig. 8. En un desvio doble de tope (vease Parte I, ¶ 10) de lados opuestos de una tangente, supongamos que las dos curvas del desvio sean de igual agudeza, y que

$G = A B$ = ancho de via;
$F = F_a = F_b$ = ángulo principal de la rana;
$F_c$ = ángulo de la bifurcacion de la rana;
$N = N_a = N_b$ = número de la rana principal;
$N_c$ = número de la bifurcacion de la rana;
$L = A P_a = B P_b$ = arranque de la rana principal;
$L_c = a P c$ = arranque de la bifurcacion de la rana;
$r = O_a a = O_b a$ = linea de centro del radio de cualquiera de las dos curvas del desvio;
$R = O_a E = O_b A = O_a P_a = O_b P_b = O_a P_c = O_b P_c = r + G/2$ = radio del carril exterior de cualquiera de las dos curvas del desvio.

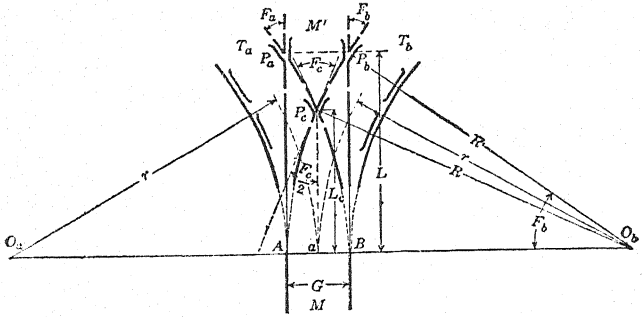

**Fig. 8.**

Entonces,

$$F_c = 2\ P_c\ O_b\ a;$$

$$L = 2\ G\ N \text{ (vease ¶ 19)}; \qquad L_c = 2\left[G + \frac{(G/2)^2}{r}\right] N_c$$

$$= \frac{G + \frac{(G/2)^2}{r}}{\tan\ (F_c/2)} \quad \ldots\ldots\ldots \quad (27)$$

O, para $L_c$, tenemos : —

$$\frac{L_c}{L} = \sqrt{\frac{R^2 - (R - G/2)^2}{R^2 - (R - G)^2}} = \sqrt{\frac{R - G/4}{2\ R - G}} \quad \ldots\ldots\ldots\ldots\ldots \quad (28)$$

De aqui, prescindiendo de $G$, tenemos, aprox : —

$L_c = \sqrt{\frac{1}{2}}\ L = 0.707\ L = \sqrt{2\ G\ N}$ ;

$L - L_c =$ aprox $(1 - \sqrt{1/2})\ L =$ digamos $0.293\ L$ ;

O, practicamente, $L_c = 0.7\ L$ ; y $L - L_c = 0.3\ L$ ..... (29)

$$N_c = \frac{\cot\ (F_c/2)}{2} = \frac{L_c}{2\ [G + (G/2)^2/r]}$$

$$= \text{aprox}\ \frac{L_c}{2\ G} = \frac{\sqrt{2\ G\ N}}{2\ G} = \frac{N}{\sqrt{2}} = 0.707\ N. \quad \ldots\ldots\ldots \quad (30)$$

**Del mismo lado.**

**33.** Fig. 9. Dos chuchos de tope de desvio, $T_a$ y $T_b$, con radio de linea de centro $r_a$ $r_b$, respectivamente, del mismo lado de la tangente, $M$ $M'$.

Sea $R_a$ ( $= O_a A = r_a + G/2) = 2 R_b = 2 (O_b A) = 2 (r_b + G/2)$.

Entonces, siendo $O_b P_b = O_b O_a$, tenemos :

$$F_a = F_b = F = \text{ángulo principal de la rana;}$$
$$N_a = N_b = N = \text{número de la rana principal} \ldots\ldots\ldots \quad (31)$$

y las dos puntas principales de la rana, $P_a$ y $P_b$, son opuestas, en la via, $T_a$.

Sea $D_a$ y $D_b$ la agudeza de la linea de centro de las curvas, $T_a$ y $T_b$, respectivamente.

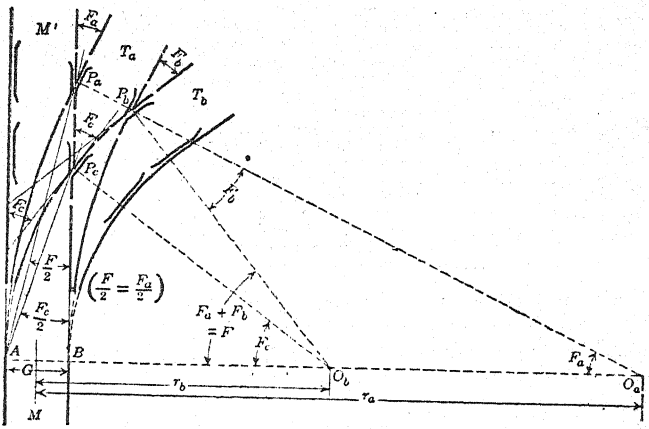

**Fig. 9.**

Entonces, aprox :

$$D_b = 2\ D_a\ ;$$

Senoverso $F_c = G/R_b = 2\ G/R_a$ ;

$L = B\ P_a$ = arranque $= R_a$ sen $F_a = 2\ G\ N$ ;

$L_c = B\ P_c$ = arranque de la bifurcación $= R_b$ sen $F_c = 2\ G\ N_c$

$$= \sqrt{0.5\ L} = \sqrt{2\ G\ N};$$

$$N_c = \frac{L_c}{2\ G} = \frac{\cot\,(F_c/2)}{2} = 0.707\quad N \ldots\ldots\ldots\ldots\ldots \quad (32)$$

## Desvios Dobles, de una Curva.

**34.** En desvios dobles del mismo lado o de lados opuestos de una curva de via principal de agudeza moderada, las dimensiones son practicamente las mismas que para desvios similares de via recta, usando los mismos ángulos de rana. Si la curvatura de la via principal es aguda, el problema puede resolverse gráficamente.

## CHUCHOS (1) DE AGUJA

### Desvios de Tangentes.

**35. Nomenclatura.** Fig. 10. Desvio de una tang con chucho de aguja. Compárese el Manual de la Ascn Am Ingo F. C. 1915, pp 182-3.

Sea

$G$ ..... = ancho de via;
$R = O\ D$..... = radio del lado de la curva del desvio, $D\ E$;
$r = O\ D - G/2$... = radio de la linea de centro de la curva de desvio, $D\ E$;
$D$ ..... = agudeza de la curva del desvio, $D\ E$;
$\Delta = D\ O\ E$..... = extension de la curva de desvio, $D\ E$, entre el extremo de la aguja del chucho y el extremo de la rana;
$M$ ..... = media ordenada de la cuerda, $D\ E$, al carril exterior;
$F = B\ P\ E = t\ O\ E$ = ángulo de la rana;
$N = \frac{1}{2}$ cot $(F/2)$.. = numero de la rana;
$C = D\ E$..... = cuerda larga del carril exterior;
$L = B\ P$..... = arranque del punto real de la punta de la aguja al punto teorico de la punta de la rana;
$T = D\ V = V\ E$.. = semitangente de la curva del desvio;
$s = Y\ A\ D$..... = angulo del chucho;
$l = A\ D$..... = largo del chucho;
$S$ ..... = distancia del extremo de la aguja, o extension, entre los anchos de via en $D$;
$W = P\ E$..... = distancia de la punta de la rana a la cabeza de la rana.
$e$ ..... = $G - S - W$ sen $F$;
$p$ ..... = grueso actual de la punta del chucho;
$t$ ..... = grueso actual de la punta de la rana;
$x, y, = t\ i, t\ k$..... = co-ordenadas de cualquier punto dado, como $n$, en el lado del carril exterior;
$a = D\ O\ n$..... = ángulo del arco, $D\ n$.

**36. Ecuaciones** para desvios de la tangente, de chuchos de aguja.

Fig. 10. Angulo de la rana, $F$; extensión del desvio, $\Delta$, y ángulo del chucho, $s$.

$F = \Delta + s$; $\Delta = F - s$;

$s = F - \Delta$ Sen $s = (S - P)/l$..... (33)

Arranque, $L$.

$$L = (l - W)\frac{\text{sen } \frac{1}{2}(F - s)}{\text{sen } \frac{1}{2}(F + s)} + (G - p)\ \text{cot}\ \frac{F + s}{2}$$

$$= (T + l)\ \text{cos}\ s + (T + W)\ \text{cos}\ F \quad \ldots\ldots (34)$$

Para *el arranque desde el vertice al punto teórico del chucho, agreguese* $p$ cot $s$.

Para el *arranque del punto real de la rana*, agreguese $N\ t$, $t$ = grueso real de la punta de la rana.

Como $T$ sen $s + T$ sen $F = T$ (sen $s$ + sen $F$) $= e$, tenemos;

$$T = R\ \text{tan}\ (\Delta/2) = \frac{e}{\text{sen}\ s + \text{sen}\ F} \quad \ldots\ldots (35)$$

*Radio r de la linea de centro del desvio.*

Como $e = D\ E$ sen $\frac{1}{2}(F + s)$

$= 2\ R$ sen $(\Delta/2)$ sen $\frac{1}{2}(F + s)$, tenemos;

$R = r + G/2 = T$ cot $(\Delta/2)$

$$= \frac{e}{2\ \text{sen}\ \frac{1}{2}(F + s)\ \text{sen}\ (\Delta/2)} = \frac{e}{\text{cos}\ s - \text{cos}\ F}\ ;\ \text{y}$$

$$r = R - G/2 \quad \ldots\ldots (36)$$

(1) Véase *N. del T.* (1), pag. 926.

Cuerda, $D\,E = 2\,R$ sen $(\Delta/2)$ ..... (37)

Agudeza $D$, de la curva del desvio.

Señ $(D/2) = 50/r$ ..... (38)

Arco $D\,E$.

$D\,E = 2\,\pi\,R\,\Delta^{\circ}/360 = 0.017\,453\,R\,\Delta.^{\circ}$ ..... (39)

*Distancia*, $D'\,E'$, desde el extremo $D'$ del chucho al extremo $E'$ de la rana.

$D'E' = L - (W + l)$ ..... (40)

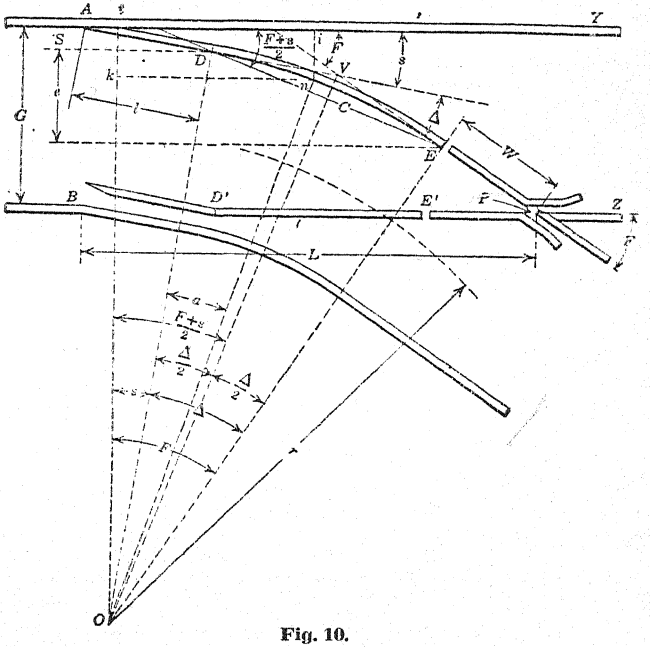

**Fig. 10.**

Co-ordenadas, $x = k\,n$; $y = i\,n$.

$x\ (= k\,n) = [l \cos s - R \text{ sen } s] + R \text{ sen } (a + s)$;

$y\ (= i\,n) = [S + R \cos s] - R \cos (a + s)$ ..... (41)

Las cantidades entre paréntesis son constantes para cantidades $N$, $l$, $s$, dadas en una rana.

La Asen Am de Ingo de F. C. Manual 1915, pagina 184, especifica: —

Grueso, $p$, de la punta del chucho.. = 0.25 pulgs ( 6 mm) = 0.020 833... pies;
Grueso, $t$, de la punta de la rana... = 0.50 — ( 12 mm) = 0.041 666... —
Juego o distancia del extremo de la aguja, o
extension, $S$..... = 6.25 pulgs (159 mm) = 0.520 833... pies;

Media ordenada, $M$ al carril exterior.

$M = R$ senoverso $(\Delta/2)$ ..... (42)

**37. Ecuaciones simples aproximadas,** usando « numero del chucho », (1) $n$.

Fig. 11. (Comparese Wellington B. Lee, Engineering News, p. 252, abril 21, 1898.

Siendo :

$G$ = ancho de via;
$W$ = distancia desde la punta a la cabeza de la rana;
$F$ = angulo de la rana;
$l$ = largo del chucho;(1)
$S$ = distancia del extremo de la aguja;
$N$ = numero de la rana;
$n = l/S$ = « numero del chucho »; (1)
$e = G - S - W \operatorname{sen} F$;
$C$ = cuerda, $D\,E$, desde el extremo de la aguja a la cabeza de la rana.

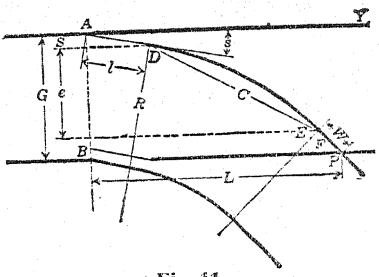

Fig. 11.

Entonces : —

$$C \text{ aprox} = 2\,e\,\frac{n\,N}{n+N}\,; \qquad (43)$$

$$R = r + \frac{G}{2}\,;\; R \text{ aprox} = C\,\frac{n\,N}{n-N}$$

= radio del lado del carril exterior ..... (44)

Con ancho de via, $G$, = 4'8.5'' (1.435 m) y $S$ = 6.25'' (158 mm) los cálculos muestran :

| $N$ = | $l$ = | $W$ = | $F$ = | $s$ = | $R - R_{app}$ | $R/R_{app}$ |
|---|---|---|---|---|---|---|
| 4 | 11 pies (3.35 m) | 3 pies 2'' (0.96 m) | 14°15'0'' | 2°36'19'' | 3.25 pulgs (82 mm) | 1.0024 |
| 16 | 33 pies (10.06 m) | 8 pies 0'' (2.44 m) | 3°34'47'' | 0°52'5'' | 8.53 pies (2.60 m) | 0.9958 |

## Ordenadas a la cuerda, C.

**38.** Donde, como se admitió, para el chucho (1) de *tope*, en ¶ 12, Figs 4, el carril exterior del desvio forma una curva continua circular, desde el comienzo $A$, del desvio al punto teórico de la rana, $P$, sus ordenadas medias y las de los cuartos puntos son aproximadamente independientes del numero de la rana, $N$ (y con ello independientes del radio); pero, donde, como en los chuchos de aguja, Fig. 10, la curva del desvio es tangencial al carril del chucho y a la pata de la rana, en $D$ y en $E$, respectivamente, las ordenadas disminuyen, como disminuye el angulo $F$ de la rana; y se convertiria en cero si el angulo de la rana, $F$, se convirtiera = al angulo del chucho, $s$; porque la curva del desvio se convertiria en una linea recta.

$$\text{Media ord} = R \operatorname{senoverso} \frac{\Delta}{2} = \left(r + \frac{G}{2}\right) \operatorname{senoverso} \frac{\Delta}{2}\,.$$ Véase Ec (42).

(1) Véase *N. del T.* (1) pag. 926.

**Dimensiones « Teóricas » y « Prácticas ».**

**39. Para disminuir y reducir el corte de carriles y el desperdicio de los mismos,** es deseable separarse de las dimensiones « teóricas » dadas por las ecuaciones 34-41 y representadas por las lineas *negras* en las figs 12, y hacer el carril de arranque recto, $D'E'$, de tal largo, $D_p'E'$, que permita la utilizacion eventual de las dos piezas en que queda cortado el carril; substituyendo asi las dimensiones « teóricas » por las « practicas ».

**40. El carril curvo de arranque,** ($D_p E_p$ fig. 12 *a*; $D_p'' E$, fig. 12*b*) puede entonces hacerse del mismo largo y numero de piezas con $D_p' E'$, poniendo opuestas las juntas de estos dos carriles, si el largo excede del carril encurvado entonces pudiera compensarse poniendolo con juntas separadas mas anchas que las $D_p' E'$. Pero, comparense las tablas de dimensiones teóricas y prácticas, ¶ ¶ 47-50.

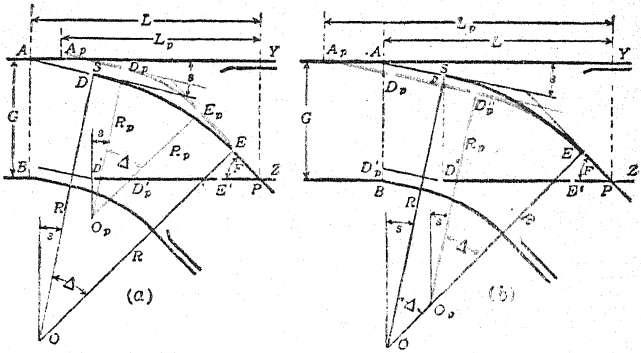

**Fig. 12.**

**41. Diagramas.** En figs 12 *a*, 12 *b*, las dimensiones « teóricas » se indican en lineas y letras *negras ;* y las dimensiones nuevas necesarias para el carril exterior del desvio, con objeto de dar dimensiones « *practicas* », en lineas y letras *rojas.* La fig. 12 *a* representa el caso donde el arranque « teórico », *L*, *excede* al arranque « practico » $L_p$ ; y *vice versa* en la fig. 12 *b*.

**42. Cambio en el largo del arranque.** Figs 12 *a*, 12 *b*. Con un largo dado de chucho, (1) $l = A\,D$, dando el angulo del chucho, $s = Y\,A\,D$, y dando el ángulo de la rana, *F*, hay solamente un largo de arranque, *L*, y solamente un radio del lado del carril exterior, $R = O\,D$, para un arco circular, $D\,E$, conectando tangencialmente el extremo del chucho, en *D*, y la cabeza de la rana, en *E*.

**43.** Si el arranque se *acorta* (como $L_p$, fig. 12*a*) debemos introducir una « tangente de rana « adicional, $E\,E_p$ ; ya que, si el arranque se alarga (como $L_p$, fig. 12 *b*) debemos introducir una « tangente de chucho » $D_p\,D_p''$ adicional. En cualquiera de los dos casos el *radio* es *acortado* como se indica.

**44. Radio Nuevo.** Para el nuevo (disminuido) radio del lado del carril exterior. $R_p$, y para las tangentes adicionales, tenemos. (Fórmulas de Via y Tablas de S. S. Roberts, pp. 12-13.)

Fig. 12 *a*.

$$R - R_p = (L - L_p)\,\frac{\text{sen } F \times \cot \tfrac{1}{2}\,(F - s)}{\text{sen } (F - s)}\,;$$

$$E\,E_p = (L - L_p)\,\frac{\text{sen } \tfrac{1}{2}\,(F + s)}{\text{sen } \tfrac{1}{2}\,(F - s)} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (45)$$

Fig. 12 *b*.

$$R - R_p = (L_p - L)\,\frac{\text{sen } s \times \cot \tfrac{1}{2}\,(F - s)}{\text{sen } (F - s)}\,;$$

(1) Véase *N. del T.* (4) pag. 926.

$$D_p\ D_p'' = (L_p - L)\frac{\text{sen } \frac{1}{2}\ (F + s)}{\text{sen } \frac{1}{2}\ (F - s)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (46)$$

**45. Coordenadas** Para un punto dado en la curva de arranque,

Sea $x$ = la abscisa (coordenada *paralela* a la via principal), medida desde la punta del chucho, (1) $A_p$;

$y$ = la ordenada (coordenada *normal* a la via principal) medida normalmente de la tangente.

En la fig. 12 *a*, donde el arranque teórico excede al práctico, las coordenadas, $x$ e $y$, a cualquier punto en la curva de arranque, $D_p\ E_p$, son como las da la ecuacion 41, sustituyendo $R_p$ por $R$; pero, en la fig. 12 *b*, donde el arranque práctico excede al teórico, estas coordenadas se modifican, como se expresa abajo, por la introduccion de la tangente del chucho, $D_p\ D_p''$. (Fórmulas de Via y Tablas; S. S. Roberts, p. 13.) Aqui, $l$ = largo del chucho, $A\ D$; $S$ = extension del extremo de la aguja; $s$ = angulo del chucho, (1) $Y\ A\ D$; $\Delta_p$ = extension del desvio del extremo de la aguja al punto dado. Las cantidades en parentesis [ ] son constantes para $N$, $l$ y $s$ dadas.

$$x = [(l + D_p\ D_p'')\cos s - R_p \text{ sen } s] + R_p \text{ sen } (\Delta_p + s);$$
$$= (\text{aprox})\ [(l + D_p\ D_p'') - R_p \text{ sen } s] + R_p \text{ sen } (\Delta_p + s);$$
$$y = [S + D_p\ D_p'' \text{ sen } s + R_p \cos s] - R_p \cos (\Delta_p + s) \quad \ldots\ldots\ldots\ldots \quad (47)$$

**46. Ranas y Chuchos** (1) **Asen Am Ingo F. C.** Manual, 1915, pp. 184-5, Nuestras. Figs 1, 10 y 13. Para arranques teóricos y prácticos, vease ¶ ¶ 48-50.

$S$ = juego del extremo de la aguja = 6,25 pulgs (159 mm);

$N$ = numero de la rana; $F$ = ángulo de la rana;

$W$ = distancia de la punta a la cabeza de la rana, medida con un cartabón de linea.

$K$ = distancia de la punta al extremo de atras de la rana; $T$ = abertura de la cabeza de la rana;

$H$ = abertura de la parte de atras del extremo de la rana;

$l$ = largo del carril de chucho;

$s$ = angulo de chucho.

**47.** *Dimensiones de Rana y Chucho.* (1)

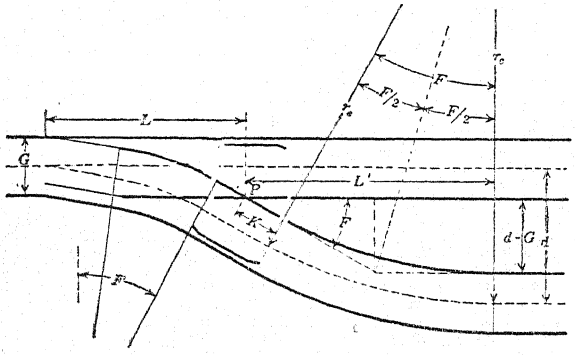

**Fig. 14.**

**Curva de Enlace.**

**51. Desvio Lateral.** Fig. 14. En el desvio « lateral » sea $d$ = distancia entre los centros de via; $d$—$G$ = dist. entre los carriles interiores de las vias; $K$ = distancia del punto teorico de la rana a la cabeza de la misma; $r_c$ = radio de la linea de centro de la curva de enlace; $L'$ = arranque del punto teórico de la rana al extremo de la curva de enlace. Entonces, recordando que

$$2\ N = \cot\ (F/2) = 1/\tan(F/2).$$

(1) Véase *N. del T.* (1) pag. 926.
* Véase *N. del T.* al pie tabla ¶ 47 y tambien ¶ 11 (*N. del T.*) pag. 926.

Tenemos :

$K + (r_c - G/2) \tan (F/2) = (d - G)/\text{sen } F$ ; de aqui :

$r_c = 2\,N\,(d - G)/\text{sen } F - 2\,N\,K + G/2$;

$L = (d - G) \cot F + (r_c - G/2)/2\,N$ ..... (48)

**52. Desvio Diamante o Equilateral.** Fig. 15. En el desvio « diamante o « equilateral », tenemos :

(Comparese el desvio Lateral, ¶ 51.)

$r$ = radio $O_t\,e$ de la linea de centro de la curva del desvio.

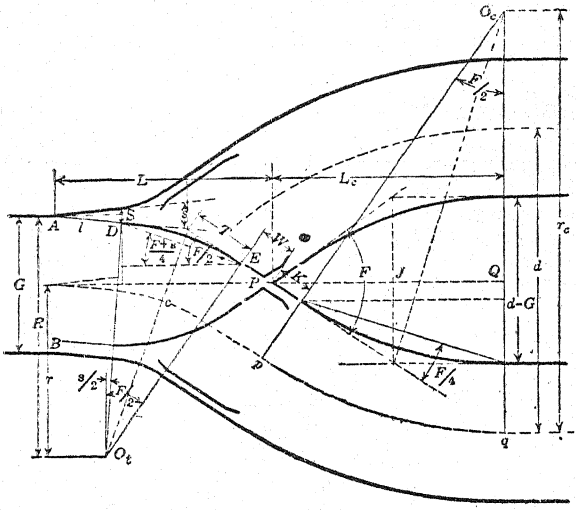

**Fig. 15.**

$$R\,(= r + G/2) = O_t\,D = T^* \cot \frac{F - s}{4} = \frac{D\,E^*}{2 \text{ sen } {}^1/_4\,(F - s)} \quad \ldots\ldots\ldots \quad (49)$$

$$L = (T + l) \times \cos\,(s/2) + (T + W) \times \cos\,(F/2) \quad \ldots\ldots\ldots\ldots\ldots \quad (50$$

*Comparacion de Dimensiones* entre un desvio diamante y un desvio de la via recta, dandose los angulos de la rana y del desvio.

Con $F = 8°$ $(N = 7{,}15)$; $s = 2°$; $G = 4'\ 8.5''$ (1,435 m). = 4.70833 pies (1.43608 m); $l = 16$ pies (4.877 m); $S = 0.5$ pies (0.152 m); $W = 5$ pies (1.524 m).

(*Vease N. del T.*, ¶ 11, pag. 926.)

| | Diamante. | Recto. | Diamante Recto. |
|---|---|---|---|
| $T$..... | 20.1285 | 20.1782 | 0.9975 |
| $R$..... | 768.6760 | 385.0226 | 1.9964 |
| $L$..... | 61.1903 | 61.0893 | 1.0017 |

$$^* T = \frac{G/2 - S/2 - W \text{ sen } (F/2)}{\text{sen } (s/2) + \text{sen } (F/2)};$$

$$D\,E = \frac{G/2 - S/2 - W \text{ sen } (F/2)}{\text{sen } {}^1/_4\,(F + s)} = 2\,R \text{ sen } {}^1/_4\,(F - s).$$

**53.** Radio y Arranque. Fig. 15. Radio, $r_c$, y arranque, $L_c$ de una curva de enlace, $p\ q$, para desvio diamante.

$d - G$ = distancia entre carriles interiores de las vias;

$r_c = O_c\ p$ = radio de la linea de centro de la curva de enlace, $p\ q$;

$K$ = distancia de la cabeza de la rana al punto teórico $P$ de la misma;

$L_c = P\ Q$ = arranque, del punto teórico de la rana al extremo de la curva de enlace;

$F$ = ángulo de la rana; $N$ = número de la rana $= \frac{1}{2}\cot(F/2)$.

Entonces

$(r_c - G/2)$ senoverso $(F/2) = (d - G)/2 - K$ sen $(F/2)$. De aqui,

$$r_c = \frac{d - G}{2 \text{ senoverso } (F/2)} - \frac{K}{\tan (F/4)} + G/2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (51)$$

$$L_c = P\ J + J\ Q = N\ (d - G) + (r_c - G/2) \times \tan (F/4) \ldots\ldots\ldots\ldots \quad (52)$$

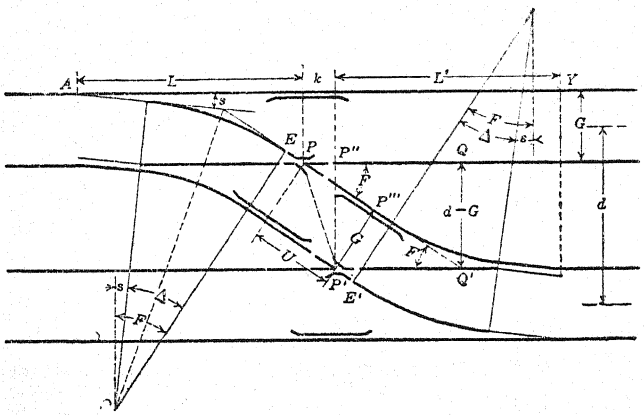

**Fig. 16.**

## Enlaces.

**54.** Figs 16, 17. Cuando la via de enlace es una tangente (fig. 16), los dos angulos de la rana son necesariamente iguales. Cuando es una curva invertida (fig. 17) se prefiere igualmente que sean iguales.

**Con via recta de enlace**, $E\ E'$. Fig. 16. Sea :

$R = O\ E$ = radio de la curva del desvio en el carril exterior;

$T$ = semitangente de la curva del desvio;

$G$ = ancho de via;

$d - G$ = distancia entre los carriles interiores de las vias.

$k = P\ P''$ = distancia teórica entre los puntos de la rana, $P$ y $P'$, || con las vias principales;

$U = P\ P'''$ = distancia teórica entre los puntos de la rana, $P$ y $P'$, || con la via de enlace;

$W$ = distancia del punto teórico de la rana, $P$, a la cabeza de la rana, $E$;

$l$ = largo del chucho. (1)

Entonces :

$$T = R \tan (\Delta/2); \qquad L = L' = (T + l) \cos s + (T + W) \cos F;$$

$$k = P\ Q - P''\ Q = P\ Q - P'\ Q' = \frac{d - G}{\tan F} - \frac{G}{\operatorname{sen} F};$$

$$A\ Y = L + k + L' = k + 2\ L;$$

$$U = P'\ Q' - P''\ Q' = \frac{d - G}{\operatorname{sen} F} - \frac{G}{\tan F} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (53)$$

Para el cambio de unidad en el valor de $d$, los cambios correspondientes en $k$ y en $U$, son, respectivamente; — en $k$, cambio = cot $F$ ; en $U$, cambio = cosec $F$.

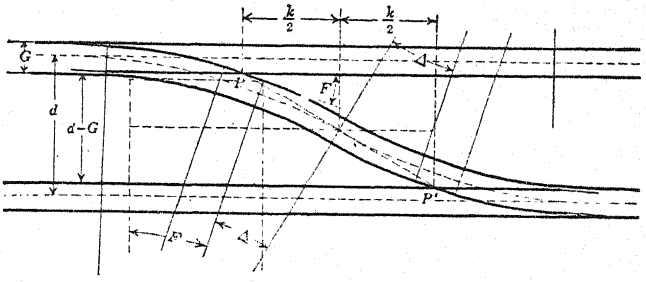

**Fig. 17.**

**55. Con curva de enlace invertida.** Fig. 17.

El uso de una curva de enlace invertida economiza espacio, especialmente donde las dos vias estan separadas ampliamente y donde el ángulo de la rana sea pequeño. El radio es generalmente el de una curva de desvio.

Sea :

$F$ = ángulo de la rana;

$\Delta$ = extension de cualquier ramal de la curva de enlace invertida;

$r$ = radio de la linea de centro de la curva de enlace invertida;

$R = r + G/2$;

= radio del carril exterior de la curva de enlace invertida;

$K$ = dist. del punto, $P$, teorico de la rana, a la cabeza de la misma;

$k$ = dist. paralela a la via, entre puntos de la rana, $P$ y $P'$.

Entonces :

$$r \cos (F + \Delta) = R \cos F + K \operatorname{sen} F - (d - G)/2;$$

$$k/2 = r \operatorname{sen} (F + \Delta) - R \operatorname{sen} F + K \cos F;$$

$$P\ P' = \sqrt{k^2 + (d - G)^2} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (54)$$

(1) Véase *N. del T.* (1) pág. 926.

## Desvio Doble.

**56.** Fig. 18. Desvio con chucho (1) de doble punta de lados opuestos a la tangente. Sean las dos ranas principales, $P$, de un mismo ángulo, y por consiguiente opuestos, y sea :

$r$ = radio de la linea de centro, del desvio;
$R = O\,E = r + G/2$ = radio del lado del carril exterior;
$\Delta_c$ = desarrollo de $D\,O\,P_c$ ;
$T_c$ = semitangente de la curva $D\,P_c$ ;
$W = E\,P$ = dist de la cabeza de la rana principal, $E$, al punto, $P$, teórico de la rana;
$S$ = juego del extremo de la aguja;
$s$ = angulo del chucho; (1)
$l = A\,D$ = largo del chucho;
$N$, $F$ = numero de la rana principal y ángulo;
$N_c$, $F_c$ = numero de la rana bifurcada y ángulo;
$L = B\,P$ = arranque a la rana principal, $P$ ;
$L_c = a\,P_c$ = arranque a la rana bifurcada, $P_c$.

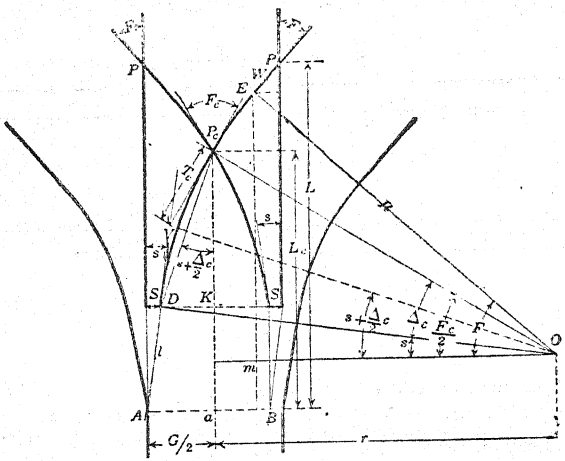

**Fig. 18.**

Entonces: —

$$\frac{F_c}{2} = \Delta_c + s\,; \qquad D\,P_c\,a = V\,O\,m = s + \frac{\Delta_c}{2} = \frac{F_c - \Delta_c}{2};$$

$$\text{Cos}\,\frac{F_c}{2} = \frac{r}{R} = \cos F + \frac{G/2 - W \operatorname{sen} F}{R}\,; \qquad \cos F = \frac{O\,m}{R};$$

$$N_c = \frac{\cot\,(F_c/2)}{2}\,;$$

$$T_c = \frac{G/2 - S}{\operatorname{sen} s + \operatorname{sen}\,(F_c/2)}$$

$$DP_c = \frac{G/2 - S}{\operatorname{sen}\,(s + \Delta_c/2)} = 2\,R \operatorname{sen} \frac{\Delta_c}{2}\,;$$

(1) Véase *N. del T.* (1) pág. 926.

$$R = \frac{D\ P_c}{2\ \text{sen}(\Delta_c/2)} = T_c \cot(\Delta_c/2) = \frac{G/2 - S}{2\ \text{sen}(\Delta_c/2)\ \text{sen}(s + \Delta_c/2)}$$

$$L_c = L - W \cos F - R\ [(\text{sen}\ F - \text{sen}\ (F_c/2)]$$

$$= a\ K + K\ P_c$$

$$= l \cos s + (G/2 - S) \cot \frac{F_c - \Delta_c}{2}$$

$$= (T_c + l) \cos s + T_c \cos (F_c/2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ (55)$$

**Desvíos en escala.**

**57. Trazado.** Fig. 19. Ordinariamente, el patio o « conjunto » de vías 2, 3, 4, etc., conectados entre sí; son paralelas a la vía principal, 1; la escala es recta, de $P_1$ a $P_1$, etc.; las vías de patio, 2, 3, 4, etc. son rectas desde la rana de la escala, $P_2$, $P_3$, etc., y la dist, $d$, entre centros de vías adyacentes paralelas es constante.

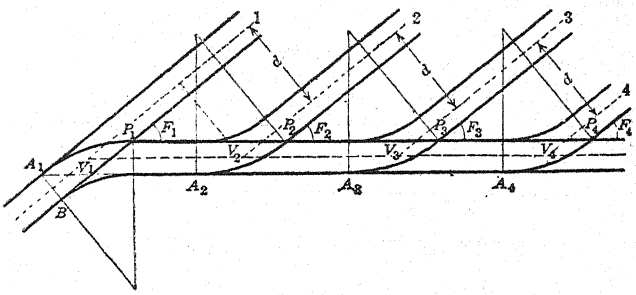

**Fig. 19.**

**58. Distancias.** Los ángulos de rana, $F_1$ $F_2$, etc., entre la vía principal y la escala, y entre la escala y las vías de patio, son entonces iguales; y las dist $A_1$ $A_2$, $A_2$ $A_3$, entre chuchos (1) consecutivos; y las dist. $P_1 P_2$, $P_2 P_3$, etc., entre ranas consecutivas; y las dist, $V_1$ $V_2$, $V_2$ $V_3$, etc., entre intersecciones consecutivas, medidas || a la escala, son todas iguales, y $V_1$ $V_2 = d/\text{sen}\ F$. (Pero véase ¶ 60). Para el cambio de unidad en el valor de $d$, el cambio correspondiente, en $d/\text{sen}\ F$, es $1/\text{sen}\ F = \text{cosec}\ F$.

**59.** La *mínima dist permitida*, a lo largo de la escala, entre un punto de la rana como $P_1$ y un punto opuesto al extremo del chucho, (1) $A_2$ del próximo desvío, es como de 10 pies (3.05 m).

**60.** « En condiciones ordinarias, *las vías deben separarse* de 13 a 14 pies (4 a 4.30 m) entre centros, y, donde sean paralelas a la vía principal o a otra vía de tráfico importante, el primer cuerpo de vía debe separarse. $\lessdot$ 15 pies (4.5 m) entre centros de la dicha principal o de otra vía importante. Las vías en escala deben espaciarse $\lessdot$ 15 pies (4.50 m) entre centros de cualquier vía paralela ». Am Ingo F. C. Manual, 1915, p. 469.

**61. Número de las Ranas.** Comunmente los patios de ferrocarril con líneas de vapor usan ranas N.os 7 y 8; pocos usan la n.º 6. Para uso general en vías en escala, la Asen Am Ingo F. C. (Manual, 1915, p. 469) recomienda ranas de no menor N.º que el n.º 8.

(1) Véase *N. del T.* (1) pág. 926.

**62. Para economizar espacio**, la escala puede sacarse de la rana de la via principal por una curva, *A B*, Figs 20, 21; de modo que forme con la via principal, un ángulo, $\theta$, mayor que el angulo, *F*, de la rana.

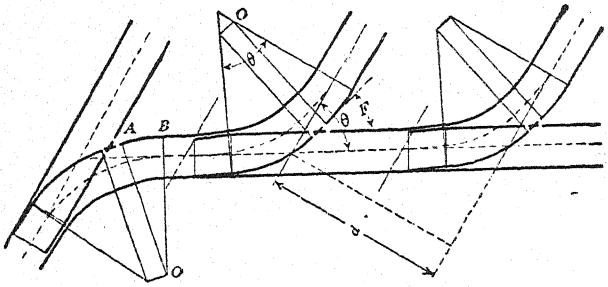

**Fig. 20.**

**63. Vias paralelas.** Fig. 20. Las vias de patio entonces dejan la escala por desvíos similares e iguales y encurvadas en direcciones opuestas, quedando asi paralelas con la via principal.

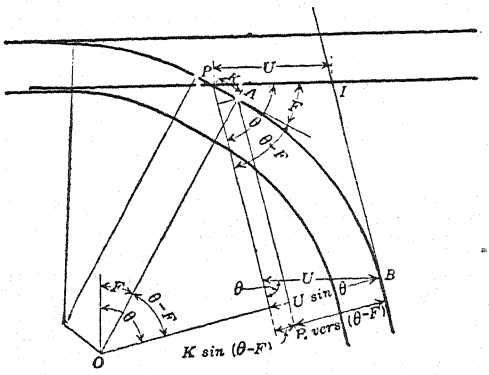

**Fig. 21.**

**64. Nomenclatura y fórmulas.** Fig. 21. Sea :
*U* = dist, *P I*, entre cualquier punto teórico de la rana, *P*, y la intersección *I*;
*K* = dist entre la cabeza de la rana y el punto teórico de la rana;
*R* = radio *O A* del carril exterior = *O B* (igual en todas las curvas).
Entonces :

$$U \text{ sen } \theta = R \text{ senoverso } (\theta - F) + K \text{ sen } (\theta - F) \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (56)$$

**65.** Fig. 20. Dist entre chuchos,(1) entre ranas y entre intersecciones (vease ¶ 58) = $d$/sen $\theta$; y cambio de unidad, en $d$, cambios $d$/sen $\theta$ por 1/sen $\theta$.

(1) Véase *N. del T.* (1) pág. 926.

**66. Desvios (de tres cursos) dobles** (vease ¶ ¶ 34-4) se usan también en conexión con las escalas.

En tales casos, puede recurrirse a métodos gráficos.

Vease tambien ¶ 73 del capitulo; Patios y Estaciones, mas adelante.

**Desvio de una curva (chucho (1) de aguja).**

**67. El cálculo dificulta el trazado.** Las ecuaciones exactas, para las dimensiones de desvios de curva de chuchos (1) de aguja, serian muy complicadas; y los problemas, que envuelven tales dimensiones se resuelven mejor por medio de dibujos hechos en una escala liberal. El asunto se discute matematicamente, en « Formulas y Tablas de via », por S. S. Roberts; New York, John Wiley and Sons, publicistas.

**68. Diferencia de agudeza.** En general y para propósitos prácticos (aun con carriles de chucho y rana rectos), la *diferencia* de agudeza entre las curvas principales y de desvio, para un numero dado de rana, puede tomarse como igual al de un desvio de una via recta, con el mismo numero de la rana, como en el ¶ 26.

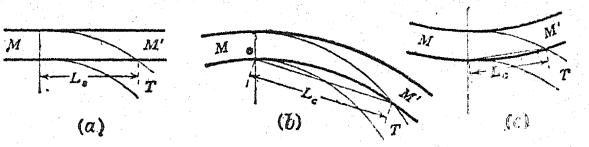

**Fig. 22.**

**69. Arranque.** Figs 22. Para un número dado de rana, el arranque puede tomarse aproximadamente como igual al calculado para un desvio de una tangente, por la ecuacion 10; pero, Mr. W. M. Camp en sus notas sobre via, p. 373 da lo siguiente : —

Sea $L_s$ = arranque para el desvio de la tangente, Fig. (*a*) ;

$L_c$ = arranque para el desvio de via encurvada con la misma rana, Figs (*b*), (*c*).

$D$ = agudeza de la curva de la via principal; $N$ = número de la rana.

Entonces :

$$L_c = L_s \pm D\ (N/12)^2 \ldots\ldots\ldots\

# CURVAS
# CURVAS SIMPLES

## GENERALIDADES

### Definiciones.

(Para ecuaciones, vease ¶ ¶ 25, etc).

**1. Fig. 4 a. Una linea de ferrocarril**, *a b c.....j*, se compone generalmente de una serie de curvas alternadas *b c, d e*, etc; y de lineas rectas, *a b, c d*, etc, que se llaman comunmente « tangentes » porque son necesariamente tangencial es a las curvas.

**Fig. 1. En una curva de ferrocarril circular o simple**, la linea de centro *A P B* de la via (y si no está a nivel, su proyeccion en un plano horizontal) es un arco circular.

**Fig. 1.** Supónganse las tangentes, *X A*, y *B Z*, en los extremos de la curva *A B*, prolongadas hasta su interseccion, *V*. Las distancias iguales, *A V*, *V B*, se llaman as *semitangentes*.

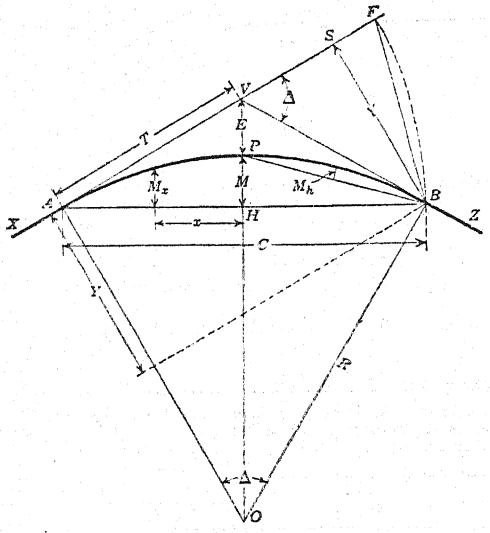

Fig. 1.

**2. Para los puntos de cambio** de la tangente a la curva, etc, etc., usamos los símbolos adoptados por la **Asen Am Ingo F. C.**, Manual de Práctica Reco mendada, 1915, p 135, como sigue : —

**Para curvas circulares**

| | | |
|---|---|---|
| **T. C.** | De tangente a curva; | Hasta aqui llamadas : |
| **C. T.** | De curva a tangente; | Punto de la curva P. C. |
| **C. C.** | — a curva; | — de tangencia P. T. |
| | | Punto de curva compuesta o invertida P. C. C. o P. R. C. |

**Para curvas espirales.** Vease p. ..., ¶ 201.

**El punto de la curva, Fig. 1. T. C.**, es el comienzo, $A$, de la curva, o el extremo a que llega el trazado en su progreso.

**El punto de tangente, C. T.**, es el otro extremo, $B$, de la curva.

**El vertice, o punto de interseccion, P, I.**, es el punto, $V$, donde las dos tangentes, $A\ V$ y $V\ B$, se encuentran.

## TRAZADO

### Funciones de la curva y sus símbolos.

**3. Fig. 1. Lista de las funciones** de una curva entera. Para una parte de curva subtendida por una unidad de cadena, vease ¶ 9.

| Funciones. | Símbolos. |
|---|---|
| Extension, desarrollo ó angulo central, (vease ¶ 10).. | $\Delta = A\ O\ B = F\ V\ B$ |
| Radio..... | $R = O\ A \quad = O\ B$ |
| Cuerda larga..... | $C = A\ B$ |
| Semitangente..... | $T = A\ V \quad = V\ B$ |
| Distancia exterior..... | $E = P\ V$ |
| Ordenada a la tangente (perpendicular a la tangente $A\ V$ o $B\ V$)..... | $Y = B\ S$ |
| Distancia tangencial (haciendo $A\ F = A\ B$)..... | $\ldots = B\ F$ |
| Ordenada media..... | $M = H\ P$ |
| Ordenada lateral, distante $x$ de $M$..... | $Mx$ |
| Media ordenada para $\Delta/2$..... | $Mh$ |

**4. Determinación de puntos en las curvas. Fig. 2.** Donde el radio $R$, es muy corto, es algunas veces practicable determinar el centro, $O$, de la curva, y trazar la curva en el terreno, usando una lienza de acero para el radio; pero ordinariamente, el centro no se determina, y los puntos, $a\ b$, etc., en la curva, se fijan poniendo el tránsito en un punto conocido de la curva (como el T. C., en $A$), trazando los ángulos periféricos conocidos, $v\ A\ a$, $v\ A\ b$, etc., de la tangente, $A\ v$ y midiendo las cuerdas, $A\ a$, $a\ b$, $b\ c$, etc., de longitud calculada.

**5. Cuerdas y Cadenas** *. En la práctica, estas cuerdas (excepto la primera y ultima, vease ¶ 24) son de igual longitud, igual (o casi igual, vease ¶ 20) a la de la lienza (generalmente 100 pies (30,48 m) o 20 metros de largo) usada en la determinacion de la linea, y se llaman « cadenas » *, con objeto de distinguirlas de otras cuerdas, como $A\ b$, $b\ d$, etc., que puedan adaptarse a la curva.

**6. Los ángulos periféricos iguales**, $a\ A\ b$, $b\ A\ c$, etc., subtendidos por estas cadenas iguales, se llaman **angulos de deflexion**, cada uno es igual a $D/2$ = mitad del **angulo central** correspondiente, $a\ O\ b$, $b\ O\ c$, etc.

**7. Angulos de Deflexion. Tangenciales y Centrales.** Samuel W. Mifflin en « Metodos de trazado para Ingenieros de Ferrocarriles » 1837, llamaba el ángulo, $e\ c\ d$ ( $= c\ O\ g = D/2$), el « *angulo tangencial* » por ser el angulo entre una cadena *, $c\ d$, y la tangente, $c\ e$, en cualquiera de sus extremos. En esto, Mifflin siguió al Coronel Stephen H. Long, del Ejercito Americano (« Manual de Ferrocarril », 1829) quien dio el nombre « *angulo de deflexion* » al angulo $f\ c\ d$, entre una cuerda $c\ d$, y la prolongacion $c\ f$, de la cuerda anterior $b\ c$; siendo igual al ángulo, $e\ h\ d$ (entre las tangentes, $c\ e$ y $h\ d$, en los dos extremos de una cuerda $c\ d$), desviación de *la linea* en la distancia subtendida por la cuerda. Es igual al ángulo *central*, $D = c\ O\ d$, subtendido por la cuerda $c\ d$.

**8.** Nosotros, « en la Practica en el Campo para trazar Curvas Circulares para Ferrocarriles » (primera edicion, 1851) y M. William Findlay Shunk en « El Ingeniero de Campo », 1880, seguimos esta nomenclatura. Ahora, no obstante el uso llama a $e\ c\ d$ el « **angulo de deflexion** » o simplemente la « deflexion » (como indicando una deflexion de la linea visual) y llama $D$ ( $= f\ c\ d$) el « **grado de la curva** ». Vease Agudeza ¶ 11.

---

* El uso de la palabra « cadena », para designar tal cuerda, viene de la época, cuando las *lienzas* de agrimensor eran desconocidas, y las medidas se tomaban por medio de cadenas hechas con eslabones de alambre. El *largo* completo tipo de tales cadenas se llamaba « una cadena ».

**9.** Figs 1 y 2. En una parte de la curva, como *a b*, fig. 2, subtendida por *una cadena* *, *c*, tenemos, extension o desarrollo $\Delta = D$, y designamos las otras varias funciones por minúsculas en lugar de mayúsculas. Así :

Las letras..... $C\ T\ E\ Y\ M\ Mx$ y $Mh$, fig. 1, ¶ 3,
se convierten, respectivamente en... $c\ t\ e\ y\ m\ mx$ y $mh$, en el arco *a b*, fig. 2.

**10. Fig. 1. La extension,** desarrollo, ó angulo del centro Δ, de la curva, es el angulo, *A O B*, de radio, *R*, y subtendido por la curva. Igual tambien al angulo, *F V B*, barrido por la tangente al girar de *V F* a *V B*. Es por consiguiente la desviacion total de la linea, debida a la curva; o es el ángulo de interseccion entre las dos tangentes. Cada *porción* de la curva tiene por consiguiente su propia extension, ó desarrollo.

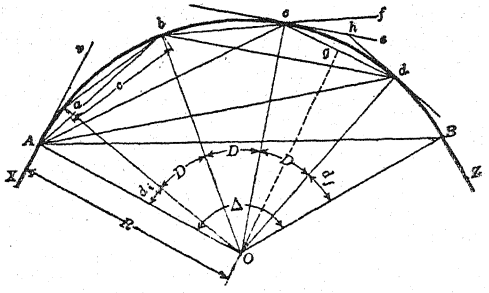

**Fig. 2.**

**11. Fig. 2. La agudeza** (comunmente llamado el « **grado de curvatura** ») se expresa generalmente por el angulo *central*, *D*, ( $= a\ O\ b = b\ O\ c$, etc.) subtendido por una *cadena* *, *a b o b c ; i. e.*, agudeza = la desviacion, *e h d* de la linea, en un largo de cadena. Una curva de « un grado », « dos grados », « tres grados treinta minutos », etc., es una curva cuya agudeza es 1º, 2º, 3º30′, etc. Vease ¶ 14.

**12.** Fig. 2. Pero algunas veces (especialmente cuando se usa el sistema metrico) la curva se nombra por el angulo de cadena *periferico*, $c\ b\ d = c\ A\ d$, etc, o angulo subtendido en la *circunferencia*, como en *b* ó *A*. Una curva dada, llamada 1º00′, 2º, 3º30 , etc., por la medida de su angulo *central* opuesto a una cadena, se llamaria (la mitad) 0º30′, 1º, 1º45′, etc., por la medida de su ángulo periférico respectivo.

Nosotros seguimos la definicion del ¶ 11.

**13.** Fig. 3. Cuando las curvas estan determinadas por medio de cadenas cortas * (vease ¶ 19), la agudeza se toma algunas veces por el desarrollo del arco subtendido por una *serie* de cadenas tales, cuya suma es igual al largo de la cadena unidad o tipo. Asi, una curva, *a p b*, en la que una serie de dos cadenas, *a p*, *p b*, de 50 pies cada una, subtende un angulo de *D*º, se llama entonces curva de *D*º, aunque sea mas aguda (tiene un radio mas corto, $R_2 = O\ b$) que la curva de *D*º, *A P B* ($R_1 = O\ B$) en el que el mismo ángulo de *D*º está subtendido por una cadena sencilla, *A B*, de 100 pies.

**14.** Fig. 1. En otros paises, fuera de los Estados Unidos, la agudeza de las curvas se determina a menudo por el largo de sus *radios*, $R = O\ A = O\ B$, etc. A mayor agudeza, menor radio.

**15. Representacion gráfica de la curvatura.** En la fig. 4, la linea de centro, *a f* (figs 4 *a* y 4 *b*) y los rectángulos (fig. 4 *b*) hacia arriba y hacia abajo representan el caso supuesto por la tabla a continuación. Como las abscisas, *a b*, *a c*, etc.

* Vease la llamada igual a esta * en el ¶ 7.

Fig 4 *b* representan distancias a lo largo de la linea, mientras que las ordenadas representan la agudeza de la curva, el área de los rectángulos representa *el desarrollo* de las curvas, o las desviaciones de las tangentes entre si. En la misma proporción las *porciones* de los rectángulos; por ej. : el rectángulo en *b' c* representa la extension o desarrollo de la porción, *b' c*, de la curva simple, *b c*.

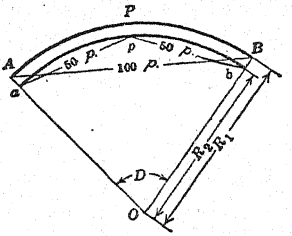

**Fig. 3.**

**16.** Las lineas inclinadas (Fig. 4*b*) representan la suavidad en los extremos de las curvas por medio de espirales (vease ¶ 194 y siguientes).

Como las posiciones de las tangentes no cambian por la introducción de las espirales, los desarrollos de las curvas, y las areas que las representan, quedan tambien sin cambiarse; asi el área del trapezoide en *B C* = área del rectángulo en *b c*.

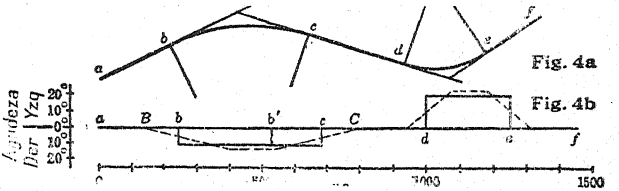

**Fig. 4.** Representaciones gráficas de las curvaturas.

## Cadenas *. Longitud de las curvas.

**17. La unidad en los ferrocarriles y para la medida de curvas** es usualmente 100 pies (30.48 m) o 20 metros (= 65.617 pies).

**18. Cadena completa** *. Es costumbre dar (100 pies, o 20 metros) al largo de la *cadena;* y entonces el **largo de la curva** se expresa (aproximadamente) como igual a la suma de los largos de *cadenas* usados en determinarla. Así, Fig. 6, en la curva, $A\ a\ b\ c\ B$, el largo se toma como $= A\ a + a\ b + b\ c + c\ B$, medido a lo largo de estas *cuerdas*, $= 43 + 200 + 36.7 = 279.7$ pies. El largo *verdadero* de esta curva es por supuesto ligeramente *mayor* que el expresado.

**19. Cadena corta** *. Las curvas agudas se determinan usualmente por medio de una cadena corta cuyo largo es la mitad o la cuarta parte de una cadena tipo o menos; estas cadenas cortas subtenden ángulos correspondientes centrales mas chicos.

Así donde la cadena tipo es de 100 pies (30.48 m) (con largo de lienza) se usan en tales curvas cadenas de 50, 25 pies o menos. En general, el largo de cadena usado no es mayor de un duodécimo a un octavo del radio de la curva. La suma de una serie de largos de cadenas cortas subtendiendo un arco dado, es evidentemente mayor (casi igual al largo del arco mismo) que la suma de los largos de cadena tipo que subtende el mismo arco. Vease ¶ 13.

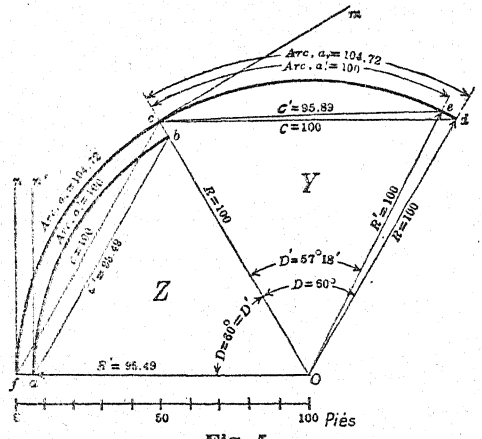

**Fig. 5.**

**20. Cadenas disminuidas** *. Si, en las curvas, el cadenero de atrás aguanta la lienza en la estaca con un pequeño margen de medida bien calculado, en lugar de ponerlo en la marca cero, disminuyendo así el largo de la cadena tomada como unidad el *arco* subtendido queda por consiguiente reducido y esta longitud así corregida corresponde entonces con su largo real, y ciertas fórmulas (¶ 42) para encontrar funciones de curvas (que de otro modo son solamente aproximadas) se hacen exactas.

**21. Agudeza. Esta se afecta por el uso de las cadenas disminuidas** *. Fig. 5 *Y*. En la curva, $c\ e\ d$, supongamos que la cadena completa, $c = c\ d = 100$ pies, subtende un ángulo central, $D = c\ O\ d = 60°$. Entonces $c\ e\ d$ es una curva de 60°, y su ángulo de deflexion, $D/2 = m\ c\ d = 30°$. Para recorrer la **misma**

* Vease la nota igual * en el ¶ 7 atrás. Y la *N. del T.* intercalada en el ¶ 11, pag. 926

**curva** con una cadena *disminuida*, $c' = c\,e$ ( = 95.89 pies, ¶ 22) debemos usar un ángulo de deflexion $m\,c\,e$, de solo 28° 39′, y $D'$ ( $= c\,O\,e$) = 57° 18′. Así, el uso de cadenas disminuidas produce una curva *nominalmente mas süave.*

**22.** Fig. 5 *Z*. Si, con cadenas disminuidas, $c' = a\,b$, usamos **el mismo ángulo de deflexion** ($n'\,a\,b = n\,f\,c$), como con la cadena completa ($c = f\,c$), debemos obtener una curva mas aguda, $a\,b$ (radio = $O\,a$) que con la cadena completa, quedaría a la curva $f\,c$ el (radio = $O\,f$). Así, el uso de cadenas disminuidas hace *realmente mas aguda*, la curva.

En las Figs 5 *Y* y 5 *Z*, las funciones se comparan como sigue :

($Q = a/c$ o $a'/c'$).

| Fig | $R$, piés | $R'$, piés | $D$ | $D'$ | $a$, piés | $a'$, piés | $c$ piés | $c'$ piés | $Q$ |
|---|---|---|---|---|---|---|---|---|---|
| 5 *Y*..... | 100.00 | ..... | 60°00′ | ..... | 104.72 | ..... | 100.00 | ..... | 1.047 |
| | ..... | 100.00 | ..... | 57°18′ | ..... | 100.00 | ..... | 95.89 | 1.043 |
| 5 *Z*..... | 100.00 | ..... | 60°00′ | ..... | 104.72 | ..... | 100.00 | ..... | 1.047 |
| | ..... | 95.49 | ..... | 60°00′ | ..... | 100.00 | ..... | 95.49 | 1.047 |

**23. Estaciones.** Como en las tangentes, los extremos de las cadenas en las curvas, se llaman « estaciones »; pero el nombre « estación » se aplica a menudo (vagamente) a *la distancia* entre dos de dichos puntos.

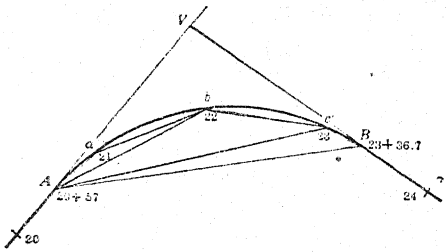

**Fig. 6.**

**24. Estacion « adicional »; sub-cadenas.** Fig. 6. Solo accidentalmente puede ocurrir que una curva empiece o termine exactamente en una estacion. En otras palabras, el T. C. y C. T. casi siempre cae *entre* dos estaciones por ej. : como en estacion $A = 20 + 57$, o en estacion $B = 23 + 36.7$; y esto requiere el uso de una sub-cadena, $A\,a$ o $c\,B$, y un sub-ángulo, $V\,A\,a$ o $V\,B\,c$ ($V\,B\,c = c\,A\,B$), en uno o en ambos extremos de la curva. Vease ¶ ¶ 44, etc.

## GEOMETRÍA

### Principios de frecuente aplicación.

**25.** Fig. 7. **Triángulos semejantes, y proporción entre cuerdas de segmentos.** Sea $O\ V$ un diámetro del círculo, $A\ V\ B\ O$; sea $A\ B\ (=C)$ una cuerda perpendicular a $O\ V$, dividida en $H$ en dos partes iguales; sea $O\ A$, $A\ V$ cuerdas en el semicírculo, $O\ A\ V$; y $O\ B$, $B\ V$, cuerdas en el semicírculo, $O\ B\ V$; sea $A\ V\ (=V\ B)$ = semitangente, $T$; y $O\ A\ (=O\ B)$ = radio, $R$, de la curva, $A\ P\ B$.

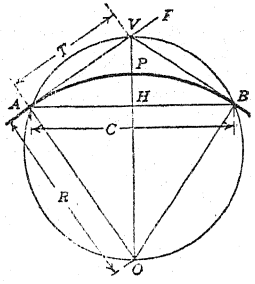

**Fig. 7.**

Entonces los 3 triángulos rectángulos, $O\ H\ A$, $A\ H\ V$ y $O\ A\ V$ son semejantes; como son tambien $O\ H\ B$, $B\ H\ V$ y $O\ B\ V$; ángulo, $O\ A\ V\ (=O\ B\ V)$, entre $R$ y $T$, $= 90°$; $A\ H = H\ B = C/2$; y

De los triángulos semejantes. Tenemos.

$O\ H\ B$, $B\ H\ V$; $O\ H : H\ B = H\ B : H\ V$;

$O\ H \times H\ V = (C/2)^2$; o bien $H\ V = (C/2)^2 \div O\ H$..... (1)

$O\ B\ V$, $B\ H\ V$; $O\ V : V\ B = V\ B : H\ V$;

$O\ V \times H\ V = T^2$; o bien $H\ V = T^2/O\ V$..... (2)

$O\ B\ V$, $O\ H\ B$; $O\ V : O\ B = O\ B : O\ H$;

$O\ V \times O\ H = R^2$; o bien $O\ H = R^2/O\ V$..... (3)

**26.** Fig. 8. **Ángulos entre dos cuerdas, entre dos tangentes, y entre una cuerda y una tangente. Valores de $\Delta/2$.**

Sea $A\ P\ B$ el arco, y $A\ B$ la cuerda que subtende el ángulo central, $A\ O\ B = \Delta = F\ V\ B = A\ O\ d + d\ O\ B = A\ O\ e + e\ O\ B$.

Entonces:

$\Delta/2$ = ángulo entre la tang, $A\ V$, en $A$ (o tang $V\ B$, en $B$) y la cuerda $A\ B$.

= ángulo externo entre dos cuerdas cualquiera, como $A\ d$ y $d\ B$, o $A\ e$ y $e\ B$, trazadas de $A$ y de $B$ respectivamente.

$= (A\ O\ d + d\ O\ B)/2 = (A\ O\ e + e\ O\ B)/2$.

= el ángulo periférico, $A\ E\ B = V\ A\ B = V\ B\ A$, subtendido por la cuerda, $A\ B$..... (4)

**27. Los ángulos pequeños** (tales como las deflexiones usuales en trabajos de ferrocarriles de vapor), son **aproximadamente proporcionales a sus senos**, y un poco menos, proporcionales a sus tangentes. Esto puede aprovecharse para facilitar muchos cálculos.

Asi, para cualquier ángulo pequeño, $A$, tenemos,
aprox : sen 0° 1′ : sen $A$ = 1 minuto : $A$, en minutos; o

$$A \text{ minutos} = \text{sen } A \div \text{sen } 0^\circ\, 1' = 3437 \text{ sen } A\,;$$
$$\text{sen } A = A \text{ minuto} \times \text{sen } 0^\circ\, 1' = 0.0002909\ A \text{ minutos} \ldots\ldots\ldots\ldots \quad (5)$$

De modo análogo (aprox) tan $A$ = $A$ minutos × tang 0° 1′ = 0.0002909 $A$ minutos.

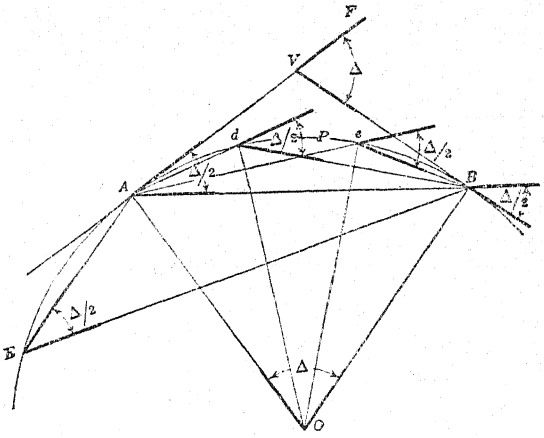

**Fig. 8.**

**Ejemplo.** Con cadena de 100 piés; donde el radio, $R$, = 1300 pies; averiguar la agudeza $D$ de la curva. Aqui, sen $(D/2)$ = 50/1300; y $D$ = 4° 24′ 30.44″.

Aprox, $D/2$ en minutos

$$= \text{sen } (D/2) \div \text{sen } 0^\circ\, 1'.$$

$$= \frac{50}{1300} \times \frac{1}{\text{sen } 0^\circ\, 1'} = 132.221.$$

Como, $D$ aprox = 264.442 minutos = $D$ − 0.065 minutos = 0.99975 $D$.

Reciprocamente; dando $D$ = 4° 24′, averiguar el radio, $R$. Aqui

$$R = \frac{50}{\text{sen } (D/2)} = 1302.497 \text{ piés}$$

$$R \text{ aprox} = \frac{50}{(D/2) \text{ en minutos} \times \text{sen } 0^\circ\, 1'}$$

$$= 1302.177 \text{ piés} = 0.99975\ R$$

Estas operaciones son convenientemente ejecutadas con la **regla de calcular**, pag. 78, etc.

**Errores de Aproximación.**

Sea $A$ en minutos; y sea

$$S = \frac{A \text{ sen } 0^\circ\,1'}{\text{sen } A}; \qquad T = \frac{A \tan 0^\circ\,1'.}{\tan A} \text{ Entonces : —}$$

| para $A$ = | $S$ = | $T$ = | para $A$ = | $S$ = | $T$ = |
|---|---|---|---|---|---|
| 0° 30′ | 1.000013 | 0.999995 | 6° 0′ | 1.001830 | 0.996342 |
| 1° 0′ | 1.000051 | 0.999898 | 7° 0′ | 1.002492 | 0.995020 |

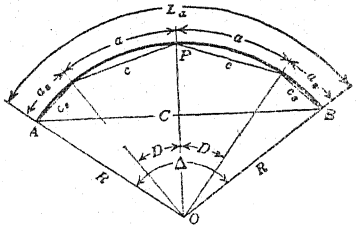

Fig. 9.

**28. Relaciones entre Δ, D, n, R, $L_a$ y $L_c$.** Fig. 9.

En cualquier curva circular, sea

$R$ = radio; $\pi = \frac{\text{circunf}}{\text{diam}}$; Δ = desarrollo; $C$ = cuerda larga;

$L_a$ = curva larga $A\ P\ B$, medida en el arco. Entonces : —

$\pi R$ = semi-circunf (subtendiendo 180°);

$\frac{\pi R}{180}$ = arco de 1°; y (Δ en *grados*)

$$L_a = \Delta \frac{\pi R}{180}; \Delta = \frac{180\ L_a}{\pi R}; \text{ y } R = \frac{180\ L_a}{\pi\ \Delta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ (6)$$

Sea $c$ = largo cadena, en piés; $a$ = arco unidad, en piés; $n$ = número de cadenas, $c$, o de arcos de unidad, $a$, en la curva*; $D$ = agudeza; $L_c$ = largo de curva, $A\ P\ B$, medido en cadenas, = suma de largos de cadenas, $L_a$ = largo verdadero de la curva. Entonces : —

* Usualmente $n$ es un número mixto. Así con dos cadenas de 100 piés cada una y subcadenas de 33,6 piés 21,8 piés respectivamente, tenemos $n = 2 + 0{,}336 + 0{,}218 = 2{,}554$.

| Con cadena *completa*, ¶ 18 | Con cadena *disminuida*, ¶ 20 |
|---|---|
| $\text{sen}\,\frac{D}{2} = \frac{c/2}{R}$ ..... (7) | $D^\circ = \frac{180\,a}{\pi\,R}$ ..... (11) |
| $\Delta = n\,D$ ..... (8) | $\Delta = n\,D$..... (12) |
| $R = \frac{c/2}{\text{sen}\,(D/2)}$ | $R = \frac{180\,L_l}{\pi\,\Delta^\circ} = \frac{180\,c}{\pi\,D^\circ}$ ..... (13) |
| $= \frac{c}{2\,\text{sen}\,(D/2)}$ ..... (9) | |
| $L_c = n\,c$; | $L_a = n\,a$; |
| $n = L_c/c = \Delta/D$..... (10) | $n = L_a/a = \Delta/D$..... (14) |

**29. Por lo tanto, para el radio,** $R_f$, en piés, o $R_m$, en metros, tenemos: —

## Ecuaciones generales de Curvas.

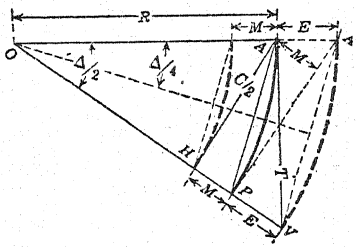
Para símbolos, vea ¶ ¶ 3 y 9, pags 951, 952.

**30.** Fig. 10. Para evitar repeticiones indebidas, toda ecuacion aqui se considera frecuentemente que sirve por trasposición y substitución, para todos los elementos que entran en ella y, aun para otros. Asi, de

$M = R$ senoverso $(\Delta/2)$; tenemos, tambien: —

$R = M/\text{senoverso}\ (\Delta/2)$; senoverso $\frac{\Delta}{2} = \frac{M}{R} = \frac{E \cos (\Delta/2)}{T \cot (\Delta/2)}$;

etc., etc. Vease ¶ 69.



$\frac{\Delta}{2} = H\ A\ V$; $\frac{\Delta}{4} = H\ A\ P = P\ A\ V = A\ V\ A'$.

**Fig. 10.**

## Funciones Angulares.

**31.** Fig. 10. **Funciones de** $\Delta/2$.

$$\text{Sen}\ \frac{\Delta}{2} = \frac{C}{2\,R} = \frac{T}{R+E} = \frac{E+M}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (17)$$

$$\text{Cos}\ \frac{\Delta}{2} = \frac{R-M}{R} = \frac{M}{E} = \frac{R}{R+E} = \frac{T^2-E^2}{T^2+E^2} = \frac{C^2-4\,M^2}{C^2+4\,M^2} \quad \ldots\ldots \quad (18)$$

$$\text{Tan}\ \frac{\Delta}{2} = \frac{T}{R} = \frac{E+M}{C/2} = \frac{C/2}{R-M} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (19)$$

$$\text{Senoverso}\ \frac{\Delta}{2} = 1 - \cos\frac{\Delta}{2} = \frac{M}{R} = \frac{E}{R+E}$$

$$= \text{sen}\ \frac{\Delta}{2} \times \tan\frac{\Delta}{4} = 2\,\text{sen}^2\,\frac{\Delta}{4} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (20)$$

$$\text{Exsec}\ \frac{\Delta}{2} = \frac{E}{R} = \frac{E-M}{M}; \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (21)$$

**32.** Fig. 10. **Funciones de $\Delta/4$.**

$$\text{Sen } \frac{\Delta}{4} = \frac{P\,H}{A\,P} = \frac{M}{\sqrt{M^2 + (C/2)^2}} = \frac{\sqrt{M^2 + (C/2)^2}}{2\,R};$$

$$\text{Sen}^2 \frac{\Delta}{4} = \frac{A\,P}{2\,R} \cdot \frac{P\,H}{A\,P} = \frac{M}{2\,R} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (22)$$

$$\text{Tan } \frac{\Delta}{4} = \frac{E}{T} = \frac{2\,M}{C} = \sqrt{\frac{2\,T - C}{2\,T + C}} = \sqrt{\frac{E - M}{E + M}} = \frac{\text{senoverso } (\Delta/2)}{\text{sen } (\Delta/2)}$$

que puede demostrarse ser

$$= \frac{T}{2\,R + E} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (23)$$

**Funciones lineales.**

**33. Fig. 10. Relaciones entre R, E y M.**

$$R + E = \sqrt{T^2 + R^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (24)$$

$$R - M = \sqrt{R^2 - (C/2)^2} = \sqrt{(R + C/2)\,(R - C/2)} \quad \ldots\ldots\ldots\ldots \quad (25)$$

$$E + M = \sqrt{T^2 - (C/2)^2} = \sqrt{(T + C/2)\,(T - C/2)} \quad \ldots\ldots\ldots\ldots \quad (26)$$

**34. Fig. 11. Ecuaciones para R, C, T, E, Y, B F, M y M*h*.**

**D = agudeza,** *en grados* a menos que no se indique otra cosa.

$$R = \frac{T}{\tan (\Delta/2)} = \frac{C}{2 \text{ sen } (\Delta/2)} = \frac{M}{\text{senoverso } (\Delta/2)} = \frac{E}{\text{exsec } (\Delta/2)}$$

$$= \frac{T^2 - E^2}{2\,E} = \frac{(C/2)^2 + M^2}{2\,M} = \frac{E\,M}{E - M};$$

$$= \text{aprox } R_1/D = (R \text{ para una curva de } 1^\circ)/D = \text{aprox } 5729{,}65 \text{ piés}/D$$

$$= \text{aprox } C^2/8\,M \text{ (vease tabla, p. 969)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (27)$$

$$C = 2\,R \text{ sen } (\Delta/2) = 2\,T \cos (\Delta/2)$$

$$= 2\,M \cot (\Delta/4) = 2\sqrt{M\,(2\,R - M)}$$

$$= 100\,\frac{\text{sen } (n\,D/2)\,*}{\text{sen } (D/2)}$$

$$= 2E\,\frac{\text{sen } (\Delta/2)}{\text{exsec } (\Delta/2)} = \text{aprox } \sqrt{8\,R\,M}. \text{ (Véase tabla, pag. 969.)} \quad \ldots\ldots \quad (28)$$

$$T = R \tan (\Delta/2) = \frac{C}{2 \cos (\Delta/2)}$$

$$= M\,\frac{\tan (\Delta/2)}{\text{senoverso } (\Delta/2)} = E \cot (\Delta/4)$$

$$= (R + E) \text{ sen } (\Delta/2) = \sqrt{E\,(2\,R + E)}$$

$$= \sqrt{(C/2)^2 + (M + E)^2} = \frac{M + E}{\text{sen } (\Delta/2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (29)$$

* $n$ = número de cadenas en la curva.

$$E = R \text{ exsec } (\Delta/2) = T \tan (\Delta/4) = M \sec (\Delta/2)$$

$$= R \tan (\Delta/2) \tan (\Delta/4) = C \frac{\text{exsec } (\Delta/2)}{2 \text{ sen } (\Delta/2)} = \frac{R\ M}{R - M}$$

= aprox $M$ (vease tabla, p. 969) ..... (30)

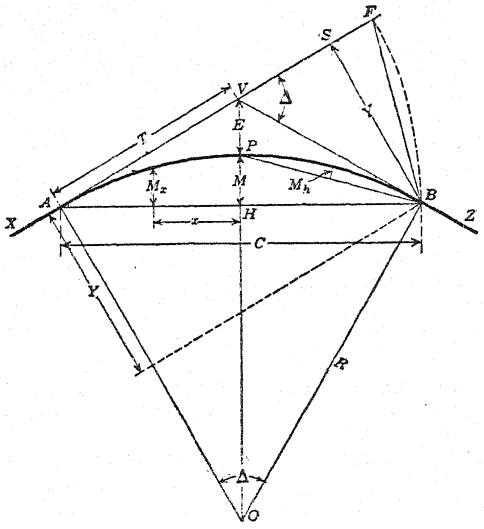


**Fig. 11.**

$$Y = R \text{ senoverso } \Delta = C \text{ sen } (\Delta/2)$$

$$= 2\ R \text{ sen}^2 (\Delta/2) = C^2/2\ R = T \text{ sen } \Delta$$

$$= \text{aprox (vease tabla, siguiente) } 4\ M = \frac{7}{8} n^2 D^{o}{}^{*} \text{ ..... (31)}$$

$$B\ F = 2\ C \text{ sen } (\Delta/4) \text{ ..... (31 } a\text{)}$$

$$M = R \text{ senoverso } (\Delta/2) = 2\ R \text{ sen}^2 (\Delta/4) = \frac{P}{2} \frac{B^2}{R} = T \frac{\text{senoverso } (\Delta/2)}{\tan (\Delta/2)}$$

$$= (C/2) \tan (\Delta/4) = E \cos (\Delta/2) = R\ E/(R + E)$$

$$= R - \sqrt{R^2 - (C/2)^2} = R - \sqrt{(R + C/2)\ (R - C/2)}$$

$$= R \text{ sen } (\Delta/2) \times \tan (\Delta/4);$$

$$= \text{aprox (vease tabla, p. 969) } 4\ M_h = Y/4 = B\ F/4$$

$$= \frac{M + E}{2} = E = \frac{C^2}{8\ R} = \frac{7}{32} n^2 D^{o}{}^{*} \text{ ..... (32)}$$

$$M_h = R \text{ senoverso } (\Delta/4) = M \frac{1 - \cos(\Delta/4)}{1 - \cos(\Delta/2)} = M \frac{\text{sen}^2(\Delta/8)}{\text{sen}^2(\Delta/4)}$$

$$= \text{aprox } \frac{M}{4} \text{ (vease la tabla abajo)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (33)$$

**Para la ordenada lateral,** $M_x$, vease ¶ 35.

**Multiplicadores para convertir** valores aproximados de las Ecuaciones arriba expresadas en **Valores Correctos.** La siguiente tabla de multiplicadores indican los grados de aproximacion de varias ecuaciones nuestras aproximadas en el ¶ 34, y nos permite obtener valores correctos de ellas.

**Ejemplo.** Dando $\Delta = 30°$; encontrar la ordenada media, $M$, para toda la curva. Aqui la ecuacion (32) da, aprox $M = B\ F/4$; pero, en la siguiente tabla, en la linea que empieza «(32) $M = B\ F/4$», y en la columna encabezada «$\Delta = 30°$», encontramos el multiplicador, 1.0088, que da el valor verdadero $M = 1.0088 \times B\ F/4 = 0.2522\ B\ F$.

(Vease *N. del T.* ¶ 11, pag. 926.)

**35. Ordenada lateral, $M_x$. Fig. 12.**

$$M_x = \sqrt{R^2 - x^2} + M - R = \sqrt{R^2 - x^2} - R\ \cos\ (\Delta/2) \quad \ldots\ldots\ldots \quad (34)$$

$$= \text{aprox}\ a\ b/2\ R\ \text{(vease la tabla, a continuacion)} \quad \ldots\ldots\ldots \quad (35)$$

donde *a* y *b* son los dos segmentos de la cuerda *C*,

$$= \text{aprox}\ 4\ M\ a\ b/C^2\ \text{(vease la tabla a continuacion)} \quad \ldots\ldots\ldots \quad (36)$$

Cuando $C = 100$ pies ( $= c$ ; $\Delta = D$), ec (36) se convierte :

$$m_x = \text{aprox}\ \frac{m\ a\ b}{2500} = \text{aprox}\ \frac{m}{0{,}25} \cdot \frac{a}{100} \cdot \frac{b}{100} \quad \ldots\ldots\ldots \quad (37)$$

o, como en el caso, $B\ F$ ( = « dist tangencial ») = 200 sen $(D/4)$ = aprox 4 *m*, tenemos, para cualquier curva y para cualquier valor de *C* :

$$M_x = \text{aprox}\ B\ F \cdot \frac{a}{100} \cdot \frac{b}{100} = \frac{B\ F \cdot a \cdot b}{10{,}000} \quad \ldots\ldots\ldots \quad (38)$$

Vease la tabla pag 969, usando coeficientes para $R = C^2/8\ M$. Asi, para $\Delta = 60°$,

$$M_x = 1{,}0718\ B\ F\ .\ a\ .\ b/10{,}000.$$

$$M_x = \text{aprox}\ D \times M_1\ \text{(vease la tabla que sigue)} \quad \ldots\ldots\ldots \quad (39)$$

donde *D* = la agudeza de la curva dada, y $M_1$ = el lado de la cuerda para una curva de 1°, a la dist dada, *x*, desde su media ordenada, *M*, en una cuerda igual, *C*.

**Coeficientes para las ecuaciones** aproximadas **anteriores** para ordenadas laterales, $M_x$.

La siguiente tabla de multiplicadores indica el grado de aproximación de varias de nuestras ecuaciones en el ¶ 35, y nos permite obtener valores correctos de ellas.

**Ejemplo.** Dando $\Delta = 20°$, y $x/C = {}^1/_4$; encontrar la ordenada, $M_x$, dist $x$ de la ordenada, media, $M$. Aquí la ecuacion (35) da, aprox, $M_x = a\ b/2\ R$; pero en la tabla siguiente, en la linea que empieza « (35) $M_x = a\ b/2\ R$ », y en la columna encabezada « $\Delta = 20°$, $x/C = {}^1/_4$ » encontramos el múltiplo correcto, 1.0096, que da el verdadero valor, $M_x = 1.0096\ a\ b/2\ R = 0.5048\ a\ b/R$.

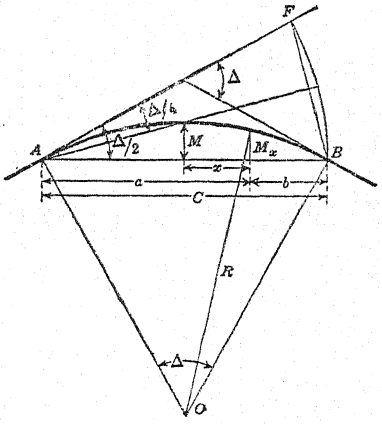

**Fig. 12.**

| Ec. No. | Ecuacion. | $\Delta = 10°$ $x/C =$ | | | $\Delta = 20°$ $x/C =$ | | |
|---|---|---|---|---|---|---|---|
| | | 1/4 | 3/8 | 19/40 | 1/4 | 3/8 | 19/40 |
| (35) | $M_x = ab/2R$ | 1.0024 | 1.0028 | 1.0024 | 1.0096 | 1.0128 | 1.0094 |
| (36) | $M_x = 4Mab/C^2$ | | | | | | |
| (37) | $m^x = mab/2500$ | 1.0005 | 1.0011 | 1.0012 | 1.0019 | 1.0051 | 1.0076 |
| (39) | $M_x = D \times M_1$ | 0.9995 | 1.0003 | 0.9965 | 1.0036 | 1.0064 | 1.0053 |

**36.** Para esa porción de una curva que está subtendida por una **cadena, c, o unidad de arco, a** (extensión, $\Delta$, = agudeza, $D$), úsense las ecuaciones del ¶ ¶ 34, 35.

Substituyendo..... $D$, $t$, $c$, $m$, $m_x$, $e$, y $y$ $m_h$.

Para..... $\Delta$, $T$, $C$, $M$, $M_x$, $E$, $Y$ y $M_h$ respectivamente.

(Vease *N. del T.* ¶ 11, pag 926.)

**Ordenadas Medias, m, en pies,** para cadenas de 100 pies, para diferentes agudezas, *D*.

**Ordenadas laterales, $m_x$, en pies separadas 5 pies**, para cadena de 100 pies.

$m_x = \sqrt{I.^2 - x^2} - R \cos (D/2)$;

$x$ = d'st, en pies, de la orde. ada lateral a la ordenada media.

(Vease *N. del T.* ¶ 11, pag 926.)

**37. Relacion, Q, del arco a la cuerda.** Fig. 9. En cualquiera curva circular de radio $R$, y desarrollo $\Delta$, tenemos (vease ¶ 28) : —

$$\text{Ec (6) longitud, } L_l, \text{ del arco} = \frac{\pi R}{180} \cdot \Delta^{\circ}; \text{ y}$$

$$\text{Ec (28) cuerda larga, } C, = 2\ R \text{ sen } (\Delta/2).$$

Por lo tanto, para la relacion, $Q$, entre el arco, $L_l$, y la cuerda, $C$, tenemos : —

$$Q = \frac{L_l}{C} = \frac{\pi}{360} \cdot \frac{\Delta^{\circ}}{\text{sen } (\Delta/2)}; \quad \ldots\ldots\ldots\

**39.** Aproximadamente : —

$$C = L_1\left(1 - \frac{L_1^2}{24\,R^2}\right);\ \text{y}\ c = a\left(1 - \frac{a^2}{24\,R^2}\right) \ldots\ (42)$$

(Vease Rankine-Civil, Engng, p. 104.) Cuando $\Delta = 50°$ da para $C$, solo 0.031 por ciento muy corto.

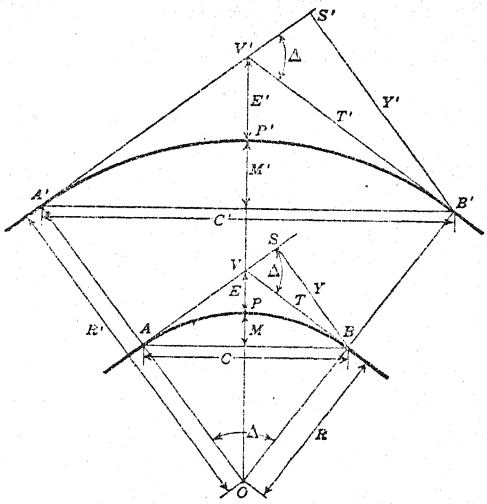

Fig. 13.

## Comparaciones de curvas.

**40.** Fig. 13. Comparación entre dos curvas de un desarrollo **dado**, $\Delta$. Relación entre las **funciones lineales** correspondientes. Sea $F$ una funcion lineal (como el radio, $R$, el arco, $A\ B$ ($A$), la semitangente, $T$, etc.) de una de las dos curvas dadas de igual desarrollo, $\Delta$, pero de diferentes agudezas, $D$, y sea $F'$ la correspondiente función, (como $R'$, $A'\ B'$ ($A'$), $T'$ etc.) de la otra curva. Entónces, de la semejanza de los triangulos, tenemos : —

$$F/F' = R/R' = C/C' = A/A' = T/T',\ \text{etc.};$$

ó bien $F' = FR'/R = FC'/C$, etc.;

$$F = F'R/R' = F'C/C',\ \text{etc} \ldots\ (43)$$

Asi, sea $C$ una unidad de cadena de 100 pies, y sea $C' = 200$ pies. Entonces, por ejemplo, $M' = MC'/C = 2\,M$; $R' = 2\,R$; etc.;

$$\frac{\text{sen}\,(D'/2)}{\text{sen}\,(D/2)} = \frac{50}{R'}\,.\,\frac{R}{50} = \frac{R}{R'}\,.$$

Nótese que, con un desarrollo dado, $\Delta$, la curva mas aguda tiene las funciones lineales mas cortas. Compárese ¶ 43.

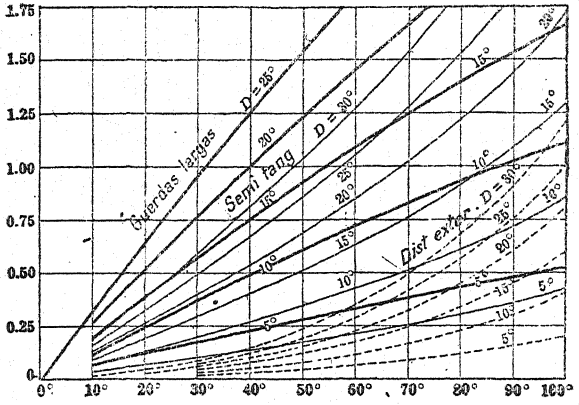
(*Vease N. del T.* — ¶ 11. — pag 926.)

## Funciones de una Curva de 1°.

**40a.** Figs 1 y 11. Tabla de Funciones, $F_1$ (semi tangentes, $T_1$; Distancias Externas $E_1$; y Cuerdas Largas, $C_1$); de una curva de 1° para diferentes desarrollos $\Delta$.
$T_1 = R_1 \tan (\Delta/2)$; $E_1 = R_1 \operatorname{exsec} (\Delta/2)$; $C_1 = 2\, R_1 \operatorname{sen} (\Delta/2)$.

**Para la funcion correspondiente**, $F$ ($T$, $E$ ó $C$) de una curva de **cualquiera otra agudeza**, $D°$, tenemos aproximadamente.

$$F = F_1/D°.$$



### Diagrama de Correcciones.

**Correcciones**, en pies, para ser sumadas a funciones de curvas aproximadas, $F$ (semitangente, $T$; Distancia Externa, $E$; y cuerda Larga, $C$) para una curva de $D°$; como se encuentra dividiendo la correspondiente función de la curva de 1°, $F_1$, de la Tabla, pags 981, etc, por $D$ en grados.

Las curvas continuas finas dan valores para sumarse a las semitangentes, $T$;
Las curvas de puntos finas dan valores para sumarse a las dist. externas, $E$;
Las curvas llenas gruesas dan valores para añadirse a las cuerdas largas $C$.

**41. Medidas Inglesas y Métricas.** Fig. 13. Comparación entre las curvas en sistema inglés y métrico (u otras medidas). Sea, otra vez

$C = c$ = una cadena de $n$ metros ($\Delta = D$).

$C' = c' =$ — — de 100 pies (30.48 m) ($\Delta = D'$).

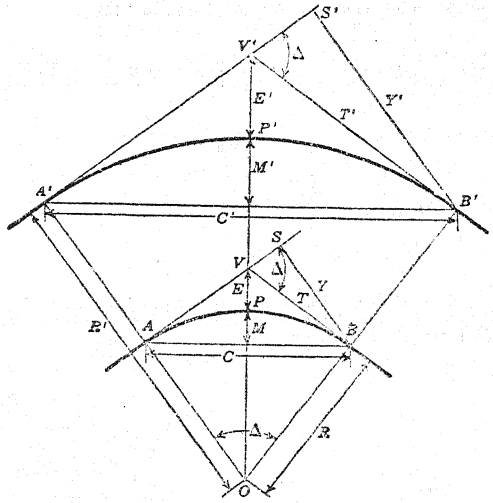

**Fig. 13. (Repetida).**

Entonces las dos curvas, en Fig. 13, aunque de diferente agudeza, son *citadas* por el mismo numero de grados; porque, en cada una, la cadena adoptada subtiende el mismo ángulo, $D = D'$.

Por ejemplo, de la ecuacion (43), tenemos : —

$$\frac{\text{R metros}}{R' \text{ pies}} = \frac{c \text{ metros}}{c' \text{ pies}} = \frac{n}{100} ; y$$

$$R \text{ metros} = R' \text{ pies} \frac{c \text{ metros}}{c' \text{ pies}} = R' \text{ pies } n/100. \text{ O, en general : —}$$

$$F = F' \; c/c' = 0.01 \; n \; F' \ldots\ldots\ldots\

Entonces, donde se use la cadena « *disminuida* » (¶ 20), tenemos ($D$ en grados).

$$D = F_1/F\,d;\ F\,d = F_1/D;\ F_1 = D\,F\,d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (45)$$

Pero, donde se use la cadena completa, estas ecuaciones son solamente aproximadas. Para la relacion, $q$, entre el verdadero valor, $F\,d$, y el valor aproximado, $F_1/D$, tenemos; $R_1 = 50/\text{sen } 0°30' = 5729.65$; $\log R_1 = 3.758\,1281$.

$$q\left(=\frac{F\,d}{F_1/D}=\frac{R\,d}{R_1/D}\right)=\frac{50}{\text{sen }(D/2)}\cdot\frac{D\text{ sen }0°30'}{50}=D\,\frac{\text{sen }0°30'}{\text{sen }(D/2)} \quad \ldots\ldots \quad (46)$$

y, como (ecua 41, ¶ 38) $Q = \frac{a}{c} = \frac{\pi}{360}\times\frac{D}{\text{sen }(D/2)}$; tenemos : —

$$\frac{Q}{q}=\frac{\pi}{360}\cdot\frac{D}{\text{sen }(D/2)}\cdot\frac{\text{sen }(D/2)}{D\text{ sen }0°30'}=\frac{\pi}{360}\cdot\frac{1}{\text{sen }0°30'}=1.000\,013\ldots\ldots \quad (47)$$

$$\text{Log }(Q/q)=0.000\,0055.$$

En otras palabras, el valor de $Q$ (= arco/cuerda), en la tabla, ¶ 37, para cualquier valor dado de $\Delta$, puede tomarse practicamente identico al valor de $q$ [$= F\,d/(F_1/D)$], para el mismo valor de $D$.

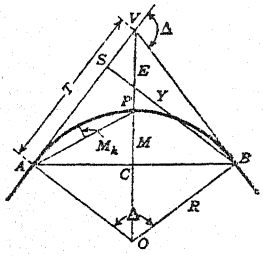

**Fig. 14a.**

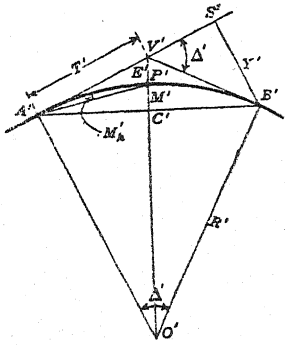

**Fig. 14b.**

*43.* Figs 14*a*, 14*b*. Entre dos curvas de **igual largo**, $L_C$ o $L_c$, la mas aguda (Fig. 14*a*) tiene por supuesto, el radio mas corto, $R$; pero tiene un ángulo, mayor, $\Delta$, y *mayores* valores para $T$, $M$, $E$, $M_h$ y $Y$. (Comparese ¶ 40.) Estos valores pueden encontrase por medio de las ecuaciones pag 967 ¶ 34.

*44.* Fig. 15. **Sub-cadenas**, $c_s$, $c_i$, $c_f$*. Vease ¶ 24. Supongamos que la curva empiece en $A$, $w$ pies despues de $y$, y que termine en $B$.

---

* Donde es necesario distinguir entre la inicial y la sub-cadena final, usamos los índices, $i$ y $f$, respectivamente. De otro modo, usamos el índice, $s$.

**Si a b = una cadena disminuida** = casi de 100 pies, y *a m b* = una unidad de arco = 100 pies (vease ¶ 20), tenemos : —

Sub-arco inicial, $A\ a = 100 - w$ ;

Sub-angulo inicial, $d_i = D\ \frac{100 - w}{100}$ ;

Sub-cadena inicial, $c_i = A\ a = 2\ R \operatorname{sen}(d_i/2) = c\ \frac{\operatorname{sen}(d_i/2)}{\operatorname{sen}(D/2)}$ ..... (48)

Habiendo determinado $b$, tenemos : —

Sub-angulo final, $d_f = b\ O\ B = 2\ b\ A\ B$ ;

Sub-arco final, $b\ B = 100\ \frac{d_f}{D}$ ;

Sub-cadena final, $c_f = b\ B = 2\ R \operatorname{sen}(d_f/2) = c\ \frac{\operatorname{sen}(d_f/2)}{\operatorname{sen}(D/2)}$ ;

$x = B\ z = 100 -$ (sub-arco final, $b\ B$) ..... (49)

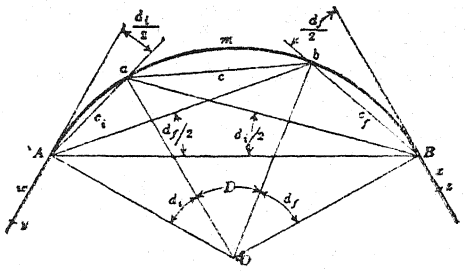

**Fig. 15.**

**45.** Fig. 15. **Con la cadena completa** ($c = a\ b = 100$ pies; unidad de arco, $a = a\ m\ b$, $> 100$ pies) tenemos : —

Sub-cadena inicial, $c_i = A\ a = 100$ pies $- w$ ;

Para sub-angulo inicial;

$$\operatorname{sen}\frac{d_i}{2} = \frac{c_i}{2\ R} = c_i\ \frac{\operatorname{sen}(D/2)}{100} \quad \ldots\ldots\ldots\ldots\ldots \quad (50)$$

Habiendo determinado $b$, tenemos, como antes : —

Sub-angulo final, $d_f = b\ O\ B = 2\ b\ A\ B$ ; y

Sub-cadena final, $c_f = b\ B = 2\ R \operatorname{sen}(d_f/2) = 100\ \frac{\operatorname{sen}(d_f/2)}{\operatorname{sen}(D/2)}$ ;

Pero $x = B_z = 100$ pies $-$ sub-*cadena* final, $c_f$ ..... (51)

**46.** Fig. 15. **Valores « nominales » o aproximados** de $c_s$ * y de $d$. **Con unidad de cadena completa o disminuida**, sea :

$c_s$ = el *verdadero* valor de cualquiera de las dos sub-cadenas, como se encuentra arriba;

$d$ = al *verdadero* valor del sub-angulo correspondiente;

$c$ = la cadena usada completa o disminuida, como sea el caso;

$c_n = c\ d/D$ = el valor aprox o « nominal » de $c_s$ ;

$d_n = D\ c_s/c$ = el valor aprox o « nominal » de $d$.

---

* Donde es necesario distinguir entre la sub-cadena inicial y final, usamos los índices, *i* y *f* respectivamente. De otro modo, usamos el índice, *s*.

Entonces:

$$c_s > c_n\,;\; d_n > d\,;\; \frac{c_s}{c_n} = \frac{d_n}{d} \qquad (52)$$

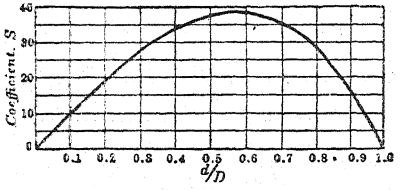
y, para la cadena de 100 pies o unidad de arco de 100 pies, aprox,

$$c_s - c_n = S\,(Q - 1) \qquad (53)$$

Donde $Q$ = valor del $\frac{\text{arco}}{\text{cuerda}}$ (tabla, ¶ 37) para el valor dado de $D$,

y $S$ = un coeficiente dado por la Fig. 16, abajo.

**Fig. 16.**



Coeficiente, $S$, para deducir el verdadero valor de $c_s$, de la sub-cadena, de su valor « nominal », $c_n = cd/D$.

**47.** Para cualquier valor, $c$, de la cadena, o unidad de arco distinto de la de 100 pies, tenemos: —

$$c_s - c_n = S\,(Q - 1)\,c/100 \qquad (54)$$

**48.** Del ¶ 27, tenemos, aprox: —

Sen 0°1′ : sen $(d/2)$ = 1 min : $d/2$ en min o bien $d/2$ en min = sen $(d/2) \div$ 0.000 2909 = 3437 $\frac{\text{sub-cadena.}}{2R}$ ..... (55)

**49.** Si, en una curva circular dada, la cadena completa y la sub-cadena se dividen en el mismo numero de partes iguales, sus ordenadas estan aproximadamente como los cuadrados de los largos de cadena.

## CURVAS COMPUESTAS

Comparense las Curvas Invertidas, ¶ ¶ 70, etc.

### Definiciones.

**50.** Figs 17, 18. Curvas compuestas. Cuando dos curvas consecutivas, $A\ P$ y $P\ B$, de radios desiguales, $R_g$ y $R_s$, se encurvan en la misma direccion (ambas a la derecha o a la izquierda), se dice que estan compuestas o combinadas, y la curva entera, $A\ P\ B$, se llama curva compuesta.

**51. Ramas.** Las dos porciones, $A\ P$ y $P\ B$, de la curva compuesta, se llaman sus ramas. Ellas caen sobre el mismo lado de la tangente comun, $v_g\ v_s$. Su punto de encuentro, $P$, o punto de tangencia comun, es el punto « C. C. » de cambio de *curva* a *curva*. Tambien se llama el punto « P. C. C. » compuesto de curvatura. Vease ¶ 2.

**52. Radios.** Los centros, $O_g$ y $O_s$ de las dos ramas, estan necesariamente en linea recta con el punto compuesto de curvatura $(P)$: *i. e.*, los dos radios son normales a la tang comun $V_g\ V_s$, en $P$ coincide en $O_s\ P$. En $A$ y en $B$ el radio es normal respectivamente a las semitangentes, $A\ V$, $V\ B$, de la curva entera.

**53. El vertice, V**, de la curva entera compuesta, no se encuentra (como está en la Fig. 17) generalmente en $O_g\ P$ prolongada. Vease ¶ ¶ 57 y 146.

**54. Indices.** $R_g$ es el radio *mayor;* y el desarrollo de su curva, semitangente, etc., correspondientes estan designadas con $\Delta_g$ (o simplemente $g$), $T_g$, etc., respectivamente; y del mismo modo para los *radios* mas cortos, $R_s$, con $\Delta_s$ (o solo $s$) semitangente, $T_s$, etc., etc.

**55. Las semitangentes** de la curva entera, $A\ P\ B$, son $T_g$ y $T_s$; respectivamente perpendiculares, en $A$ y en $B$, o *vice versa*, al radio, $R_g$ y $R_s$. Las semitangentes de las dos ramas son respectivamente, $t_g = v_g\ P$, y $t_s = P\ v_s$.

**56.** Si (como es costumbre y como está en las figs 17, 18) $\Delta < 180°$, encontramos $T_g > T_s$; pero, cuando $\Delta > 180° < 360°$, $T_g < T_s$. Vease ¶ 69. Si $\Delta = 180°$, $T_g$ y $T_s$ son infinitas, y no hay vertice, $V$.

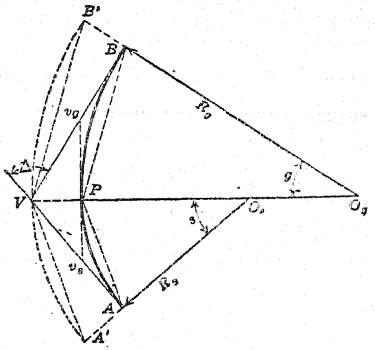


**Fig. 17.**

## Ecuaciones.

**57.** Fig. 17. En el **caso especial** en que el vertice, $V$, queda en la linea radial comun, $O_g\ P$, prolongada, como en fig. 17, tenemos :

$$V\ P = R_g \text{ exsec } g = R_s \text{ exsec } s.$$

Por tanto :

$$\frac{R_g}{R_s} = \frac{\text{exsec } s}{\text{exsec } g} = \frac{1 - \cos s}{\cos s} \cdot \frac{\cos g}{1 - \cos g} \quad \ldots\ldots\ldots \quad (56)$$

Y, en este caso especial, tenemos $s > g$, o el radio *mas corto*, $R_s$, corresponde la mayor *extension*, $s$, y *vice versa*.

Tambien en este caso, tenemos :

$$T_g = R_s \text{ tang } g\,; \qquad T_s = R_s \text{ tang } s\,;$$

$$T_g \text{ tang } (g/2) = T_g \text{ tang } V\ B\ P = T_g \text{ tang } B'\ V\ B$$
$$= B'\ B = V\ P = A'A$$
$$= T_s \text{ tang } (s/2); \text{ o}$$

$$\frac{T_g}{T_s} = \frac{\text{tang } (s/2)}{\text{tang } (g/2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (57)$$

**Desarrollos (ó amplitud ó ángulos del centro), etc.,** $\Delta_g$, $\Delta_s$, $\Delta$.

**58.** Figs 18. Los desarrollos, $\Delta_g$ (ó $g$) y $\Delta_s$ (o, $s$) de las dos ramas, pueden ser iguales o desiguales; y, en general cualquiera puede ser el mayor; pero véase el caso especial del ¶ 57.

Como ambas ramas se encurvan en la misma direccion (derecha o izquierda), tenemos, para, $\Delta$, de la curva entera compuesta, $A\ P\ B$ :

$$\Delta = g + s\,; \qquad g = \Delta - s\,; \qquad s = \Delta - g \ldots\ldots\ldots\ldots\ldots\ldots \quad (58)$$

Vease tambien ec (60).

| En la fig. 18 *a*. | En la fig. 18 *b*. |
|---|---|
| Trácese $Puw \perp O^s B$. Entonces sen $s$. | Tracese $Puw \perp O_g A$. Entonces sen $g$. |

$$= \frac{P\,w}{R_g} = \frac{P\,u}{R_s} = \frac{u\,w}{O_g\,O_s} = \frac{P\,w - P\,u}{R_g - R_s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (59)$$

**59. Angulos, A y B.** Sea $V\,A\,B = A$; $V\,B\,A = B$. Entonces:
$\Delta\ (= 180^o - A\ V\ B) = A + B$; $A = \Delta - B$; $B = \Delta - A$.. ... (60)
Vease tambien ec (58).

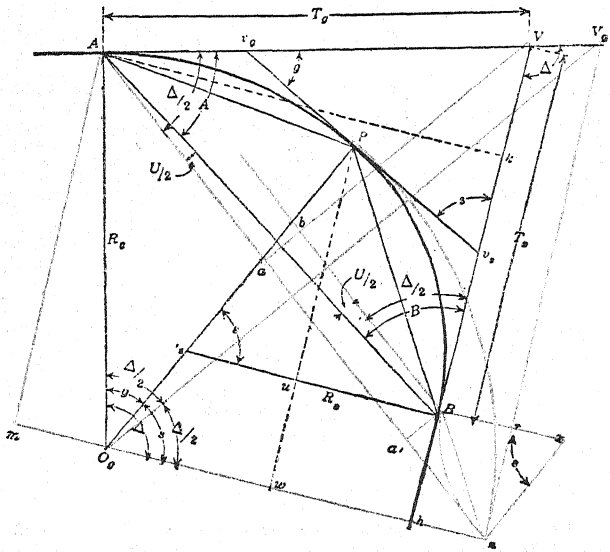

**Fig. 18 a.**

**60. Angulos V A P y V B P.**

$V\,A\,P = g/2$; $V\,B\,P = s/2$;
$V\,B\,P + V\,A\,P = s/2 + g/2 = (s + g)/2 = \Delta/2$
$V\,B\,P - V\,A\,P = s/2 - g/2 = (s - g)/2 = \Delta/2 - g$..... (61)

**61. Cuerda larga,** *C delta* = **A B.** Vease tambien ¶ 64.

| En fig. 18 *a*. | En fig. 18 *b*. |
|---|---|
| Trase $A\,k \perp B\,V$. Entonces: $A\ k = C$ *delta* sen $B = T_g$ sen $\Delta$. | Trácese $B\,k \perp A\,V$. Entonces: $B\ k = C$ *delta* sen $A = T_s$ sen $\Delta$. |

y $C$ *delta* $= T_g$ sen $\Delta$/sen $B = T_s$ sen $\Delta$/sen $A$..... (62)
Tambien vease ecs (69) y (67).

| Fig. 18 *a*. | Fig. 18 *b*. |
|---|---|
| **62.** Prolonguese la rama $A\ P$. hasta $n$, haciendo. $O_g n \parallel O_s B$. Entonces $P$, $B$ y $n$. | Prolonguese la rama $B\ P$. hasta $n$, haciendo. $O_s n \parallel O_g A$. Entonces $P$, $n$ y $A$. |

Estan en linea recta.

**Angulo, U/2.**

| | |
|---|---|
| Unase $A\ n$, y prolónguese $n\ V_g \parallel B\ V$. Trácese $B\ b \parallel A\ n$. Sea $B\ A\ n\ (= A\ B\ b) = U/2$. | Unase $B\ n$, prolónguese $n\ V_s \parallel A\ V$. Trácese $A\ a \parallel B\ n$. Sea $A\ B\ n\ (= B\ A\ a) = U/2$. |

Entonces..... $A = \Delta/2 - U/2 = (\Delta - U)/2$

$$B = \Delta/2 + U/2 = (\Delta + U)/2 \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (63)$$

Sumando, tenemos $A + B = \Delta$, como en ec (60);
Restando, tenemos:

$$B - A = U\ ;\ B = A + U\ ;\ A = B - U\ ;$$

$$U = \Delta - 2\ A = 2\ B - \Delta \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (64)$$

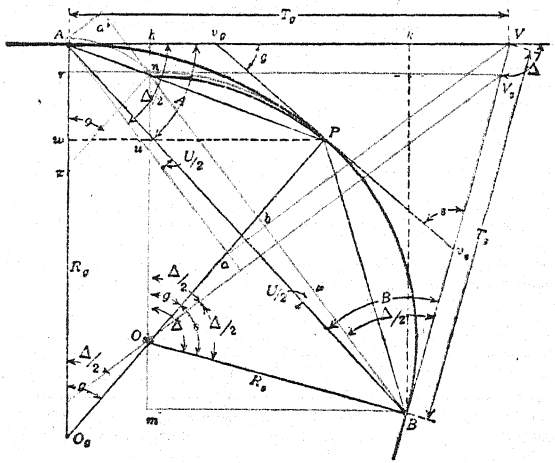

**Fig. 18 b.**

**63.** Entonces.

| En la Fig. 18 *a*. | En la Fig. 18 *b*. |
|---|---|
| $O_g\ V_g$, $\perp A\ n$, divide $A\ n$ en partes iguales; $A\ O_g\ n = \Delta$; y $A\ O_g\ V_g = V_g\ O_g\ n = \Delta/2$. | $O_s\ V_s$, $\perp B\ n$, divide $B\ n$ en partes iguales; $B\ O_s\ n = \Delta$; y $B\ O_s\ V_s = V_s\ O_s\ n = \Delta/2$..... (65) |

**64. Cuerda larga,** $Cdelta = \mathbf{A\,B}$. Vease tambien ¶ 61.

| Fig. 18 *a*. | Fig. 18 *b*. |
|---|---|
| Tracese $V\,a$ y $B\,a' \parallel O_g V_g \perp A\,n$.<br>Entonces $Cdelta$ sen $(U/2) = B\,a'$. | Tracese $V\,a$ y $A\,a' \parallel O_s\,V_s \perp B\,n$.<br>Entonces $Cdelta$ sen $(U/2) = A\,a'$. |

$$= V\,a - V\,b$$
$$= T_g \text{ sen } (\Delta/2) - T_s \text{ sen } (\Delta/2)$$
$$= (T_g - T_s) \text{ sen } (\Delta/2).$$

Por lo tanto:

$$Cdelta = (T_g - T_s)\,\frac{\text{sen } (\Delta/2)}{\text{sen } (U/2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (66)$$

Vease tambien ecuaciones (62) y (67).

Tenemos, tambien

| | |
|---|---|
| $Cdelta = \sqrt{A\,k^2 + B\,k^2} =$<br>$\sqrt{(T_g \text{ sen } \Delta)^2 + (T_s - T_g \cos \Delta\,\dagger)^2}$ | $Cdelta = \sqrt{B\,k^2 + A\,k^2} =$<br>$\sqrt{(T_s \text{ sen } \Delta)^2 + (T_g - T_s \cos \Delta\,\dagger)^2}$<br>$\ldots\ldots$ (67) |

Vease tambien ecuaciones (62) y (66).

**65. Semitangentes,** $T_g$ y $T_s$. Tracese $n\,x \parallel = O_g O_s = R_g - R_s$.

| | |
|---|---|
| Encontrandose $O_s\,E$ prolongadas, en $x$.<br>Entonces $B\,x\,n = s$.<br>Tracese $n\,r$ y $A\,m \parallel B\,V \perp O_s\,x$.<br>Entonces $A\,k = T_g$ sen $\Delta$.<br>$= m\,n - k\,n$.<br>$= m\,n - B\,r$.<br>$= R_g$ senoverso $\Delta - (R_g - R_s)$ senoverso $s$. | Encontrandose $O_g\,A$ en $x$.<br>Entonces $A\,x\,n = g$.<br>Tracese $n\,r$ y $B\,m \parallel A\,V \perp O_g\,x$.<br>Entonces $B\,k = T_s$ sen $\Delta$.<br>$= m\,n + h\,n$.<br>$= m\,n + A\,r$.<br>$= R_s$ senoverso $\Delta + (R_g - R_s)$ senoverso $g$. $\ldots\ldots\ldots\ldots$ (68) |

**66. Semitangentes de ramas,** $t_g$ y $t_s$; y **tangentes comunes,** $v_g\,v_s$.

$$t_g\ (= v_g\,P) = R_g \tan (g/2)$$
$$t_s\ (= v_s\,P) = R_s \tan (s/2)$$

Tangente comun, $v_g\,v_s = t_g + t_s$ $\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots$ (69)

| | |
|---|---|
| $B\,n = 2\,(R_g - R_s)$ sen $(s/2)$. | $A\,n = 2\,(R_g - R_s)$ sen $(g/2)$. (70) |

**67.** Las Figs 18 *a*, 18 *b* y las Ecs (58) y (68) nos permiten encontrar los elementos necesarios de las curvas compuestas, dandose otros elementos. Veanse los ejemplos a continuacion:

**Ejemplos.**

| Dandose.... | **Buscar** los elementos indicados en tipo **grueso.** |
|---|---|
| $R_g\ R_s\ g\ s$... | $\Delta$ se encuentra inmediatamente por la Ec (58) y $\mathbf{T}_g$ y $\mathbf{T}_s$ por Ec (68). |
| $R_s\ T_s\ \Delta\ s$... | $\mathbf{g = \Delta - s}$, ec (58).<br>$\mathbf{R}_g$ senoverso $g = T_s$ sen $\Delta + R_s$ senoverso $g - R_s$ senoverso $\Delta$. (71)<br>$\mathbf{T}_g$ sen $\Delta = R_g$ senoverso $\Delta - (R_g - R_s)$ senoverso $s$ .... (72) |

† Vease ¶ 69.

| | |
|---|---|
| $R_g\ T_g\ \Delta\ g$.. | $\mathbf{s} = \Delta - g$, ec (58)<br>$\mathbf{R_s}$ senov $s = R_g$ senov $s + T_g$ sen $\Delta - R_g$ senov $\Delta$ .... (73)<br>$\mathbf{T_s}$ sen $\Delta = R_s$ senov $\Delta + (R_g - R_s)$ senov $g$..... (74) |

★ En nuestras figs 18, $\Delta$, $> 90°$, y cos $\Delta$ es por consiguiente *negativo*. Vease ¶ 69.

## CURVAS INVERTIDAS

### Definiciones.

**70.** Figs 20-23. Comparese Curvas Compuestas, ¶ ¶ 50-69. Cuandos dos curvas circulares consecutivas, $A\ P$ y $P\ B$, de igual o desigual radio, $R_a$ y $R_b$, se encurvan en direcciones *opuestas* (una que vaya a la derecha, y la otra a la izquierda) se dice que son invertidas, y la combinacion se llama una curva *invertida*. Las curvas invertidas algunas veces son inevitables, como en algunos enlaces y desvios; pero en otras partes deben evitarse.

**71. Las dos ramas**, $A\ P$ y $P\ B$, descansan en lados *opuestos* de la tangente comun, $v_a\ v_b$. Su punto de encuentro, $P$, o el punto comun de tangencia, es el punto, « C. C. » de cambio de *curva* a *curva*; o el punto de curvatura invertido. « P. R. C. » Vease ¶ 2.

**72. Los centros**, $O_a$ y $O_b$, de las dos ramas, están necesariamente en linea recta con el C. C. $(P)$, **los dos radios** son normales a la tangente comun, $v_1\ v_b$, en $P$, En $A$ y en $B$, los radios son normales respectivamente a las tangentes, $A\ V$, $V\ B$. de la curva entera. El vertice, $V$, está hacia el lado de *la curva de mayor extension*.

**73. Las semitangentes** de la curva entera invertida son $T_a = A\ V$ y $T_b = B\ V$. Vease ¶ 77. Las semitangentes de las dos ramas respectivamente, son $t_1 = v_1\ P = v_a\ A$, y $t_b = v_b\ B$. **Tangente comun**, $v_1\ v_b = t_1 + t_b$.

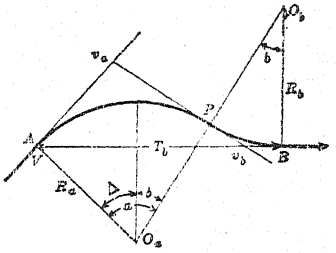

**Fig. 20 a.**

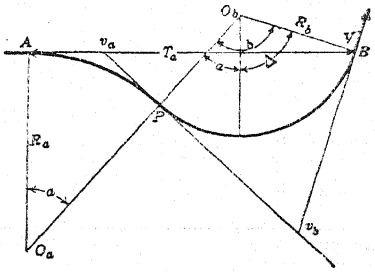

**Fig. 20 b.**

**74.** Figs 20.

Fig. 20 *a*. Si $V$ coincide con $A$, tenemos :

$$T_a\ (= A\ V) = 0,\ \text{y}\ T_b\ (= V\ B) = A\ B.$$

Fig. 20 *b*. Si $V$ coincide con $B$, tenemos :

$$T_b\ (= B\ V) = 0,\ \text{y}\ T_a\ (= V\ A) = A\ B.$$

**75. Los desarrollos,** $\Delta_a$ y $\Delta_b$ (o, simplemente, $a$ y $b$) de las dos ramas, pueden ser iguales o desiguales, y cualquiera puede ser el mayor.

**76.** Como las dos ramas se desvian en direcciones opuestas, la desviacion resultante, $\Delta$, debido a la inversion de la curva en conjunto, es :

$$\Delta = \textit{diferencia} \text{ entre } a \text{ y } b \ldots\ldots\ldots\ldots\ldots \quad (81)$$

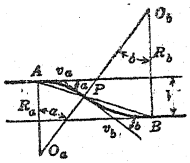

**Fig. 21.**

**77.** fig. 21. Cuando las tangentes son paralelas, tenemos $a = b$ y $\Delta$ ( $= a - b$ ) $= 0$. Entonces $T_a$ ( $= A\ V$) y $T_b$ ( $= B\ V$) son infinitos, no habiendo vértice, $V$. Véase ¶ 79.

También, $P$ está en la linea $A\ B$.

## Ecuaciones.

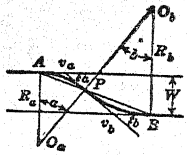
**78.** Figs 22 y 23. **Semitangentes,** $A\ v_a$ y $v_b\ B$ **no paralelas.**
El « P. R. C. » ($P$) no esta en $A\ B$.

| **Radios desiguales.** Fig. 22. | **Radios iguales.** Figs 23. $R_a = R_b = R$. |
|---|---|
| De la semitangente, $A\ v_a$, en $A$, trácese $X\ A\ D = Z\ D\ A = \Delta/2$. | |
| Midase la cuerda. $A\ D = 2\ R_a \operatorname{sen} (\Delta/2)$. | Midase la cuerda. $A\ D = 2\ R \operatorname{sen} (\Delta/2)$. |

Entonces $D$ es un punto de la curva $A\ P$ (prolongado, figs 22 $b$, 23 $b$). Dibujese $O_a\ D \parallel O_b\ B$. Entonces $A\ O_a\ D = \Delta$. Por $D$, tracese la tangente, $Z\ N \parallel B\ V$, distante $D\ B' = W$, de $B\ V$. De $D$ tracese arco $D\ P$ ($D\ O_a\ P = b$), determinando $P$.

| | |
|---|---|
| Midanse las cuerdas. $D\ P$ y $P\ B$. Entonces : $D\ B = D\ P + P\ B$ $= W/\operatorname{sen}\ (b/2)$ $= 2\ (R_a + R_b) \operatorname{sen}\ (b/2)$. (82) | Midanse las cuerdas. $D\ P = P\ B$. Entonces : $D\ B = D\ P + P\ B$ $= 2\ D\ P = 2\ P\ B$ $= W/\operatorname{sen}\ (b/2)$ $= 4\ R \operatorname{sen}\ (b/2) = 2\sqrt{W\ R}$ ... (82′) |
| $R_b = R_a\ P\ B/D\ P$ $= \dfrac{D\ B}{2 \operatorname{sen}\ (b/2)} - R_a$..... (83) | $R = R_a = R_b$ $= \dfrac{D\ P}{2 \operatorname{sen}\ (b/2)} = \dfrac{P\ B}{2 \operatorname{sen}\ (b/2)}$ ... (83′) |
| Tangente comun : $v_a\ v_b = t_a + t_b$ $= R_a \tan\dfrac{a}{2} + R_b \tan\dfrac{b}{2}$. (84) | Tangente comun : $v_a\ v_b = t_a + t_b$ $= R\left(\tan\dfrac{a}{2} + \tan\dfrac{b}{2}\right)$. (84′) |

$$\text{Sen } D\ B\ v_b = \operatorname{sen}\ (b/2) = W/D\ B \ldots\ldots\ldots\ldots \quad (85$$



**79.** Fig. 21. **Semitangentes, $Av_a$, $v_bB$, paralelas.**

$A\,B$ corta á la tangente comun, $v_a\,v_b$, en el C. C. $(P)$. $a = b$; $\Delta = a - b$ $(o,\ b - a) = 0$; $T_a$ y $T_b$ infinito; $B\,A\,v_a = A\,B\,v_b = a/2 = b/2$.

| $A$..... | —— | $V\ B\ A$ = | $\Delta/2 = d_f/2 + 3\ D/2 + d_i/2$ | $c_i = a\ A.$ |

**82. Para la tangente**, en cualquier estacion dada, como $B$, tenemos:

Mirando atrás al T. C., $A$;

$z\ B\ x = V\ B\ A = V\ A\ B$ = suma de los ángulos trazados, en $A$, desde la tang, $A\ V$, a la estacion dada, $B$;

Mirando hacia atras a otra estacion, como $b$;

$z\ B\ y = V\ B\ b = e\ b\ B$ = suma de los ángulos trazados en $b$, desde la tangente, $b\ e$, a la estacion dada, $B$, etc., etc.

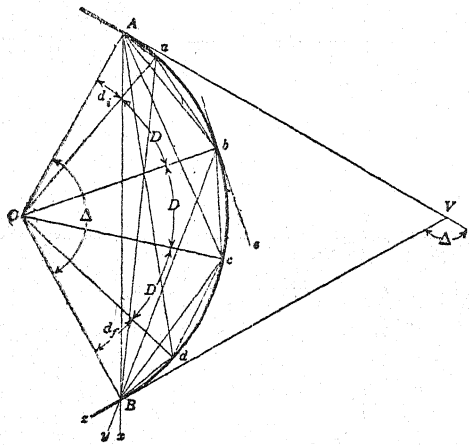

**Fig. 24.**

* Mirando de cualquier extremo de la curva, al otro extremo, donde la cadena empieza, el punto deseado se determina por la interseccion de la línea visual con la tangente, $B\ V$ o $A\ V$.

† Las cadenas dadas, $ci$, $c$, etc, se refieren a sus varios *ángulos de cadena*, $V A a$, $a\ A\ b$, $b\ A\ c$, etc. El ángulo total, $V\ A\ c$, por ejemplo, requiere cadenas $ci + c + c$.

## Cambio del Instrumento. Puntos de Tránsito *.

**33.** Fig. 24. Cuando la suma, $V\,A\,d$, de los angulos, trazados o marcados desde la tangente con el instrumento en un punto como $A$, excede, digamos de 15° o 20°, entonces, con el extremo de atrás de la cadena sostenida en la estacion que preceda a la ultima, como, $c$, el extremo libre de la cadena puede estar en una posicion distinta de la que le corresponde, en $d$, sin que lo pueda comprobar el operador del tránsito; y esta dificultad aumenta con el mayor largo de la visual.

**34.** En este caso, o cuando un obstáculo impide el trazado del próximo angulo, el instrumento se cambia a otro punto (« punto de transito » *), en la curva, y el trabajo se continua desde alli.

**35.** La posibilidad de errar esta mas reducida, observando en todo su curso, el método sistemático siguiente:

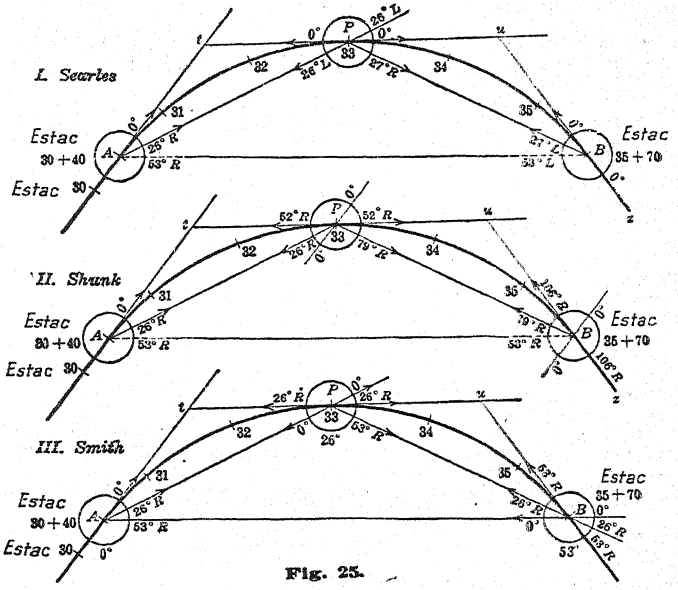

**Fig. 25.**

Figs 25. Ejemplo. En la curva de 20° $A\ P\ B$, marquemos las tres estaciones nos 31, 32 y 33 ($P$) desde la T. C. ($A$, estacion 30 + 40); entonces determinemos las tres estaciones, nos 34, 35 y 35 + 70 ($B$), desde $P$; y luego fijemos la tangente final, $Bz$, desde la C. T. ($B$, estacion 35 + 70).

Los circulos, en $A$, en $P$ y en $B$, en cada Fig. indican la orientacion del instrumento, los angulos girados y la lectura que resulta del vernier, o nonio.

En cada una de las tres figs (vease Figs 25, I) sea:

$$\text{Angulo } t\ A\ P = 0.6 \times 10° + 10° + 10° = 26°;$$
$$\text{—} \quad u\ P\ B = 10° + 10° + 0.7 \times 10° = 27°.$$

* Tales puntos se llaman á menudo « puntos de cambio » pero esto es propenso a confusion con los « puntos de cambio » en nivelación.

**Tres metodos** están en uso comun en coneccion con el cambio del tránsito a un punto nuevo. Estos pueden llamarse: —

I. Searles. Vease « Field Engineering », pp 53, 57, etc.
II. Shunk. Vease « The Field Engineer », pp 66, etc *.
III. Smith. Vease « Eng News, 1876 Aug 26, p 277 reimpreso 1888 sept 29, p 245; * tambien « Engineer Field Book » de *Cross*, pp 56, etc.

**Metodo I (Searles)** esta ya suficientemente descrito en la primera de las tres secciones de la tabla comparativa en el ¶ 86.

**Metodo II (Shunk)** puede hacerse mas claro por la siguiente aplicacion de este metodo al mismo caso. Vease Figs 25, II. Aqui todos los angulos son a la derecha (*R*) del cero.

| | | | |
|---|---|---|---|
| Instrumento en.. | $A$ | $P$ | $B$ |
| Visual al punto viejo..... | $t$ | $A$ | $P$ |
| Lectura del vernier en el punto.. viejo..... | 0° | $\left\{\begin{array}{c} t\,A\,P = \\ t\,P\,A = \\ 26° \end{array}\right\}$ | $\left\{\begin{array}{c} 2\,t\,A\,P + u\,P\,B \\ = 52° + 27° \\ = 79° \end{array}\right\}$ |
| Agregar..... | 0° | $\left\{\begin{array}{c} A\,P\,t = \\ t\,A\,P = \\ 26° \end{array}\right\}$ | $\left\{\begin{array}{c} P\,B\,u = \\ u\,P\,B = \\ 27° \end{array}\right\}$ |
| Visual a la tang.. | $A\,t$ | $t\,u$ | $u\,z$ |
| Lectura del vernier en la tang.. | 0° | $\left\{\begin{array}{c} t\,A\,P + A\,P\,t \\ = 2\,t\,A\,P - 0° \\ = 2 \times 26° - 0° \\ = 52° \end{array}\right\}$ | $\left\{\begin{array}{c} 79° + 27° = \\ 2 \times 79° - 2\,t\,A\,P \\ = 158° - 52° \\ = 106° \end{array}\right\}$ |
| Agregar..... | $t\,A\,P = 26°$ | $u\,P\,B = 27°$ | |
| Visual al nuevo punto..... | $P$ | $B$ | |
| Lectura del vernier en el nuevo punto..... | $\left\{\begin{array}{c} t\,A\,P = \\ 0° + 26° \\ = 26° \end{array}\right\}$ | $\left\{\begin{array}{c} 2\,t\,A\,P + u\,P\,B \\ = 52° + 27° \\ = 79° \end{array}\right\}$ | |
| Cambio al nuevo punto..... | $P$ | $B$ | |

Despues de cambiar el instrumento de un punto viejo, $p$ (no indicado), a un punto nuevo, $p'$, la lectura del vernier, $C$, que colocará al anteojo en la tangente nueva, se determina asi: — Sea.

$A$ = lectura del vernier mirando el punto nuevo, $p'$, desde $p$;
$B$ = lectura del vernier mirando a lo largo de la tangente vieja, en $p$;
$C$ = lectura del vernier mirando a lo largo de la tangente nueva, en $p'$.
Entonces:

$$C = 2\,A - B.$$

Método III (Smith) se describe en ¶ ¶ 89 a 91.

**86.** La siguiente tabla indica el procedimiento por los tres metodos respectivos. M. S. = movimiento superior del tránsito, M. I. = movimiento inferior del transito.

$R$ = derecho; $L$ = izquierda.

* En su 9ª edicion, 1890, M. Shunk describe el metodo « Smith » (III), atribuyéndoselo a M. Robert Burgess, C.E., quien lo describe en Eng News, 1888, Sep 22.

† En obsequio de la uniformidad, aqui supondremos que, al usar el metodo III (Smith), movemos el instrumento lo mismo a $P$ que a $B$, y que, despues de cambiarlo asi, miramos a las mismas estaciones ($A$ y $P$, respectivamente) como en los metodos I y II; pero, de hecho, con el metodo III, la condicion descrita en ¶ 90, se obtendra sin que importe a qué estacion nos cambiemos, o a qué estacion miremos desde él. Véase 91.

| a — 33 (*P*)..... | 27° *I* | 79° *D* | 26° *D* |
| a — 35 + 70 (*B*) (tan). | 0° | 106° *D* | 53° *D* |

**89. En el Metodo III (Smith)**, figs 25, III, antes de empezar a correr la curva, calcúlese y anótese en la libreta de campo (como en la ultima columna de la tabla, ¶ 88), opuesta a cada estacion (como 30 + 40, 31, etc.), y opuesta a cualquiera otros puntos, en la curva, que por cualquier razon, pueda desearse determinarlos, el ángulo total (como $t\,A\,t = 0°$, $t\,A$ 31, $t\,A\,P$, $t\,A\,B$, etc.), entre la tangente *original*, $At$, y la cuerda, $A$-31, $A$-$P$, $A$-$B$, etc.) desde $A$ a tal estacion, como si cada uno de los puntos, en toda la curva entera, fuera a ser determinado desde el punto $A$ de la curva.

**90.** Entonces, despues de hacer estacion en cualquier punto que sea de la *curva*, póngase el vernier con el ángulo asi anotado en la libreta de campo opuesto a cualquier otro punto conveniente, $x$, en la curva, y vease hacia $x$, con el instrumento asi orientado. Entonces, si el vernier esta puesto para el movimiento superior, a la lectura registrada, como arriba, opuesto a cualquier otro punto, $y$, en la curva, el instrumento será mirado en $y$. Con el vernier en el ángulo registrado opuesto al *punto ocupado*, el instrumento esta en la *tangente que pasa por ese punto.*

* Buscando la uniformidad, aqui suponemos que, al usar el III metodo (Smith), cambiamos el instrumento ya sea a $P$ ó a $B$, y que despues de cambiarlo, miramos las mismas estaciones ($A$ y $P$, respectivamente, como en los metodos I y II, pero, de hecho, con el metodo III, la condicion, descrita en ¶ 90 se obtendrá sin que importe a qué estacion nos cambiamos, o de qué estacion miramos desde él. Vease ¶ 91.

**91.** Si la agudeza de la curva está expresada por un numero entero de grados, si la curva empieza con una sub-cadena, y si se van a poner muchas estaciones, puede convenir **hacer una adicion arbitraria a cada angulo,** para dar, a las estaciones completas, angulos expresados por un numero entero de grados (o en grados y medios grados); simplificando asi los calculos. † Por ejemplo, en una curva de 3°, si los angulos actuales son como en la linea *A*, por debajo, podiamos añadir 0°18′ a cada angulo, haciendolos leer como en la linea *B*.

| Estación | 30 + 20 (*A*) | 31 | 32 | 33 | 34 | 34 + 40 (*B*) |
|---|---|---|---|---|---|---|
| *A*. | 0° | 1°12′ | 2°42′ | 4°12′ | 5°42′ | 6°18′ |
| *B*. | 0°18′ | 1°30′ | 3°0′ | 4°30′ | 6°0′ | 6°36′ |

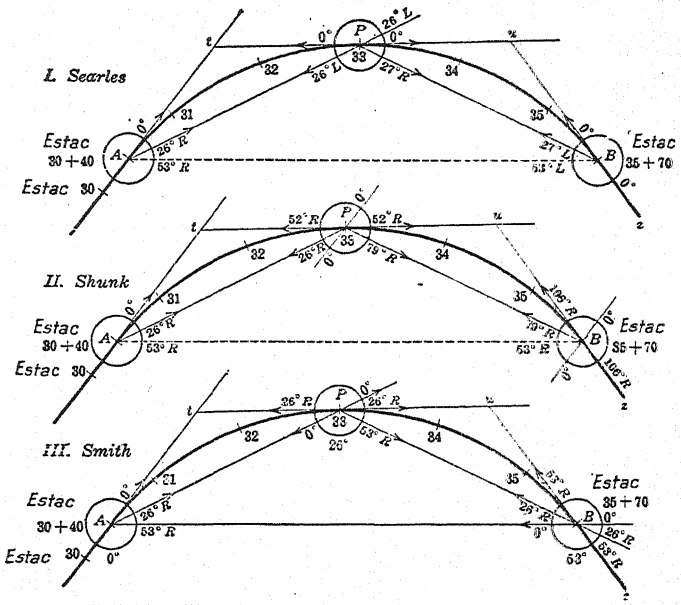

**Fig. 25. (Repetida.)**

## Miscelánea de Métodos.

**92. Trazar una curva sin el tránsito.** Fig. 26. Sean $a\ b$, $b\ c$, cadenas; $a\ b = b\ c = c$; sean $a\ t$ y $b\ n$ las tangentes en $a$ y en $b$, respectivamente. Prolónguese la cuerda $a\ b$ hasta $f$, y hágase $a\ t = b\ f = a\ b = c$. Entonces :

$$t\ b = 2\ c \operatorname{sen} (D/4);\ f\ c = 2\ c \operatorname{sen} (D/2) = 2\ c \frac{c}{2\ R} = \frac{c^2}{R} \ldots\ldots\ldots\ldots \quad (95)$$

† T. Appleton, Revista de Assen Engng Socs, Marzo, 1883.

**93.** Las distancias, $t\ b$ y $f\ c$, pueden usarse para determinar un curva sin el transito. Asi:

(1) Habiendo trazado $a\ t\ (=c)$ a lo largo de la tangente, $a\ t$, para determinar $b$; desde $a$, trácese $a\ b\ (=c)$ para encontrar $t\ b$ trazada desde $t$.

(2) Habiendo trazado $b\ f\ (=c)$ a lo largo de la cuerda $a\ b$ prolongada para determinar $c$; desde $b$, trace $b\ c\ (=c)$ para encontrar $f\ c$ trazada desde $f$.

(3) Habiendo trazado $c\ e\ (=c)$ a lo largo de la cuerda $b\ c$ prolongado para encontrar la tangente, $e\ t'$, en $e$; desde $c$, trácese $c\ t'\ (=c)$ para encontrar $e\ t\ (=t\ b)$ trazado desde $e$.

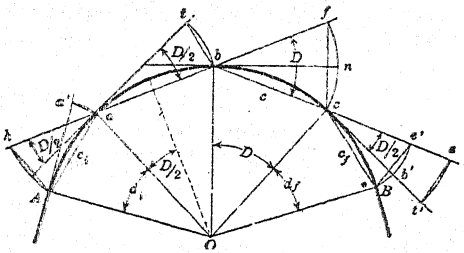

**Fig. 26.**

**94. Para las sub-cadenas**, $A\ a = c_i$, y $c\ B = c_f$, **sub-angulos**, $d_i$ y $d_f$, etc., tenemos las siguientes ecuaciones:

| Distancias. | Angulos. | Aproximado. |
|---|---|---|
| $a'\ a = 2\ c_i$ sen $(d_i/4)$ | sen $(d_i/2) = \dfrac{c_i}{2\,R}$ | $a'\ a = t\ b\ \dfrac{c_i^2}{c^2}$ ... (96) |
| $B\ b' = 2\ c_f$ sen $(d_f/4)$ | sen $(d_f/2) = \dfrac{c_f}{2\,R}$ | $B\ b' = e\ t'\ \dfrac{c_f^2}{c^2}$ ... (97) |
| $A\ h = 2\ c_i$ sen $(A\ a\ h/2)$ | $A\ a\ h = \dfrac{D}{2} + \dfrac{d_i}{2}$ | $d_i = D\ \dfrac{c_i}{c}$ .... (98) |
| $B\ e' = 2\ c_f$ sen $(B\ c\ e'/2)$ | $B\ c\ e' = \dfrac{D}{2} + \dfrac{d_f}{2}$ | $d_f = D\ \dfrac{c_f}{c}$ .... (99) |

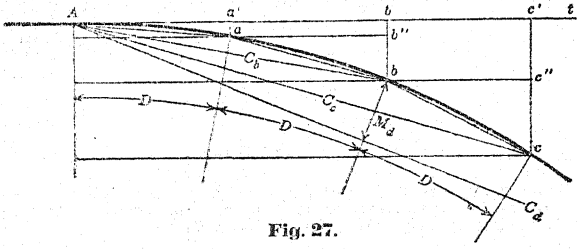

**Fig. 27.**

**95. Por ordenadas desde la tangente, A t.** Fig. 27. Sea $R$ = radio; $c$ =, largo de cadena, $A\ a$, $a\ b$, etc; $C_b$, $C_c$, $C_d$, etc = cuerda larga $A\ b$, $A\ c$, $A\ d$, etc, desde $A$ a estacion 2ª, 3ª, 4ª etc; $M_b$, $M_c$, $M_d$, etc = media ordenada para $C_b$, $C_c$ $C_d$, etc; $D/2 = a'\ A\ a$; $3\ D/2 = b''a\ b$; $5\ D/2 = c''\ b.c$, etc. Entonces:

*Distancias en la tangente.*

$$A\,a' = c\cos(D/2) = R\,\text{sen}\,D \ldots\ldots = C_b/2 \ldots\ldots (100)$$

$$A\,b' = c\,[\cos(D/2) + \cos(3\,D/2)] = R\,\text{sen}\,(2\,D) \ldots\ldots = C_d/2 \ldots\ldots (101)$$

$$A\,c' = c\,[\cos(D/2) + \cos(3\,D/2) + \cos(5\,D/2)] = R\,\text{sen}\,(3\,D) \ldots\ldots = C_f/2 \ldots\ldots (102)$$

*Ordenadas desde la tangente.*

$$a'\,a = c\,\text{sen}\,(D/2) = c^2/(2\,R) = R\,\text{senoverso}\,D = M_b \ldots\ldots (100\,a)$$

$$b'\,b = c\,[\text{sen}\,(D/2) + \text{sen}\,(3\,D/2)] = C_b\,\text{sen}\,b'\,A\,b = C_b\,\text{sen}\,D = (C_b)^2/(2\,R).$$
$$= R\,\text{senoverso}\,2\,D = M_d \ldots\ldots (101\,a)$$

$$c'\,c = c\,[\text{sen}(D/2) + \text{sen}\,(3\,D/2) + \text{sen}\,(5\,D/2)].$$
$$= C_c\,\text{sen}\,(3\,D/2) = (C_c)^2/(2\,R).$$
$$= R\,\text{senoverso}\,3\,D = M_f \ldots\ldots (102\,a)$$

Así, sea $c = 100$ pies; $D = 12°$. Entonces:
(Vease *N. del T.* ¶ 11, pag 926.)

| Para la dist $A\,c'$, sobre la tang. | Para la ordenada, $c'\,c$ desde la tang. |
|---|---|
| Cos $(D/2)$ = cos 6° = 0.99452 | Sen $(D/2)$ = sen 6° = 0.10453 |
| Cos $(3\,D/2)$ = cos 18° = 0.95106 | Sen $(3\,D/2)$ = sen 18° = 0.30902 |
| Cos $(5\,D/2)$ = cos 30° = 0.86603 | Sen $(5\,D/2)$ = sen 30° = 0.50000 |
| Suma de cosenos = 2.81161 | Suma de los senos = 0.91355 |
| $A\,c' = 2.81161\,c = 281.16$ pies. | $c'\,c = 0.91355\,c = 91.355$ pies. |

**96.** Primero, desde $A$, aliniense los puntos $a'$, $b'$, $c'$, etc., en la tangente, $A\,t$ Entonces, desde $a'$, $b'$, $c'$, etc., trácese $a'\,a$, $b'\,b$, $c'\,c$, etc., normal a $A\,t$; o trácese, $a'\,a$, $b'\,b$, etc., al azar, a cruzarse con $A\,a$, $a\,b$, $b\,c$, etc., cada una $= c$.

**97.** Si, como es costumbre, la curva comienza o termina con una sub-cadena, pudiera ser preferible dividir la curva (desarrollo $= \Delta$) en un numero conveniente, $n$, de partes iguales, cada una $= \Delta/n$, y substituir $\Delta/n$ por $D$, y $2\,R\,\text{sen}\,/(\Delta 2\,n)$ por $c$, etc.

A medida que el trabajo avanza, y los angulos $a\,b\,b''$, $b\,c\,c'$, etc., se vuelven mas agudos, y el trabajo resulta menos exacto.

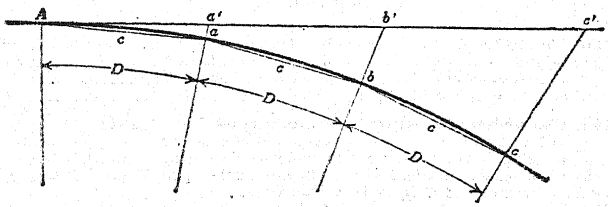

**Fig. 28.**

**98. En la Fig. 28, las dists,** $a\,a'$, $b\,b'$, etc., estan **en linea con los radios** en $a$, en $b$, etc. Aquí:

$$A\,a' = R\,\text{tang}\,D;\ A\,b' = R\,\text{tang}\,2\,D;\ A\,c' = R\,\text{tang}\,3\,D,\ \text{etc.} \ldots\ldots (103)$$

$$a\,a' = R\,\text{exsec}\,D;\ b\,b' = R\,\text{exsec}\,2\,D;\ c\,c' = R\,\text{exsec}\,3\,D,\ \text{etc.} \ldots\ldots (104)$$

Desde $A$, aliniese $a'$, $b'$, $c'$, etc. Desde $A$ y desde $a'$, simultaneamente, trácese $a'\,a$, respectivamente, determinando el punto $a$. Entonces, desde $a$ y desde $b'$, respectivamente, trácese simultáneamente, $c$, y $b'\,b$, determinando el punto $b$, y asi sucesivamente. Vease ¶ 97.

**99. Dando dos estaciones consecutivas.** Fig. 29. Teniendo dos estaciones consecutivas, $z$ y $A$, y la direccion de la tangente, $m\ n$, en $A$, determinar una tercera estacion, $a$.

Desde $A$, en la tangente, $m\ n$, tracese $A\ n = c \cos (D/2)$. Entonces tracese $A\ a = c$, para encontrar $n\ a = c$ sen $(D/2) = R$ senoverso $D = 2\ R$ sen$^2$ $(D/2)$, trazado desde $n$; o, desde $A$, $\perp\ m\ n$, tracese $A\ A' = c$ sen $(D/2)$; y desde $A'$ trace $A'\ a = c \cos (D/2)$, para encontrar $A\ a = c$ trazado desde $A$, o bien, $n\ a = c$ sen $(D/2)$, trazado desde $n$.

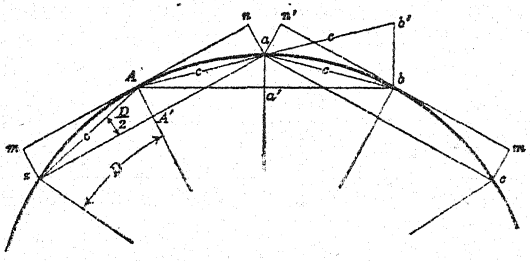

**Fig. 29.**

Para determinar la proxima estacion, $b$; en $A\ a$ prolongado, hágase $a\ b' = c$, y búsquese $b$ por medio de ¶ ¶ 92, 93, donde $f\ c = b'\ b$, Fig. 29.

Para la direccion de la tangente, $n'\ m'$, en $b$; determinese la próxima estacion $c$, como arriba; desde $a$ y desde $c$, $\perp\ a\ c$, trácese $a\ n'$ y $c\ m'$ respectivamente; $a n' = c\ m' = c$ sen $(D/2)$.

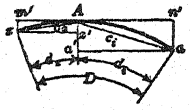

**Fig. 30.**

**100.** Fig. 30. En el caso de una sub-cadena, $c_i = A\ a$, sea $d_i =$ el sub-angulo: $d_z = D - d_i$; $c_i\ (= A\ a) = 2\ R$ sen $(d_i/2)$; $c_z\ (= z\ A) = 2\ R$ sen $(d_z/2)$. Entonces;

$a\ a' = A\ n' = c_i \cos (d/2)$; $A\ a' = n'\ a = c_i$ sen $(d!/2)$ ..... (105)

$z\ z' = m'\ A = c_z \cos (d_z/2)$; $A\ z' = m'\ z = c_z$ sen $(d_z/2)$ ..... (106)

**101. Por ordenadas sobre cuerdas largas.** Fig. 31. Sea:

$c = 1$ cadena $= a\ b = b\ c =$ etc., que subtiende $D$;

$c_i =$ sub-cadena inicial, $A\ a$, subtendiendo el sub-angulo inicial, $A\ O\ a = d_i$;

$c_f =$ sub-cadena final $h\ B$, subtendiendo el sub-angulo final $h\ O\ B = d_f$;

$\Delta =$ desarrollo, $A\ O\ B$, de la curva entera.

Entonces, para las abscisas, $A\ a'$, $A\ b'$, $A\ c'$, etc., tenemos:

$$A\ a' = c_i \cos a\ A\ a' = c_i \cos \frac{\Delta - d_i}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (107)$$

$$a'\ b' = a\ b'' = c \cos b\ a\ b'' = c \cos \frac{\Delta - 2d_i - D}{2}$$

$$b'\ c' = b\ c'' = c \cos c\ b\ c'' = c \cos \frac{\Delta - 2d_i - 3D}{2}$$

etc. y

$A\ c' = A\ a' + a'\ b'$;

$A\ c' = A\ b' + b'\ c'$, etc ..... (108

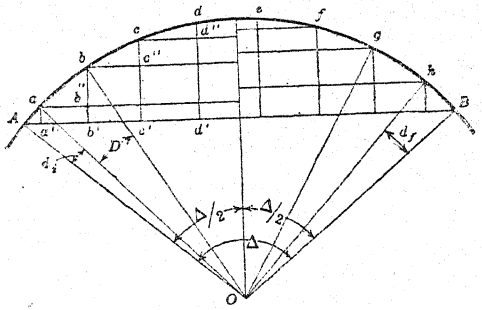

**Fig. 31.**

De modo análogo para las ordenadas, $a'\,a$, $b'\,b$, $c'\,c$, etc., tenemos :

$$a'\,a = c_i \text{ sen } \frac{\Delta - d_i}{2};$$

$$b''\,b = c \text{ sen } \frac{\Delta - 2\,d_i - D}{2};$$

$$c''\,c = c \text{ sen } \frac{\Delta - 2\,d_i - 3\,D}{2}; \text{ etc., y}$$

$$b'\,b = a'\,a + b''\,b\,;\; c'\,c = b'\,b + c''\,c, \text{ etc} \ldots\ldots\ldots\ldots\ldots\ldots \quad (109)$$

**102.** Fig. 32. *Para eliminar las sub-cadenas* (vease ¶ 97), sea la curva. $A\,P\,B$, divida en un numero conveniente de arcos iguales; y sea :

$c_e$ = la cuerda, $A\,a = a\,b$, etc., subtendiendo uno de estos arcos;
$D_e$ = el angulo central, $A\,O\,a$, subtendido por $c_e$;
$C$, $C'$, $C''$, etc = las cuerdas largas, $A\,B$, $a\,h$, $b\,g$, etc., respectivamente;
$M$, $M'$, $M''$, etc = las medias ordenadas, $E\,P$, $E'\,P$, $E''\,P$, etc. de $C$, $C'$, $C''$, etc., respectivamente.

Entonces :

Abscisas.

$C/2 = A\,E = R$ sen $(\Delta/2)$;
$C'/2 = a\,E' = R$ sen $(\Delta/2 - D_e)$;
$C''/2 = b\,E'' = R$ sen $(\Delta/2 - 2\,D_e)$; etc.

$$A\,a' = C/2 - C'/2 = c_e \cos a\,A\,a' = c_e \cos \frac{\Delta - D_e}{2};$$

$$a'\,b' = a\,b'' = C'/2 - C''/2 = c_e \cos b\,a\,b'' = c_e \cos \frac{\Delta - 3\,D_e}{2};$$

$$b'\,c' = b\,c'' = C''/2 - C'''/2 = c_e \cos c\,b\,c'' = c_e \cos \frac{\Delta - 5\,D_e}{2};$$

etc.; y

$$A\,b' = A\,a' + a'\,b';$$
$$A\,c' = A\,b' + b'\,c'; \text{ etc} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (110$$

Ordenadas.

$M = E\ P = R$ senoverso $(\Delta/2)$;
$M' = E'\ P = R$ senoverso $(\Delta/2 - D_c)$;
$M'' = E''\ P = R$ senoverso $(\Delta/2 - 2\ D_c)$; etc.

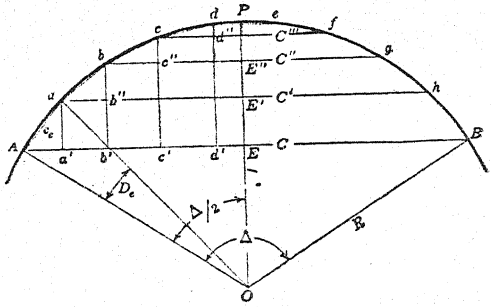

Fig. 32.

$$a'\ a = M' - M' = c_e \text{ sen } \frac{\Delta - D_c}{2};$$

$$b''\ b = M' - M'' = c_e \text{ sen } \frac{\Delta - 3\ D_c}{2};$$

$$c''\ c = M'' - M''' = c_e \text{ sen } \frac{\Delta - 5\ D_c}{2}; \text{ etc.; y}$$

$b'\ b = a'\ a + b''\ b = M - M''$;
$c'\ c = b'\ b + c''\ c = M - M'''$; etc..... (111)

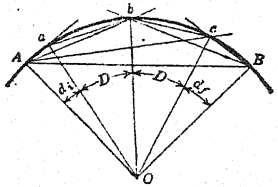

Fig. 33.

**103. Por medio de Dos Tránsitos, sin medidas lineales.** Fig. 33. Es útil cuando es imposible usar la cadena, como en pantanos, etc.

Dando cualquiera de las dos estaciones, *A* y *B*, cada una visible de la otra;

De cada una de las dos estaciones, *A* y *B*, vease a la otra y trácense los ángulos encontrados, como abajo, determinando los puntos, *a*, *b*, etc., por medio de las intersecciones de las visuales.

Así, sea *a b*, *b c*, las cadenas; *A a*, *c B*, las sub-cadenas. Entonces para determinar el punto *b*, en la interseccion de *A b* y *B b*; tenemos:

$$b\ A\ B = b\ O\ B/2 = (D + d_f)/2;$$
$$b\ B\ A = b\ O\ A/2 = (D + d_i)/2 \ldots\ldots\ldots\ldots\ldots (112)$$

Similarmente, para el punto *c* (interseccion de *A c* y *B c*), tenemos:

$$c\ A\ B = c\ O\ B/2 = d_f/2;$$
$$c\ B\ A = c\ O\ A/2 = (2\ D + d_i)/2 \ldots\ldots\ldots\ldots\ldots (112')$$

**104. Por Cuerdas Largas desde el Instrumento. Fig. 34.** Sea $a\,b = b\,c = c = 1$ cadena; $A\,a = c_i$ = sub-cadena inicial; $c\,B = c_f$ = sub-cadena final.

Entonces en la fig. 34 :

$$t\,A\,a = d_i/2; \qquad A\,a = 2\,R \operatorname{sen} t\,A\,a;$$
$$t\,A\,b = (d_i + D)/2; \qquad A\,b = 2\,R \operatorname{sen} t\,A\,b;$$
$$t\,A\,c = (d_i + 2\,D)/2; \qquad A\,c = 2\,R \operatorname{sen} t\,A\,c;$$
$$t\,A\,B = (d_i + 2\,D + d_f)/2 = \Delta/2; \qquad A\,B = 2\,R \operatorname{sen} t\,A\,B. \ldots\ldots \quad (113)$$

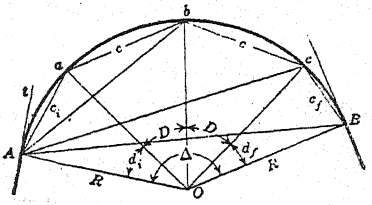

**Fig. 34.**

**105. Plantillas auxiliares.** La determinacion de curvas sobre el plano se facilita grandemente con el uso de *plantillas*, en escalas adecuadas.

**106.** El transportador de curva transparente de Wm. F. Shunk suministra un número de curvas en escala de 1 pulg = 400 pies.

**107.** En la revista Eng News 1902 jun 19, p. 500-501, Chas H. Quimby Jr. sugiere un « *proyectador de curvas y escalas* » (del cual se ha solicitado patente) que es un transportador de curvas transparente en el cual cada curva esta perforada a cada 100 pies de su longitud por la escala, a fin de que, con un instrumento de punta, los puntos correspondientes puedan marcarse en el plano que está debajo.

**108. Ordenadas.** En curvas agudas pueden determinarse puntos adicionales, intermedios de las estaciones, por medio de ordenadas a una cuerda que una dos estaciones consecutivas. Generalmente se estira un cordel entre las dos estaciones consecutivas, y las ordenadas se miden, tan cerca como se pueda a angulo recto con él por medio de una vara graduada o lienza. Los puntos a lo largo del cordel desde el cual se han de medir las ordenadas (especialmente el punto del medio y los dos puntos a la mitad entre este y los extremos), se distinguen por nudos o de otro modo.

**109.** La distancia entre las ordenadas por su puesto que depende de las condiciones del trabajo y de la agudeza de la curva. Para guiar los movimientos de tierra 50 pies (15 m) es bastante cerca, o 25 pies (7,5 m) para radios menores de 1.000 pies (digamos 300 m) para tendido de via, la distancia puede variar de 25 pies (7,5 m) en curvas fáciles a 10 pies (digamos 3 m) y aun 5 pies (digamos 1,5 m) en las mas agudas.

Vease ecs (32) y (34) a (39), y tabla de ordenadas, pags 974 á 977.

## OBSTÁCULOS

Otros métodos, ademas de los que se han indicado aqui pueden idearse para acomodarse a estos u otros casos.

**110. Visual interceptada.** Las siguientes indicaciones se refieren a casos que surgen en el método usual de determinacion por angulos perifericos, ¶ ¶ 81, etc.; pero la dificultad puede algunas veces evitarse abandonando ese metodo y usando en su lugar uno u otro de los metodos de determinacion mencionados en ¶ ¶ 92-104. Véase tambien en Agrimensura p. 291 1ª linea « caso » 5°.

**111.** Fig. 35. Teniendo, determinados $a$ y $b$, desde $A$, por medio de ángulos periféricos, $t'\,A\,a$ y $t'\,A\,b$, y cadenas, $A\,a$ (sub-cadena) y $a\,b$, encontramos que un obstáculo obstruye la visual, $A\,c$, a la próxima estacion, $c$.

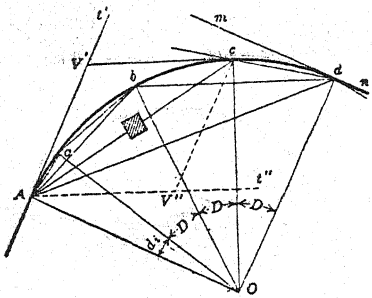

Fig. 35.

**112.** Determínese la próxima estacion, $d$, despues de $c$, trazando $t'\,A\,d = t'\,A + D$, y trazando $b\,d = 2\,R$ sen $D$, o, $A\,d = 2\,R$ sen $t'\,A\,d$ (vease tabla, p. 970). En curvas para F. C. de vapor, podemos tomar aprox, $b\,d = 2\,c$; y $A\,d = 3\,c + ci$; donde $c$ = a la unidad de cadena; y $ci$ = sub-cadena inicial, $A\,a$.

Para la tangente, $m\,n$, en $d$, tenemos $A\,d\,m = t'\,A\,d = \Delta/2$.

Para determinar $c$, entonces tenemos $m\,d\,c = D/2$; y $d\,c$ = cadena, $c$.

**113. O, podíamos determinar c directamente,** así: en la tang, $A\,t'$, trazar $A\,V' = R$ tang $t'\,A\,c = R$ tan $(di/2 + D)$. En $V'$ trazar $t'\,V'\,c = 2\,(t'\,A\,c)$, y $V'\,c\,(= A\,V')$ hacia $c$. Si $V'$ es inaccesible, podemos en su lugar determinar $V''$ (haciendo $b\,A\,V'' = t'\,A\,d = (D/2) + t'\,A\,c$; y $A\,V'' = A\,V'$); trazando $t''\,V''\,c = t'\,V'\,c = 2\,t''\,A\,c$, y hacer $V''\,c = V'\,c = A\,V''$.

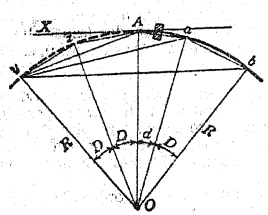

Fig. 36.

**114.** Fig. 36. ($A\,a$ = sub-cadena inicial.) Si un obstáculo impide la visual de $A$ hacia $a$, podemos mirar atras desde $A$ a lo largo de la tangente, $A\,X$, y extender la curva hacia atrás desde $A$, una o mas cadenas, como sea necesario, digamos hasta $z$ ó $y$. Entonces, con el instrumento puesto en $y$, por ejem., podemos mirar hacia $A$, trazando $A\,y\,a = \frac{1}{2}\,A\,O\,a = d/2$, y la cuerda larga, $y\,a = 2\,R$ sen $(y\,O\,a/2)$ = (en la fig. 36) $2\,R$ sen $(D + d/2)$. Para $b$, tenemos $a\,y\,b = \frac{1}{2}\,a\,O\,b = D/2$, y $a\,b$ = unidad de cadena; o, $y\,b = 2\,R$ sen $(y\,O\,b/2)$; etc., etc.

**Posición de un punto inaccesible necesario.**

**115. Vertice, V, inaccesible.** Fig. 37. Dando $\Delta$ y $R$ o $D$, buscar los puntos de la curva, $A$, $B$. Midase la dist, $a\ b$, entre cualquiera de los dos puntos accesibles sobre las dos tangentes respectivamente. Midanse los angulos $z\ b\ a$ e $y\ a\ b$, y búsquese $V\ b\ a$ ( $= 180° - z\ b\ a$) y $V\ a\ b$ ( $= 180° - y\ a\ b$). Entonces $V\ b\ a + V\ a\ b$ ( $= 180° - a\ V\ b$) $= \Delta$, ó $a\ V\ b = 180° - \Delta$.

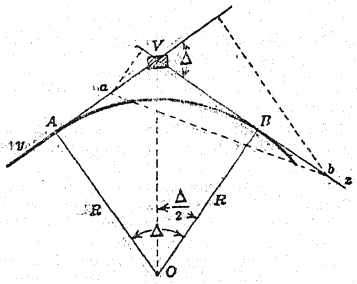

Fig. 37.

Encuéntrese, $V\ a = a\ b$ sen $V\ b\ a$/sen $\Delta$;
y $V\ b = a\ b$ sen $V\ a\ b$/sen $\Delta$.

Entonces :

$$A\ a = A\ V - V\ a = R \text{ tang } (\Delta/2) - V\ a;$$
$$B\ b = B\ V - V\ b = R \text{ tang } (\Delta/2) - V\ b.$$

Nótese que, donde (como en el ultimo caso) $B\ b$ es negativo, $b$ está *despues* de $B$ y $B\ b$ debe marcarse desde $b$ *hacia* el vertice, $V$, para determinar $B$.

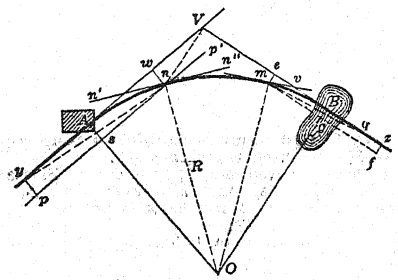

Fig. 38.

**Cualquiera de los puntos, A o B de la curva inaccesibles.**

**116. T. C. (A) inaccesible.** Fig. 38. Se necesita determinar un punto accesible, $n$, en la curva, y una tangente, $n'\ n''$, en el punto $n$. El punto, $n$, (se prefiere una estacion) debe dominar una visual, $n\ p$, paralela a la tangente, $A\ V$.

Sea $A\ O\ n$ la extension del arco, $A\ n$, (aprox, $A\ O\ n^\circ = D^\circ \times A\ n/100$). Sea $w\ n$ normal a la tangente $A\ V$, y sea $n\ s = p\ s$. Entonces $n\ s = p\ s = w\ A = y\ A = R$ sen $A\ O\ n$; $w\ n = A\ s = y\ p = R$ senoverso $A\ O\ n$; y $V\ w = V\ A - A\ w = T - A\ w = T - n\ S$.

Buscar la linea $n\,p$ (o, la $n\,p'$), y el punto, $n$, por uno de los dos métodos alternativos siguientes :

(1) Desde $p$, trazar $p\,n \parallel A\,V$, haciendo $p\,n = 2\,p\,s = 2\,R_s$ en $A\,O\,n$. O bien :

(2) Desde $V$, trazar $V\,w$ a $w$ ; midase $w\,n$ hasta $n$ ; y desde cualquier otro punto, $y$, sobre la tang $A\,V$, midase $y\,p = w\,n$ ; o desde $n$, trácese $y\,n\,p$ (tang $y\,n\,p = w\,n/w\,y$); o, desde $n$, tracese $V\,n\,p'$ (tang $V\,n\,p' = w\,n/V\,w$).

Entonces, para la tang, en $n$, tracese $n'\,n\,s = n''\,n\,p' = A\,O\,n$.

**117. C. T. (B) inaccesible.** Fig. 38. Se requiere determinar un punto, como $z$ ó $q$, en la tangente, $V\,B$, mas allá de $B$.

Damos tres metodos alternativos, como sigue :

Desde cualquier punto, como $m$, en la curva, a una distancia conocida desde $B$, tirese $m\,f \parallel$ a la tangente, $V\,B$. Entonces :

(1) Desde $m$, y desde cualquier otro punto, como $f$, en $m\,f$, tracense ordenadas $= m\,e = f\,z = R$ senoverso $B\,O\,m$, determinando la tangente, $V\,B$, y el punto, $z$. O bien :

(2) Desde $m$, trácese cualquier angulo, $f\,m\,q$, a una linea, $m\,q$, intersectando la tang $V\,B$, y trácese $m\,q = e\,m/\text{sen}\ f\,m\,q$, a $q$ que estará en la tang $V\,B$. Entonces $B\,q = q\,e - e\,B = m\,e \cot f\,m\,q - R$ sen $B\,O\,m$. O bien :

(3) Desde $m$, trácese $f\,m\,v = B\,O\,m$, determinese la tang, $m\,v$, y trácese $m\,v = R$ tang $(B\,O\,m/2)$. Entonces $v$ sera un punto en la tang $V\,B$. Desde $v$ vease hacia $m$, y tracese $m\,v\,V = B\,O\,m$. Pongase el anteojo, mirando a lo largo de la tang, $V\,B$. Entonces un punto, $z$ ó $q$, despues de $B$, puede encontrarse por los métodos dados en ¶ 110, etc., para obstáculos en las lineas rectas.

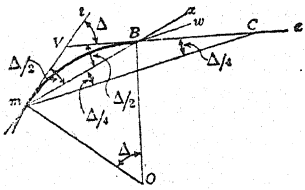

**Fig. 39.**

**118. Fig. 39. La C. T. (B) aunque accesible, no es ap ropiada**pa a punto del tránsito. Se necesita encontrar la tangente, $B\,z$.

Fijese cualquier punto conveniente, $m$, en la curva. Midase la cuerda, $m\,B$. Sea $\Delta$ = el angulo, $m\,O\,B$ = extension de la curva entre $m$ y $B$.

Desde $m$, tracese una tang, $m\,t$. Mirese hacia $B$. Entonces el angulo $t\,m\,B = \Delta/2$. Tracese $B\,m\,C = \Delta/4 = t\,m\,B/2$.

Tracese $B\,C = B\,m$, hasta encontrar la linea $m\,C$. Entonces $C$ es un punt en la tangente, $B\,z$.

Demostracion.

Como $m\,B\,C$ es isosceles, tenemos $B\,C\,m = B\,m\,C = \Delta/4$.

Extiendase $m\,B$, como hasta $x$, y tracese $B\,w \parallel m\,C$.

Entonces, del paralelismo de los lados :

$$x\,B\,w\ (= B\,m\,C) = \Delta/4;$$
$$w\,B\,C\ (= B\,C\,m) = \Delta/4;$$
$$\text{y}\ x\,B\,C\ (= x\,B\,w\ + w\,B\,C) = \Delta/2.$$

Sea $B\,z$ una tangente a la curva en $B$.

Entonces $x\,B\,z$ ( = el angulo opuesto $V\,B\,m$) $= \Delta/2 = x\,B\,C$, y $B\,C$ por consiguiente coincide con la tangente, $B\,z$.

## PROBLEMAS DEL TRAZADO DE CURVAS

(Vease tambien : Replanteo, ¶ ¶ 155, etc.)

### Soluciones Gráficas.

**119.** Gran parte de los problemas de curvas pueden resolverse con facilidad gráficamente, con suficiente aproximacion, y con la ventaja adicional de que el dibujo muestra las relaciones de las distintas líneas con mas claridad que el cálculo, y asi reduce la posibilidad de un error serio. La escala que se adopte depende de la naturaleza del problema y del grado de aproximacion que se requiera. Rara vez ser amenor de 1 pulg = 20 pies (digamos $^1/_{250}$). Lo que sigue se da como indicacion. Véase también ¶ 128.

**120. Ejemplo.** Fig. 46. Se desea resolver graficamente el problema del ¶ 131, a saber : Dadas dos curvas, $A\ B'$ y $B\ G$ de diferentes radios, $R_g$ y $R_s$, y diferentes centros, $O_g$ y $O_s$, y dando las tangs, $A\ V$ y $V\ B$, con su extension o desarrollo, $\Delta$; se desea buscar la linea radial comun $O_g\ E$, de las dos curvas; sus respectivos desarrollos, $g$ y $s$, y la dist mas corta, $d$ (que estara en la linea $O_g\ E$) entre ellos; donde se desee unir tambien las dos curvas por una espiral.

Desde $A$, tracese $A\ O_g \perp A\ V$ y ademas $= R_g$.
Desde $B$, tracese $B\ O_s \perp B\ V$ y ademas $= R_s$.
Por $O_g$ y $O_s$ tracese $O_g\ E$, como radio a ambas curvas.
Midanse los angulos, $g$ y $s$, y la dist, $d$.

Vease carta de C. M. Estabrook, Eng Record 1906 abril 7, p. 466.

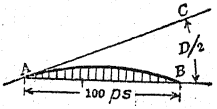

**Fig. 40.**

**121. Trazar una curva circular de radio grande.** Fig. 40. Tracese una cuerda, $A\ B$, que represente 100 pies en la escala. Divídase $A\ B$ en 20 espacios iguales. En cada punto de division, levantese una ordenada normal a la cuerda, dándoles el largo de las 19 ordenadas que correspondan en la tabla, pp. 976-7 para la agudeza dada, $D$. Unanse los extremos de las ordenadas.

**122.** Si la curva $A\ B$ es la linea de centro, las curvas para los carriles, pueden trazarse a una dist de $A\ B$ igual a la mitad del ancho de via. Ordinariamente es bastante exacto medir estas distancias en las direcciones de las ordenadas, ya trazadas. De lo contrario las distancias deben medirse radialmente desde la curva, $A\ B$; i. e., a angulos rectos con las tangentes trazadas (vease ¶ 124) en los extremos de las 19 ordenadas.

**123.** El angulo, $C\ A\ B$, entre la cuerda de 100 pies, $A\ B$, y una tangente, $A\ C$ en cada extremo, $A$ ó $B$, de la cuerda, es $D/2$, donde $D$ = la agudeza de la curva = desarrollo (angulo central) subtendido por la cuerda de 100 pies.

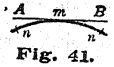

**Fig. 41.**

**124. Trazar una tangente a una curva**, en un punto dado, $m$, fig. 41, Desde $m$, tracense dos distances iguales, $m\ n$, $m\ n$, a la curva. Por $m$, tracese $A\ B$. paralela a $n\ n$. Entonces $A\ B$ sera tangente a la curva en $m$.

## Soluciones en el campo.

**125.** Muchos problemas son generalmente, con suficiente aproximacion y facilidad, resueltos por **tanteo en el campo**, ayudados, donde es necesario, por plantillas o transportadores de curva (vease ¶ ¶ 105-107) y un tablero de croquis de campo.

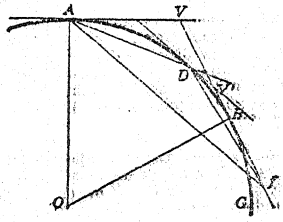

**Fig. 42.**

**126. Ejemplo.** Fig. 42. En una curva dada, $A\ G$, encontrar el punto $B$, desde el cual podamos trazar la tang. $B\ f$ por un punto dado, $f$.

Esto se resuelve trigonometricamente en el ¶ 129, fig. 44.

Con el instrumento en cualquier punto como $A$, en la curva, vease a lo largo de la tangente, $A\ V$; midase el angulo, $V\ A\ f$, y tracese el angulo, $V\ A\ D = V\ A\ f/2$. Con el instrumento en $D$, donde la linea $A\ D$ corta a la curva, repitase el procedimiento, mirando a lo largo de la tangente, $D\ V'$, y a $f$, midiendo el angulo $V'\ D\ f$, y trazando $V'\ D\ f/2$ (no señalado) a la curva en un punto cerca de $B$, y asi lo demas aproximandose a $B$. Cuando $f$ se ve en la tangente, $B\ f$, el instrumento está en el punto, $B$ que se busca.

## Soluciones Geométricas.

A continuacion se dan soluciones geometricas de unos pocos problemas tipico de frecuente uso.

**Advertencia.**

**127.** Cuando $\Delta$ es grande, tengase cuidado con los **cambios necesarios en los signos** + y −. Vease ¶ 69.

Asi, en la fig. 46, ¶ 131, si $\Delta > 90^\circ < 180^\circ$, tenemos sen $\Delta$ positivo pero cos $\Delta$ negativo; haciendo $B'\ I$ positivo, pero $V\ i$ negativo.

En general, el uso de los signos, + y −, en nuestro texto, se refiere a nuestras figs, en las cuales, por conveniencia, la extension $\Delta$ se hace generalmente $< 90^\circ$

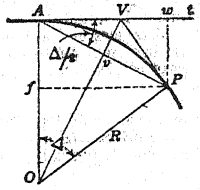

**Fig. 43.**

**128. Pasar una curva por un punto dado**, $P$. Fig. 43.

Dando, direccion de la tangente, $A\ t$; la T. C., $A$; y las co-ordenadas, $A\ w$ y $w\ P$, del punto dado, $P$;

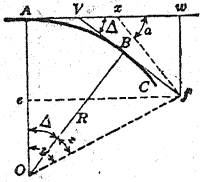
Se desea conocer, $\Delta$ y $R$ (o $D$), para la curva, $A\ P$. Aqui : tang $(\Delta/2) = w\ P/A\ w$; $R = f\ P/\text{sen}\ \Delta = A\ w/\text{sen}\ \Delta = w\ P/\text{senoverso}\ \Delta$.

Dando $R$ en lugar de $A\ w$; se requiere, $\Delta$ y $A\ w$. Aqui : senoverso $\Delta = w\ P/R$; $A\ w\ (= P\ f) = R$ sen $\Delta$.

Graficamente, únase $A\ P$, midase angulo, $w\ A\ P = \Delta/2$, divídase la cuerda $A\ P$ en $v$, tírese una línea en la dirección $O\ v\ V$, perpendicular a $A\ P$, que corta $A\ t$ en $V$, y midase $A\ V$ y $V\ P$. Entonces $V$ es el vértice de la curva $A\ P$ que une $A$ y $P$ y es tangencial a $A\ t$ en $A$; $A\ V$ y $V\ P$ son sus semitangentes; y tenemos:

$$\Delta = 2\ w\ A\ P; \qquad R = A\ V/\tan\ (\Delta/2) = V\ P/\tan\ (\Delta/2).$$

Fig. 44.



**129.** Fig. 44. En una curva dada, $A\ C$, **buscar el punto B, desde donde una tangente, B f, pase por un punto dado, f.** Para solucion con el instrumento y aproximada, vease ¶ 126. Fig. 42.

Dando, el radio, $R$, punto de la curva, $A$, la dirección de la tangente inicial, $A\ V$, y las co-ordenadas, $A\ w$ y $w\ f$, del punto dado, $f$.

(Si las co-ordenadas, $A\ w$ y $w\ f$, no son dadas, vease abajo.) Se desea el angulo, $\Delta$. Por $f$, tírese $e\ f \perp A\ O$. Entonces:

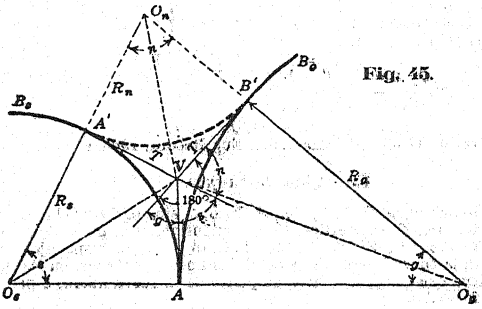
$$A\ e = w\ f; \qquad e\ f = A\ w;$$

$$\text{y tang } y = \frac{e\ f}{e\ O} = \frac{A\ w}{R - w\ f}; \qquad \cos z = \frac{R}{O\ f} = \frac{R}{A\ w/\text{sen } y}; \quad \Delta = y - z.$$

**Si las co-ordenadas, A w y w f, no son dadas,** y si no pueden medirse facilmente; tómese cualquier punto conveniente, como $x$, en la tang inicial, $A\ V$; midase $x\ f$ y $A\ x$, y el angulo, $A\ x\ f$, ó su suplemento, $a = 180° - A\ x\ f$. Entonces:

$$A\ w = A\ x + x\ w = A\ x + x\ f \cos a;$$
$$w\ f = x\ f \text{ sen } a = x\ w \text{ tang } a.$$

Fig. 45.



**130.** Fig. 45. **Teniendo dos curvas,** $A\ B_\beta$ y $A\ B_g$, empezando desde un punto comun de la curva, $A$, se desea **conectarlas por medio de una tercera curva,** $A'\ B'$, tangente a ambas curvas y que empieza desde un punto dado, $A'$ en una de las dos curvas.

Dando, ambos radios, $R_\beta$ y $R_g$, y el desarrollo, $\Delta_\beta$, (o $\beta$) $= A'\ O_\beta\ A$, de la curva que contiene el punto dado, $A'$;

Se busca la semitangente comun, $T$; la extension, $\Delta_g$ (o $g$) de $A\ B'$, y el desarrollo $\Delta_n$ (o $n$) y el radio, $R_n$, para la nueva curva, $A'\ B'$.

Aqui tenemos :

$T = A\ V = A'\ V = B'\ V = R_s \text{ tang } (s/2) = R_g \text{ tang } (g/2) = R_n \text{ tang } (n/2).$

Por lo tanto :

$\text{Tang } (g/2) = T/R_g\ ; \qquad n = 180° - (s + g); \qquad R_n = T/\text{tang } (n/2).$

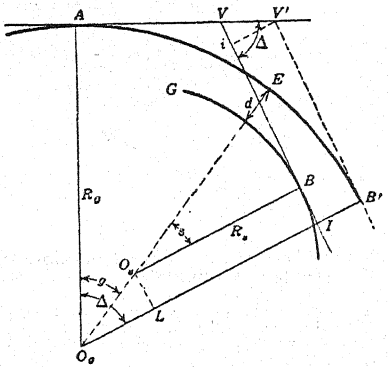


**Fig. 46.**

**131. Fig. 46, Dando dos curvas.** *A E* y *B G*, con radios diferentes dados, $R_g$ y $R_s$, y centros diferentes, $O_g$ y $O_s$, y dandose las semitangentes, *A V* y *V B*, con sus angulos centrales o desarrollos, Δ; se requiere buscar la linea radial comun, $O_g$ *E*, de las dos curvas, sus ang centrales, $\Delta_g$ (o *g*) y $\Delta_s$ (o *s*) y la distancia mas corta, *d*, entre ellas (*d* estará en la linea $O_g$ *E*, que une los centros, $O_g$ y $O_s$, de las dos curvas). Para la solucion gráfica, vease ¶ 120.

Tracese $O_g B' \perp V B$, y extiéndase la curva *A E* que intercepta $O_g B'$ en *B'*. Tracese $V' B' \parallel V B$. Desde *V'* tracese $V' i \perp V E$. Entonces :

$B'\ V' = A\ V' = R_g \text{ tang } (\Delta/2); \qquad V\ V' = A\ V' - A\ V;$

$B'\ I\ = V'\ i = V'\ V \text{ sen } \Delta; \qquad V\ i = V'\ V \cos \Delta.$

Trácese $O_s L \perp O_g B'$. Entonces :

$O_s L = B\ I\ = B'\ V' + V\ i - V\ B;$

$O_g L = O_g B' - L\ I\ - B' I = R_g - R_s - B' I;$

$\text{Tang } s = O_s L/O_g L;$

$\Delta_g = \Delta - \Delta_s;$ y

$d = R_g - R_s - (O_g L) \text{ sec } s.$

Véase carta de Wm. R. Dunham, Jr., Eng Record, 1906, abril 7, p. 466.

## Cambios de Lugar.

**132.** En lo que sigue, *R*, *T*, *E*, etc., *A*, *V*, *B*, Δ, etc., indican : el radio dado, semitan, dist ext, etc., T. C., vertice, C. T., extension, etc., para la curva *existente*; y *R'*, *T'*, *E'*, etc., *A'*, *V'*, *B'*, Δ', etc., indican largos correspondientes, puntos y angulos para la curva *nueva*. En general, las lineas *continuas*, en las figs, se refieren a la curva existente; las lineas de punto de la curva *nueva*, o para la demostracion de formulas.

### Con Tangentes Inalterables.

**133.** Fig. 47. Cambio de curva que une dos tangentes dadas (Δ y *V* constante); se requiere el cambio de *R*, *T* y *E* (*E* = *V P*) dados.

Aqui :

$T\ (= A\ V) = R \text{ tang } (\Delta/2); T'\ (= A'\ V) = R' \text{ tang } (\Delta/2); T - T' = A\ A';$

$E\ (= V\ P) = R \text{ exsec } (\Delta/2) = T \text{ tang } (\Delta/4); E'\ (= V\ P') = R' \text{exsec } (\Delta/2) = T' \text{ tang } (\Delta/4); E - E' = P\ P'; R - R' = (O\ O') \cos (\Delta/2).$

Por consiguiente :

1. Dando $T'$; buscar $R'$ y $E'$.

$$R - R' = (T - T') \cot (\Delta/2);$$
$$E - E' = (R - R') \operatorname{exsec} (\Delta/2) = (T - T') \tan (\Delta/4).$$

2. Dando $E'$; buscar $R'$ y $T'$.

$$R' = R\,E'/E; \; R - R' = \frac{E - E'}{\operatorname{exsec} (\Delta/2)};$$

$$T - T' = (R - R') \tan (\Delta/2) = (E - E') \cot (\Delta/4).$$

3. Dando $R'$; buscar $T'$ y $E'$.

$$T - T' = (R - R') \tan (\Delta/2);$$
$$E - E' = (R - R') \operatorname{exsec} (\Delta/2) = (T - T') \tan (\Delta/4).$$

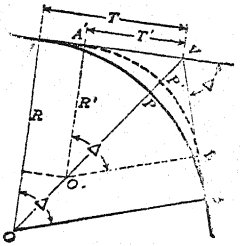

**Fig. 47.**

**34. Cambios en las tangentes.** Donde solamente una de las tangentes se cambia, suponemos por razon de uniformidad que esta sea la tang *final*, la tang *inicial* permanece inalterable; pero con los cambios en las letras, las instrucciones dadas se aplican igualmente al caso contrario; por tanto, donde la tangente *inicial* se cambia, la tangente *final* permanece inalterable.

**Una tangente movida paralela** a si misma ($\Delta$ constante). Cambiado el punto de la tang. $B$.

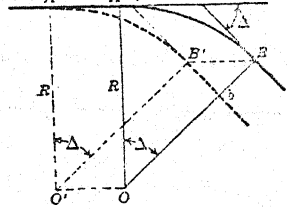

**Fig. 48.**

**135.** (1) Fig. 48. El radio, $R$, constante; punto de la curva, **A, corrido.** $A\,B\,B'$, $O\,O'$, $V\,V'$ iguales y paralelos.

Dando, la dist, $B\,b$, entre tangs. Buscar la dist movida, $A\,A'$.

$$A\,A' = B\,B' = \frac{B\,b}{\operatorname{sen} \Delta}.$$

**136.** (2) Fig. 49. Punto de la curva, $A$, constante; radio, **R, cambiado.** $A$, $B$ y $B'$, estan en linea recta; $B'$ es la interseccion de la nueva tang $V'B'$, con la cuerda larga, $A\,B$. $B\,b$ = dist entre las tangs nueva y vieja, $T = A\,V$; $T' = A\,V'$.

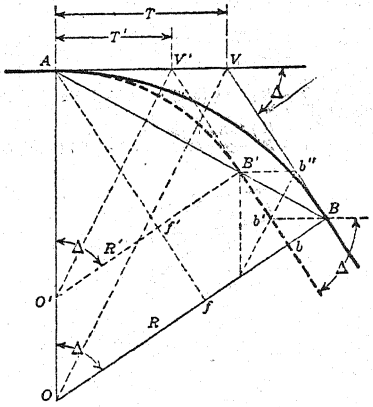

**Fig. 49.**

Se desean, $R'$, y $V\,V'$.
Desde $A$, trácese $A\,j$, $\perp O\,B$.
a. Dando, $B\,b$.
$B\,b = B\,f - b\,f = B\,f - B'\,f' = R\,\text{senov}\,\Delta - R'\,\text{senov}\,\Delta = (R - R')\,\text{senov}\,\Delta$.

Por tanto $R - R' = \dfrac{B\,b}{\text{senoverso}\,\Delta}$; $\qquad R' = R - \dfrac{B\,b}{\text{senoverso}\,\Delta}$;

b. Dando, $B\,B'$.

$$R - R' = \frac{B\,B'}{2\,\text{sen}\,(\Delta/2)}; \qquad R' = R - \frac{B\,B'}{2\,\text{sen}\,(\Delta/2)};$$

c. Dando $B\,B'$ y $A\,B$,

$$R' = R\,\frac{A\,B - B\,B'}{A\,B}.$$

En cada caso:
$V\,V' = T - T' = (R - R')\,\text{tang}\,(\Delta/2) = B'\,b'' = B\,b' = B\,b/\text{sen}\,\Delta$.

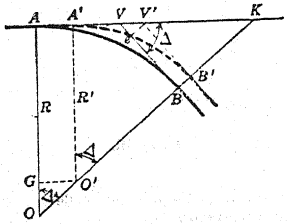

**Fig. 50.**

**137.** (3) Fig. 50. El punto **A, movido; R, cambiado.** El nuevo punto de la tang $B'$, opuesto al punto viejo $B$ de la tang.

Dando, $B\,B'$. Se desea $R'$, $A\,A'$ y $V\,V'$. Trácese $O'\,G \parallel A\,K$; y $V'\,e \parallel B\,B'$. Prolonguese el radio $O\,B$ hasta encontrar la tang $A\,K$ en $K$.

$$B\,B' = B\,K - B'\,K = R \operatorname{exsec} \Delta - R' \operatorname{exsec} \Delta = (R - R') \operatorname{exsec} \Delta.$$

Por tanto $R - R' = \dfrac{B\,B'}{\operatorname{exsec} \Delta}$; y $R' = R - \dfrac{B\,B'}{\operatorname{exsec} \Delta}$;

$$A\,A' = G\,O' = G\,O \operatorname{tang} \Delta = (R - R') \operatorname{tang} \Delta = \frac{B\,B'}{\operatorname{exsec} \Delta} \operatorname{tang} \Delta = \frac{B\,B'}{\operatorname{tang} (\Delta/2)};$$

$$V\,V' = \frac{V'\,e}{\operatorname{sen} \Delta} = \frac{B\,B'}{\operatorname{sen} \Delta}.$$

**138. Cada tang movida, paralela** a si misma. $\Delta$ constante. $R$ constante. Punto $A$, de la curva, y punto $B$, de la tang, cambiados.

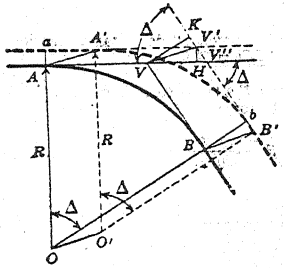

**Fig. 51.**

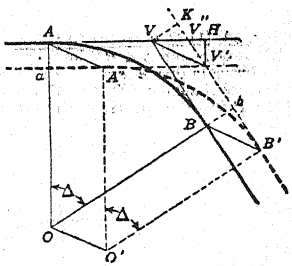

**Fig. 52.**

(1) Fig. 51. **Ambas tangs movidas** hacia afuera, como se indica, o ambas hacia adentro.

Supongamos la tang $A\,V$ movida la dist $A\,a$; la tang $V\,B$ la dist $B\,b$.

Entonces $A\,A'$, $B\,B'$, $O\,O'$ y $V\,V'$ son iguales y paralelas.

Se desea $a\,A'$ y $b\,B'$.

Sea V'' la interseccion de $A\,V$ y $V'\,B'$.

Trácese $V''\,K \parallel B\,b$, y $V'\,H \parallel A\,a$. Entonces :

$$a\,A' = V\,H = V\,V'' - V''\,H = \frac{B\,b}{\operatorname{sen} \Delta} - \frac{A\,a}{\operatorname{tang} \Delta}.$$

$$b\,B' = K\,V' = K\,V'' - V''\,V' = \frac{B\,b}{\operatorname{tang} \Delta} - \frac{A\,a}{\operatorname{sen} \Delta}.$$

**139.** (2) Fig. 52. **Una tang movida hacia adentro, la otra hacia afuera.**

Sea $A\,a$, una de las movidas y considerese como *negativa*. Entonces $V''\,H$ y $V''\,V'$ son negativas; y

$$a\,A' = V\,V'' \textit{ plus } V''\,H; \qquad b\,B' = K\,V'' \textit{ plus } V''\,V'.$$

**Tangentes divergentes, $V\,z$ y $V'\,z'$, formando un angulo $a$.**

**140. Figs 53, 54, 55. Tangentes que se cortan en el punto B, de la tangencia.**

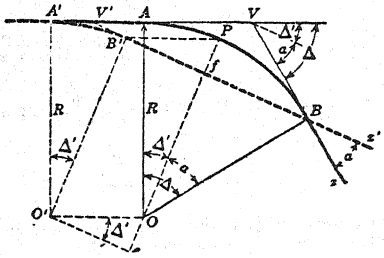

**Fig. 53.**

Fig. 53. (1) **R constante** ; $A$ movida; punto nuevo, $B'$ de la tang. Dando el radio $R$ de la curva $A\,B$ y los angulos, $\Delta$ y $a$, $\Delta' = \Delta \pm a$ *.

Se busca la dist $A\,A'$.

Hágase el angulo $A\,O\,P = \Delta'$, y por $O$, trácese $e\,P$ a la curva $A\,B$ en $P$, haciendo $O\,e = P\,f = R$ senoverso $a$. Unase $O\,O'$ y $e\,O'$. Entonces :

$$\mathbf{A\,A'} = O\,O' = \frac{O\,e}{\text{sen}\,\Delta'} = R\,\frac{\text{senoverso}\,a}{\text{sen}\,\Delta'}.$$

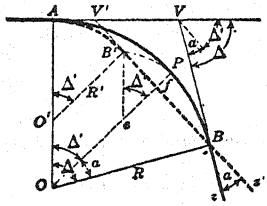

**Fig. 54.**

**141.** Fig. 54. (2). **A constante**; $R$ cambiada; punto nuevo. $B'$, de la tang.

Se busca, $R'$.

*Nota.* — A fin de que las tangs se corten en $B$, debemos tener $R' < R$. Con e objeto de que $A$ permanezca constante, $V'\,B'$ debe encontrar $A\,V$ en un punto, $V'$, delante de $A$. $a$ = angulo, $z\,B\,z'$, entre las dos tangs. $\Delta' = \Delta - a$.

Hagase $A\,O\,P = \Delta'$, y trácese $O\,P$, cortando la curva, $A\,B$, en $P$. Trácese $B'\,e \parallel O\,A$. Entonces :

$$\mathbf{R - R'}\ (= O\,O') = B'\,e = \frac{P\,f}{\text{senoverso}\,\Delta'} = R\,\frac{\text{senoverso}\,a}{\text{senoverso}\,\Delta'};$$

$$R' = R\left(1 - \frac{\text{senoverso}\,a}{\text{senoverso}\,\Delta'}\right).$$

---

* En la fig 53, $a$ es negativo, y $\Delta' = \Delta - a$. Si, como en la fig 55, $V$ está entre $A$ y $V$ $a$ es positivo, y $\Delta' = \Delta + a$.

**142.** Fig. 55 (3). **B constante**; $A$ movido; $R$ cambiado.
Se busca, $R'$ y la dist, $A\,A'$.

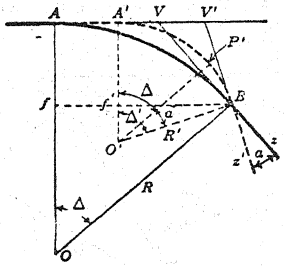

**Fig. 55.**

Trácese $B\,f \perp O\,A$, y $O'\,P' \parallel O\,B$. Entonces:

$$A\,f = A'\,f' = R \text{ senoverso } \Delta = R' \text{ senoverso } \Delta.$$

$$\therefore \mathbf{R'} = R\,\frac{\text{senoverso } \Delta}{\text{senoverso } \Delta'};$$

$$\mathbf{A\,A'} = B\,f - B\,f' = R \text{ sen } \Delta - R' \text{ sen } \Delta'.$$

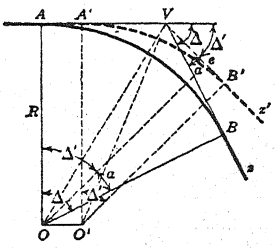

**Fig. 56.**

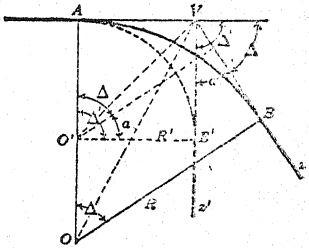

**Fig. 57.**

Figs 56 y 57. **Tangentes que se cortan en el vértice, V.**

**143.** Fig. 56 (1). **R constante**; $A$ movido; $B'$ punto nuevo, de la tang.
Dando, $R$, $\Delta$ y $a$.
Se desea correr $A\,A'$, para $A$.

$$A\,V = R \text{ tang } (\Delta/2); \qquad A'\,V = R \text{ tang } (\Delta'/2);$$

$$\therefore \mathbf{A\,A'} = A\,V - A'\,V = R\,[\text{tang } (\Delta/2) - \text{tang } (\Delta'/2)].$$

**144.** Fig. 57 (2). **A constante**; $R$ cambiado; $B'$, punto nuevo, de la tang $R'$ puede ser mayor o menor que $R$.
Dando, $R$, $\Delta$ y $a$.
Se busca, $R'$.

$$A\,V = R \tan (\Delta/2) = R' \tan (\Delta'/2);$$

$$\therefore \mathbf{R'} = \frac{A\,V}{\tan\ (\Delta'/2)} = R\,\frac{\tan\ (\Delta/2)}{\tan\ (\Delta'/2)}.$$

## Problemas de Curvas Compuestas.

**145. El punto P inaccesible.** Fig. 58. Buscar la tang comun $v_s\ v_g$, asi: $A\ v_s = v_s\ P = R_s$ tang $(s/2)$; y $B\ v_g = v_g\ P = R_g$ tang $(g/2)$; o, desde cualquier punto conveniente, como $K$ o $K'$, en cualquier ramal de la curva, trácese $K\ L$, o, $K'\ L'$ paralelo a $O_g\ P$; $K\ L = M\ P = R_s$ senoverso $K\ O_s\ P$; y $K'\ L' = M'\ P =$

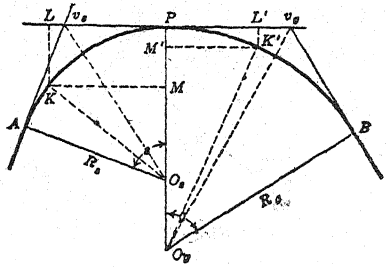

Fig. 58.

$R_g$ senoverso $K'\ O_g\ P$. Entonces $L\ P = K\ M = R_s$ sen $K\ O_s\ P$; $L'\ P = K'\ M' = R_g$ sen $K'\ O_g\ P$. Desde la tangente, $v_s\ v_g$, asi encontrada, las ramas de la curva pueden determinarse por el metodo dado en ¶ ¶ 95-98.

Si la tang comun, $v_s\ v_g$, esta obstruida, podiamos usar, en la misma forma, una linea paralela. $K\ M$ o $K'\ M'$, encontrada como se expresa arriba, dejando margen para la distancia, $M\ P$ o $M'\ P$, entre ella y $v_s\ v_g$.

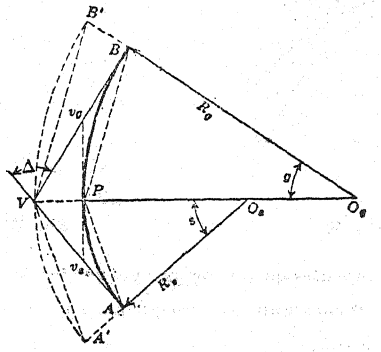

Fig. 59.

**146.** Fig. 59. Caso especial. El vértice, $V$, viene a caer en la linea radial comun $O_g\ P$, prolongada. Vease ¶ 57.

Dando, $\Delta\ (= s + g)$; $T_s = A\ V$, y $T_g = V\ B$.

Se busca, $s$, $g$, $R_s$ y $R_g$.

$$\text{Sen}\ \frac{s-g}{2} = \text{sen}\left(\frac{s}{2} - \frac{g}{2}\right) = \text{sen}\ \frac{\Delta}{2}\left(\frac{T_g - T_s}{T_g + T_s}\right) *;$$

* Véase nota al pie, pág 1023.

$s = \Delta/2 + (s - g)/2$; $\qquad g = \Delta - s$;

$\mathbf{R}_s = T_s/\tan s$; $\qquad \mathbf{R}_g = Tg/\tan g$.

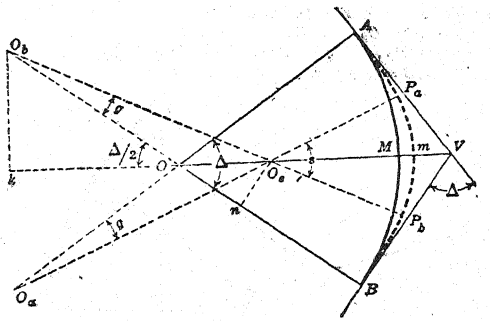

**Fig. 60.**

**147.** Figs 60-61. Sea, una curva simple, $A\ M\ B$, que une dos tangentes, $A\ V$ y $V\ B$. Conservando las mismas tangs, se desea reemplazar aquella por **una curva compuesta de tres centros.**

**148.** Fig. 60. **A. Conservando A y B.** Curva compuesta $A\ P_a\ m\ P_b\ B$.

Sea $R = O\ A = O\ M = O\ B =$ radio de la curva simple, $A\ M\ B$;

$R_s = O_s\ P_a = O_s\ m = O_s\ P_b < R$;

$R_g = O_a\ A = O_b\ B > R$;

$s = P_a\ O_s\ P_b$; $\qquad g = A\ O_a\ P_a = B\ O_b\ P_b$;

$\Delta = A\ O\ B = s + 2\ g =$ desarrollo o angulo central de la curva simple, $A\ M\ B$;

$M\ m =$ dist entre los puntos medios de las dos curvas.

Prolonguese $V\ O$ hasta $k$, y trácese $O_b\ k \perp V\ K$. Entonces :.

$O_b\ k = O_b\ O \operatorname{sen}(\Delta/2) = (R_g - R) \operatorname{sen}(\Delta/2) = O_b\ O_s \operatorname{sen}(s/2) = (R_g - R_s) \operatorname{sen}(s/2)$;

De donde :

$$\operatorname{Sen} s/2 = \frac{(R_g - R) \operatorname{sen}(\Delta/2)}{R_g - R_s}; \qquad g = \frac{\Delta - s}{2};$$

$$\mathbf{R}_g = \frac{R \operatorname{sen}(\Delta/2) - R_s \operatorname{sen}(s/2)}{\operatorname{sen}(\Delta/2) - \operatorname{sen}(s/2)}.$$

Trácese $O_s\ n \perp O\ B$. Entonces :

$$O\ O_s = O_s\ n/\operatorname{sen}(\Delta/2) = (R_g - R_s) \operatorname{sen} g/\operatorname{sen}(\Delta/2);$$

y $$\mathbf{M\ m} = O\ O_s + O_s\ m - O\ M = O\ O_s - (O\ M - O_s\ m)$$

$$= (R_g - R_s) \frac{\operatorname{sen} g}{\operatorname{sen}(\Delta/2)} - (R - R_s).$$

---

* De las ecuaciones para $\operatorname{sen}(A + B)$, $\cos(A + B)$, $\operatorname{sin}(A - B)$ y $\cos(A - B)$, ¶¶ 15, 16, pag 106 se tiene que

$$\operatorname{sen} \frac{s - g}{2} = \operatorname{sen} \frac{\Delta}{2} \times \frac{\tan(s/2) - \tan(g/2)}{\tan(s/2) + \tan(g/2)},$$

y de $Tg = T_s \dfrac{\tan(s/2)}{\tan(g/2)}$, ¶ 57 y pag 39, ¶ (5), tenemos

$$\frac{Tg - T_s}{Tg + T_s} = \frac{\tan(s/2) - \tan(g/2)}{\tan(s/2) + \tan(g/2)}$$

**149. Fig. 61. B. Conservando el mismo punto medio, M.** Curva compuesta, $A' P_a M P_b B'$.

Sea $R = O\ A = O\ M = O\ B$ = radio de la curva simple, $A\ M\ B$;

$R_s = O_s\ P_a = O_s\ M = O_s\ P_b < R$;

$R_g = O_a\ A' = O_b\ B' > R$;

$= P_a\ O_s\ P_b$; $\quad g = A'\ O_a\ P_a = B'\ O_b\ P_b$;

$= A\ O\ B = s + 2\ g$.

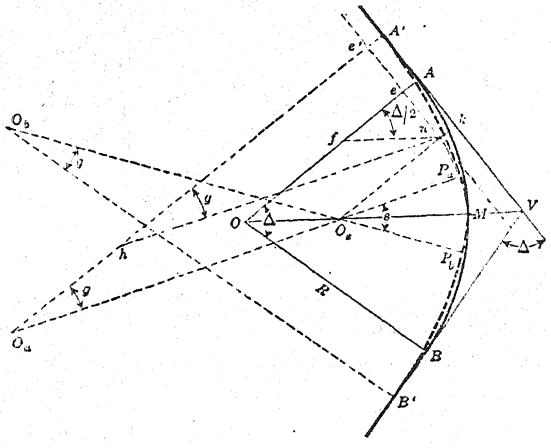

**Fig. 61.**

En la fig., prolonguese la curva, $P_b\ M\ P_a$, hasta encontrar en $n$ la linea $O_s k$, $\| O\ A$; y tracese $n\ h \| P_a\ O_a$, y $nf = O_s\ O$. Entonces $n$ es un punto en la cuerda larga, $M\ A$ (no dibujada), y en la cuerda larga, $P_a\ A'$ (no dibujada); la tang, $e\ n$, por $n$, es $\| A\ V$; y

$n\ k = A\ e = n\ f$ senoverso $(\Delta/2) = (R - R_s)$ senoverso $(\Delta/2)$

$= A'\ e' = n\ h$ senoverso $g \quad = (R_g - R_s)$ senoverso $g$;

de donde tenemos:

$$\text{senoverso } \mathbf{g} = \frac{n\ k}{R_g - R_s} = \frac{(R - R_s) \text{ senoverso } (\Delta/2)}{R_g - R_s};$$

$$\mathbf{R}_g = R_s + (n\ k/\text{senoverso } g);$$

$$\mathbf{R}_s = R - [n\ k/\text{senoverso } (\Delta/2)].$$

$$\text{Cot } (\mathbf{g}/2) = \text{cot } (\Delta/4) + (A\ A'/n\ k); \qquad \mathbf{s} = \Delta - 2\ g;$$

$$\mathbf{A\ A'} = \mathbf{B\ B'} = k\ A' - k\ A = n\ k\ [\text{cot } (g/2) - \text{cot } (\Delta/4)].$$

**150. Correr C. T. a lo largo de su tangente.** Fig. 62. Dando una curva compuesta, $U\ P\ E$, que une dos tangs, $U\ V$ y $V\ E$. Conservando la misma direccion de las tangentes, y el radio inicial dado, $R_u$, se desea que la segunda rama una la misma tang final, $V\ E'$, como antes pero en $E'$, en lugar de $E$.

Se busca, el nuevo radio final, $R_e'$, y la nueva distribucion del desarrollo, $\Delta$, entre las dos ramas; *i, e.*, los nuevos valores ($u'$ y $e'$), de los desarrollos, $u$ y $e$. El cambio envuelve la corrida del C. C, desde $P$ a un punto nuevo, como $P'$.

Sea $y$ ( $= E\ E'$) *positivo* cuando se mide hacia *adelante* desde $E$, como en la fig. 62.

Como en la fig. 62, supongamos, que el indice, $e$ se refiere a la rama cuyo radio $R_e$, se vaya a cambiar, y el indice $u$ a la otra rama.

Como las direcciones de las tangentes son inalterables, tenemos $\Delta = u + e = u' + e'$; y $u' = u + e - e'$.

En la Fig. prolonguese la rama $u$, $U P$, hasta encontrar, en $n$, la linea $O_u n$, paralela a $O_e E$ ($n$ esta en cualquier linea recta $P E$, $P' E'$, que una C. C. con el correspondiente punto de tangencia). Trácese $n i$, $\parallel$ y ademas $= O_u O_e = R_e - R_u = i E$. Trácese $n k'$, $\perp O_e E$ y $\perp O_e' E$.

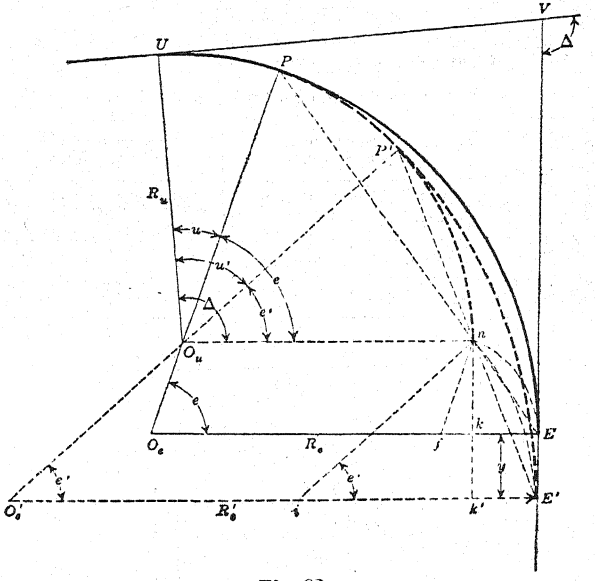

**Fig. 62.**

(1) Dando el cambio ($= P O_u P' = u' - u = e - e'$) en los desarrollos o angulos centrales; se busca $R_e'$ y ($= E E'$). Aqui tenemos $e' = P' O_e' E' = P' O_u n = \Delta - (u + P O_u P')$. En la Fig. trácese $n i \parallel$ y tambien $= O_u O_e' = R_e' - R_u$. Entonces:

$E' k' = (R_e' - R_u)$ senoverso $e' = E k = (R_e - R_u)$ senoverso $e$. Por tanto,

$$\mathbf{R}e' (= O_e' E') = O_e' i + \frac{E k}{\text{senoverso } e'} = R_u + (R_e - R_u) \text{ senoverso } e/\text{senov } e';$$

$$\mathbf{y} (= \mathbf{E E}' = n k' - n k) = E' k' \cot (e'/2) - E k \cot (e/2)$$
$$= E k [\cot (e'/2) - \cot (e/2)].$$

(2) Dando $R_e'$; se busca $P O_u P' (= u' - u = e - e')$ y ademas $y (= E E')$. Aqui tenemos:

$$\text{Senoverso } e' = \frac{E' k'}{n i} = \frac{E k}{n i} = \frac{(R_e - R_u) \text{ senoverso } e}{R_e' - R_u}; \text{ y}$$

$$\mathbf{P O_u P'} = e - e'; \; u' = u + P O_u P'.$$

$\mathbf{y} (= \mathbf{E E}')$ como se expresa arriba.

(3) Dando $y$ ( $= E E'$ ); se busca $P O_u P'$ ( $= e - e'$ ) y $R_e'$.

Como (vease arriba) $y$ ( $= E E'$ ) $= E k$ [cot $(e'/2)$ − cot $(e/2)$], tenemos:

$$\frac{y}{E k} = \cot (e'/2) - \cot (e/2); \text{ y } \cot (e'/2) = \cot (e/2) + \frac{y}{E k}$$

$$= \cot (e/2) + \frac{y}{(R_e - R_u) \text{ senoverso } e}. \text{ Entonces:}$$

**P $O_u$ P'** y **R'** pueden encontrarse como arriba.

**Signos mas y menos.** Vease pag 993, ¶ 69.

| | $E'$ despues de $E$ ($y$ positivo). | | $E'$ entre $E$ y $V$ ($y$ negativo). | |
|---|---|---|---|---|
| | $R_e > R_u$ (Fig. 62). | $R_e < R_u$ | $R_e > R_u$ | $R_e < R_u$ |
| $PO_uP'$..... | Positivo. | Negativo. | Negativo. | Positivo. |
| $e'$..... | $< e$ | $> e$ | $> e$ | $< e$ |
| $R_e'$..... | $> R_e$ | $> R_e$ | $< R_e$ | $< R_e$ |

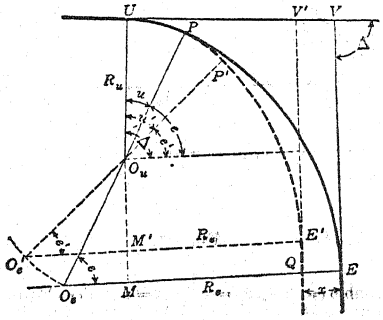

**Fig. 63.**

**151.** Fig. 63. Dando una curva compuesta, $U P E$, que una las tangs $U V$ y $V E$. Se desea **correr la tangente final**, $V E$, paralela a si misma, a la nueva posicion, $V' E'$, conservando el radio original, $R_u$ y $R_e$. El cambio envuelve la corrida del C. C. desde $P$, a un punto nuevo, como $P'$.

Como en la Fig. 63, sea el indice, $e$, el que se refiere a esa rama que una la tang, $V E$, que se va a correr; y el indice, $u$, a la otra rama.

Como $V E$ y $V' E'$ son paralelas, tenemos $\Delta = u + e = u' + e'$, o $u' = u + e - e'$.

Dando $e$, $R_e$, $R_u$ y la corrida, $x$ ( $= E Q$) de la tang (llamase *x positiva* cuando esté medida hacia dentro desde $E$, como en la Fig. 63);

Se busca la nueva distribucion del desarrollo o angulo central, $\Delta$, entre las dos ramas; y ademas los nuevos valores ($u'$ y $e'$), de los desarrollos, $u$ y $e$.

Trácese $O_u M \perp O_e E$ y $\perp O_e' E'$. Entonces:
(1) $O_e' M' = R_e - E' M' = O_e' O_u \cos e' = (R_e - R_u) \cos e'$;
(2) $O_e M = R_e - E M = O_e O_u \cos e = (R_e - R_u) \cos e$.
Restando (2) de (1), tenemos.
$E M - E' M' (= E Q) = x = (R_e - R_u)(\cos e' - \cos e)$ y.

$$\cos e' = \cos e + \frac{x}{R_e - R_u}; \quad u' = \Delta - e'.$$

**Signos mas y menos** ($\Delta < 90°$). Vease ¶ 69.

| $V' E'$ interior de $V E$ ($x$ positivo). | | $V' E'$ exterior de $V E$ ($x$ negativo). | |
|---|---|---|---|
| $R_e > R_u$ (Fig. 63). | $R_e < R_u$ | $R_e > R_u$ | $R_e < R_u$ |
| $e' < e$..... | $e' > e$ | $e' > e$ | $e' < e$ |

**152.** Figs 64. Dando una curva compuesta, $U P M E$, que una las tangs, $U V$ y $V E$; se desea que la **direccion de la tangente V E se cambie** a $V' E$, formando $V' E$, con $V E$, el angulo, $a = V E V'$, y pasando por $E$.

Conservando el primer radio, $R_u$, y el punto de la curva, $U$, se busca el radio nuevo, $R_e'$, que reemplaza $R_e$, y los cambios en $u$ y $e$. El cambio envuelve la corrida del C. C. desde $P$ al punto nuevo, $P'$.

$\Delta$, $\Delta'$ = extension o ang central de la curva compuesta para curva vieja y nueva respectivamente.

$R_u$ = radio inicial (invariable en este problema).

$R_e$, $R_e'$ = radio final para curvas viejas y nuevas respectivamente.

$u$, $u'$ = desarrollo o ang central de $R_u$ para curvas viejas y nuevas respectivamente.

$e$ = desarrollo o ang central de $R_e$.

$e'$ = desarrollo o ang central de $R_e'$.

$a = V E V'$.

Entonces $\Delta = u + e = \Delta' \pm a$; $u = \Delta - e = \Delta' \pm a - e$.
$e = \Delta - u = \Delta' \pm a - u$

$\Delta' = u' + e' = \Delta \pm a$; $u' = \Delta' - e' = \Delta \pm a - e'$
$e' = \Delta' - u' = \Delta \pm a - u'$.

Se busca, $R_e'$, $\Delta'$, $e'$, y $u'$.

**153. (1) Dando $\Delta$, a, u, e, $R_u$ y $R_e$.** Metodo grafico.

Desde $E$, trácese una linea en la direccion, $E O_e' \perp V' E$. En esta linea midase $E H = R_u$. Una $H O_u$. Dividase $H O_u$ en $h$, y trácese $h O_e' \perp H O_u$, hasta encontrar $E H$ (prolongando si fuera necesario), en $O_e'$. Entonces, $R_e' = R_u \pm H O_e' = R_u \pm O_u O_e' = E H \pm H O_e' = E O_e'$.

Desde $O_e'$, por $O_u$, trácese $O_e' P'$, hasta tocar la rama $U$, $U P$ (prolongada si fuera necesario), en el C. C. nuevo, en $P'$. Entonces:

$$e' = P' O_e' E; \; u' = U O_u P'.$$

| Cuando. | Fig. | Tenemos $R_u$. | $O_e$ y $O_e'$ en. | Focos. | Eje mayor |
|---|---|---|---|---|---|
| $R_e > R_u$. | $a$, | $= O_e' E - O_e' O_u$<br>$= O_e E - O_e O_u$<br>$= R_e - (R_e - R_u)$ | Hiperbola. | $O_u$, $E$ | $m n = R_u$ |
| $R_e < R_u$. | $b$, | $= O_e' E + O_e' O_u$<br>$= O_e E + O_e O_u$<br>$= R_e + (R_u - R_e)$ | Elipse. | $O_u$, $E$ | $m n = R_u$ |

**154. Figs 64. (2) Dando $\Delta$, a, u, e, $R_u$, $R_e$, U V y E V.**

O, si $U V$ y $E V$ no son dados, tenemos:

**U V** sen $\Delta = R_u$ senoverso $\Delta + (R_e - R_u)$ senoverso $e$; vease ec (74).

**E V** sen $\Delta = R_e$ senoverso $\Delta - (R_e - R_u)$ senoverso $u$; vease ec (72).

$\mathbf{E\ V'} = E\ V$. sen $\Delta$/sen $\Delta'$; $\mathbf{V\ V'} = E\ V$, sen $a$/sen $\Delta'$;

$\mathbf{U\ V'} = U\ V \pm V\ V'$;

$$\text{Tang}\ \frac{\mathbf{e'}}{2} = \frac{U\ V' \text{ sen } \Delta' - R_u \text{ senoverso } \Delta'}{E\ V' + U\ V' \cos \Delta' - R_u \text{ sen } \Delta'}.$$ Vease ec (77);

$$\mathbf{u'} = \Delta' - e' = \Delta \pm a - e';$$

$\mathbf{R_e}$ sen $e' = E\ V' + U\ V' \cos \Delta' - R_u$ sen $\Delta' + R_u$ sen $e'$ vease ec (78);

$\mathbf{P\ O_u\ P'} = \pm (e - e' \pm a) = \pm (u' - u)$.

Usar + (como en las Figs 64) $U\ V' > U\ V$, entonces $\Delta > \Delta'$, y $Re' < Re$ · y vice-versa. Esto afecta los signos (+ y −) de los otros valores.

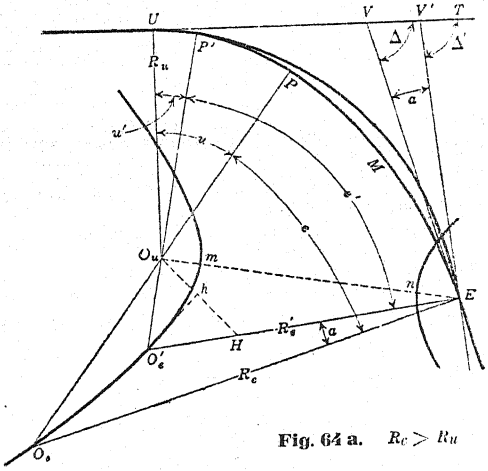

**Fig. 64 a.** $R_e > R_u$

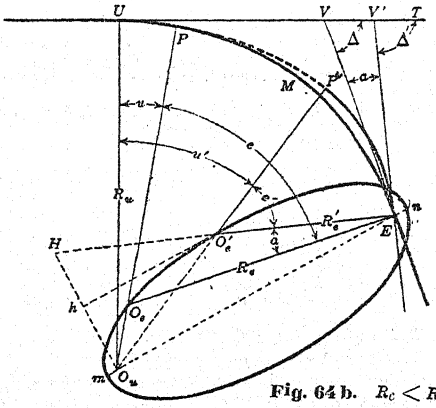

**Fig. 64 b.** $R_e < R_u$

## RETRAZADO DE CURVAS

### Buscar la agudeza, D, de una curva existente.

**155. Fig. 65. Vertice, V, accesible,** y se dan las direcciones de las tangs $V A$ y $V B$. Se busca el radio, $R$ (o la agudeza, $D$); $A$ y $B$.

Con el instrumento en $V$, midase $\Delta$; y desde cualquier tang tracese el ángulo, $B\ V\ P$ o $A\ V\ P = (180^o - \Delta)/2$. Midase el exterior, $E = V\ P$, desde $V$ a la línea de centro de la via existente. Entonces tenemos :

$$R\ (= O\ A = O\ B) = E/\text{exsec}\ (\Delta/2);$$

$$T\ (= A\ V = V\ B) = E/\text{tang}\ (\Delta/4) = R\ \text{tang}\ (\Delta/2);$$

$$\text{Sen}\ (D/2) = 50/R.$$

Aprox, tenemos $D = 5730/R$.

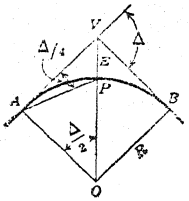

Fig. 65.

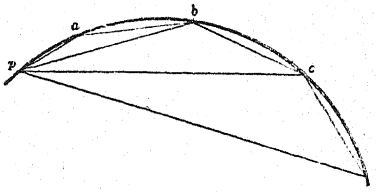

Fig. 66.

**156. Fig. 66. Vertice, V** (no indicado), **inaccesible.**

Levantese sobre la curva un punto, como $p$, en la linea de centro de la curva (preferible en, o cerca de cualquier extremo); y tracense y midanse los angulos periféricos, $a\ p\ b$, $b\ p\ c$, etc., cada uno subtendido por una unidad de cadena (como $a\ b$, $b\ c$, etc.) en la curva. El promedio de estos angulos pueden tomarse (aproximadamente) como el angulo periferico, $D/2$, de la curva; y dos veces $(D/2) = D$ como la agudeza *.

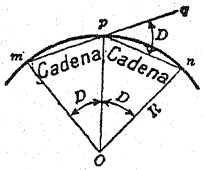

Fig. 67.

**157.** Fig. 67. O bien levántese sobre la curva cualquier punto, $p$, en la línea de centro de la via. Midase una cadena, $p\ m = p\ n$, en cada direccion, a $m$ y a $n$, tambien en la linea de centro. Midase el angulo $q\ p\ n = D$ *.

---

* En todo este trabajo, la curva entera debe recorrerse tanto como sea posible. El metodo se repite, sobre diferentes partes de la curva, y se toma un promedio; porque en curvas que se han usado por algun tiempo, se encuentra frecuentemente que la curvatura varia de un punto a otro; la via se ha corrido por el trafico y quizas ha sido alineada de nuevo a simple vista sin tener en cuenta las estacas de centro.

**153. Por ordenadas medias.** Fig. 68. En cualquier círculo :

$$(2\ R - m)\ m = (c/2)^2.$$

Aproximadamente, $2\ R\ m = (c/2)^2$;

$$\text{o aprox., } R = \frac{c^2/4}{2\ m} = \frac{c^2}{8\ m}.$$

Entonces, si una cuerda, de cualquier largo dado, $c$, subtendiendo un ang cent pequeño, se tiende entre dos puntos, $n$ y $p$, en el lado interior de la cabeza del carril exterior, y si su media ordenada, $m$, se mide en la cabeza del carril, tenemos:

$$R = (c^2/8\ m) - \text{la mitad del ancho de vía.}$$

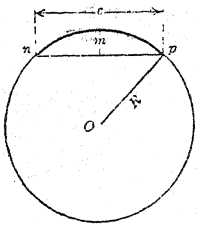

**Fig. 68.**

Usualmente la mitad del ancho de vía puede omitirse.

Entonces sen $(D/2) = 50/R$; o, aprox, $D = 5730/R$.

Si la cuerda es de 100 pies de largo (30,48 m) ( = un largo de cadena), y la ordenada media $m$, medida en pies, $D$, puede tomarse de la tabla, pags 974-5 *.

Vease *N. del T.* ¶ 11, pag. 926.)

**159. Reciprocamente, para encontrar la ordenada media, M** en pulgs, o $m$ en pies, correspondiendo a cualquiera cuerda de largo, dado $c$, en pies, y para cualquiera agudeza dada, $D$, o radio, $R$, tenemos (aprox).

$$M, \text{ pulgs} = 12\ m = 12\ c^2/8\ R = 1.5\ c^2/R.$$

Asi, con un carril de 30 pies ($c = 30$ pies aprox), en una curva de 3° ($R = 1910$ pies), tenemos, aprox : $M = 1.5 \times 900/1910 = 0{,}707$ pulgs.

Asimismo (aprox) $c = \sqrt{8\ m\ R} = \sqrt{8\ m\ 5730/D} = 214\ \sqrt{m/D}$.

Si, ahora, hacemos $M$ = la ordenada media en pulgs $= 12\ m = D$, en grados, o bien $m = D/12$, tenemos, aprox :

$$c = \sqrt{\frac{8\ D}{12} \cdot R} = \sqrt{\frac{8\ D}{12} \cdot \frac{5730}{D}} = \sqrt{3820} = 61.81 \text{ pies.}$$

Entonces, con una cuerda, $c$, 61.81 (o 62) pies largo, tenemos :

$M$ = ordenada media en pulgs = agudeza, $D$, de la curva en grados *. Compárese ¶ 178.

**160.** Fig. 69. Desde cualquier punto, como $a$ (preferible una union de carril), en el lado interior del carril exterior, diríjase una visual a otro punto tal, como $b$, de tal modo que la visual, $a\ b$, sea tangente el carril interior, como en $p$.

---

* En todo este trabajo, la curva entera debe recorrerse tanto como sea posible. El método se repite, sobre diferentes partes de la curva, y se toma un promedio ; porque en curvas que se han usado por algun tiempo, se encuentra frecuentemente que la curvatura varia de un punto a otro, la vía se ha corrido por el tráfico y quizás ha sido alineada de nuevo a simple vista sin tener en cuenta las estacas de centro.

Entonces, para la media ordenada de la cuerda, $a\ b$, tenemos $p\ p' = G =$ ancho de via. (Vease *N. del T.* ¶ 11; pag. 926.)

Sea $l =$ largo del carril, en pies; $N =$ numeros de largos de carril en el arco, $a\ p'\ b$. Entonces, $N\ l =$ arco, $a\ p'\ b$, en pies.

Sea $\delta =$ angulo, $a\ O\ b$; $C =$ cuerda, $a\ b$; $R' =$ radio del carril exterior; $R =$ radio de la linea de centro; $D =$ agudeza de la linea de centro.

Midase $C = a\ b$; o cuentese $N$, búsquese $N\ l$, y (generalmente bastante aproximado) supongase la cuerda, $a\ b =$ arco, $N\ l$. Entonces:

Tang $(\delta/4) =$ tang $p'\ a\ p = 2\ G/C$; $R' = C/2$ sen $(\delta/2)$;

$R = R' - (G/2)$; sen $(D/2) = 50/R$; o, aprox, $D = 5730/R$.

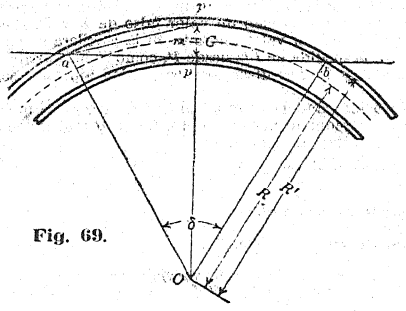

Fig. 69.

## Clasificacion de los Casos de replanteo de Curva.

**161.** Segun el método elegido los casos de replanteos, pueden clasificarse como sigue:

*A.* Vertice, $V$, accesible; curvas cortas;

*B.* Vertice, $V$, inaccesible.

1. Curvas de largo moderado;
2. Curvas largas.

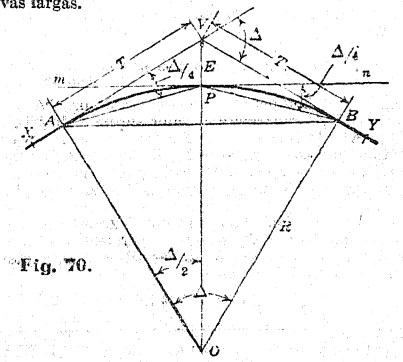

Fig. 70.

## Procedimiento.

### A. Vertice, V, accesible; curvas cortas.

**162.** Fig. 70. Fijado el vertice, $V$, así; con el instrumento, en un punto, $X$, sobre una tangente, digamos 50 pies atras del punto $A$ de la curva, mirese hacia atras por la tangente, y corrase el anteojo, mirando hacia $V$. Haciendo lo mismo en $Y$, en la otra tang, $V\ B$, encontramos la interseccion, $V$, de las dos tangs.

Encontrar $\Delta$, $E$, $R$, $D$ y $T$ como en el ¶ 155.

Entonces :

$L$ ( = largo de la curva, $A\ P\ B$, en cadenas de unidad de longitud) $= \Delta/D$.

Fíjense los puntos de la curva, $A$ y $B$, trazando $T = V\ A = V\ B$, desde $V$, o trazando $L/2$, en pies, a lo largo de la linea de centro de la curva, desde $P$. $L/2$, en cadenas de longit de unidad $= \Delta/(2\ D)$; $L/2$, en pies, $= 50\ \Delta/D$. (Vease *N. del T.*, ¶ 11, pag. 926.)

Con el instrumento en $P$, trácense los angulos rectos, $V\ P\ m$ y $V\ P\ n$, determinando la tang, $m\ n$ ; y comprobando los angulos $m\ P\ A = n\ P\ B = \Delta/4$; o bien :

Con el instrumento en $A$ y en $B$, comprúebese el angulo $V\ A\ B = V\ B\ A = \Delta/2$, o $V\ A\ P = V\ B\ P = \Delta/4$.

Si la carrilera se ha corrido en $P$, dando un valor falso de $E$, las ecuaciones anteriores daran por supuesto tambien un valor falso de $R$ y $D$. Comparese el valor de $D$, asi encontrado, con el valor anotado. Si la carrilera se ha corrido entre $P$ y $A$ o entre $P$ y $B$, la medida de $L/2$ desde $P$, como se hizo arriba, puede dar posiciones falsas para $A$ y $B$. Las discrepancias pueden ajustarse segun las circunstancias.

Trácese la curva marcándola provisionalmente. Observese qué espacio (juego), y en qué direccion, se requiere en cada punto. Reajustese si es necesario, y métanse las estacas para marcar el trazado final.

### B. Vértice, V, inaccesible.

### Curvas de largo moderado.

### a. Por Curvas de Prueba. Fig. 71.

**163.** Se da, la agudeza, $D$, de una curva vieja, cuya posicion original era $A\ B$, y las direcciones de sus tangs, $A\ V$ y $V\ B$. Se busca $\Delta$ y las posiciones de la T. C, $(A)$ y C. T. $(B)$.

Sea $A''$ la posicion supuesta de la T. C., o un punto cerca de la T. C., sobre la tang o en la tang prolongada. Situese en $A''$, y empiecese a marcar una curva de prueba, $A''\ m$, de la agudeza dada, $D$, marcando los puntos de cadena de 100 pies provisionalmente.

Si $A''$ esta distante de la T. C. $(A)$, como en la fig. 71 *, la curva de prueba, $A''\ m$, pronto se encontrara considerablemente desviada de la carrilera vieja $A\ B$ como en $m$. Midase la distancia, $m\ s$, entre la curva de prueba, $A''\ m$, y la linea de centro, $A\ B$, de la carrilera vieja. Entonces, para la movida $A''\ A$, que se busca para el punto T. C., tenemos :

$$A''\ A = m\ n = (\text{aprox})\ m\ n' * = \frac{m\ s}{\text{sen}\ \Delta_m}\ \dagger$$

donde $\Delta^m$ (o bien, $m$ †) = ang del cent de la curva de prueba entre $A''$ y $m$ *.

Supongamos que $A''\ A'$ represente el valor aproximado asi encontrado para la movida $A''\ A$. Muevase el instrumento a $A'$, y recorrase la curva de prueba, con $D$ como antes, tomando puntos de transito, $T_1$, $T_2$, etc., (con preferencia a distancias de, digamos 500 pies (como 150 m). De cada punto de tránsito, fíjese una linea corta, como $T_3\ x$, paralela a la tang original, $A\ V$. Marcando dicha linea con una aguja, como en $x$.

Tracese la curva de prueba, $A'\ T_3$, en una extension, $s$ †, hasta un punto, como $T_4$, donde su tang final, $v'\ T_4$, se supone paralela a la tang $V\ B$, de la curva vieja, $A\ B$. Por $T_4$ trácese una linea, $T_4\ u$, paralela a $V\ B$, y midase el angulo, $t$ †, entre $T_4\ u$ y $v'\ T_4$ prolongada. Entonces :

$$\Delta = s \pm t\ \dagger.$$

---

* Para facilitar la ilustracion, los angulos centrales en la fig 71, estan grandemente exagerados. En la práctica, las tangs de las dos curvas, en $m$ y en $s$, son aproximadamente paralelas.

† En la fig 71, los angulos, $\Delta_m$, $\Delta_s$ y $\Delta_t$ estan designados como $m$, $s$ y $t$, respectivamente para evitar el amontonamiento de letras.

Determinese el término, $B'$, de la curva de prueba, $A'\ B'$. La tang, $V'\ B'$, es entonces paralela a la tang $V\ B$, por $B$, y el ángulo $F\ V'\ B' = F\ V\ B = \Delta$.

Midase la dist, $B'\ e$, desde $B'$ a la linea de centro de la carrilera vieja *. Entonces, para la movida de $A'\ A = B'\ B$, que todavia se busca para traer $A'$ y $B'$ a sus propias posiciones, $A$ y $B$, respectivamente, tenemos :

$$B'\ B = \frac{B'\ e}{\text{sen}\ \Delta}\ *.$$

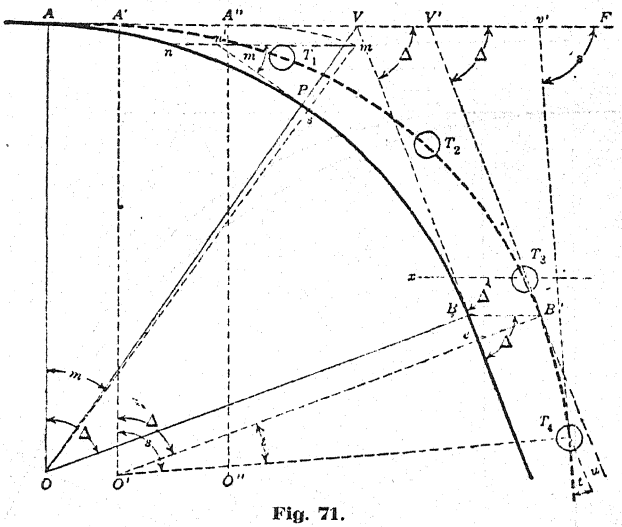

**Fig. 71.**

Cada uno de los puntos de tránsito, $T_1$, $T_2$, etc., tambien se mueve una dist $= B'\ B$, en la direccion, $T_3\ x$, paralela a la tang original, $A\ V$; la curva entera se mueve asi, en esa direccion en una dist $= B'\ B$.

Si la curva, $A'\ B'$, hubiera caido dentro (en lugar de afuera) de la carrilera existente, esta movida de la curva de prueba se hubiera hecho, por supuesto en la direccion opuesta.

De cada punto de tránsito, asi movidos, y desde $A$, la curva puede ser ahora recorrida en cada direccion, coincidiendo casi con la carrilera existente. La dist máxima desde el instrumento a la estaca, será la mitad de la dist entre dos puntos de tránsito.

---

* Para facilitar la ilustración, los angulos centrales, fig. 71, estan grandemente exagerados. En la práctica, las tangs de las dos curvas, en $m$ y en $n$, son aproximadamente paralelas.

**164.** Fig. 72. Pero si una curva de prueba, $A\ B$, requiere una movida demasiado grande de la carrilera existente (no mostrada); busquese, por un trazado, otra curva, $A_1\ B_1$, de diferente agudeza, (dentro ó afuera de $A\ B$) que reduzca la movida de la carrilera. Sobre el trazado midase la distancia, $E = V\ P$, de la curva de prueba, $A\ B$, y la movida, $P\ P_1$ que la linea preferida, $A_1\ B_1$, necesita en el punto del medio, $P$, de la curva de prueba. Entonces busquese el radio, $R_1$ de la curva preferida, $A_1 B_1$, por medio de la ecuacion :

$$\text{Radio de la curva preferida} = R_1 = \frac{E \pm P\ P_1}{\text{exsec } (\Delta/2)}.$$

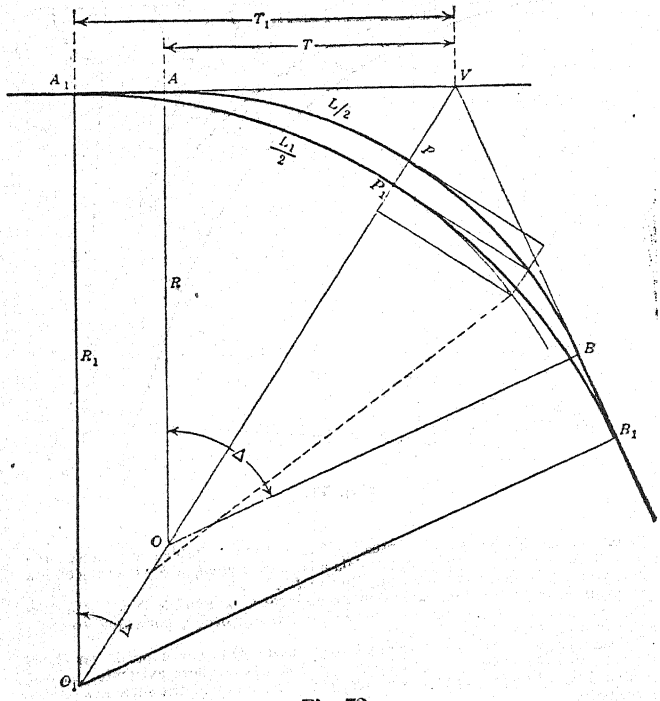

**Fig. 72.**

Entonces, para correr los puntos de la curva $A$ y $B$, hacia $A_1$ y $B_1$ respectivamente, como en ¶ 163, tenemos :

$$A\ A_1 = B\ B_1 = T - T_1 = \text{(aprox) } L/2 - L_1/2\text{; donde :}$$

$$T_1 = R_1 \text{ tang } (\Delta/2); \quad T = R \text{ tang } (\Delta/2);$$

$$T - T_1 = (R - R_1) \text{ tang } (\Delta/2); \quad L/2 \text{ en piés} = 50\ \Delta/D;$$

$$\text{y } L_1/2 \text{ en pies} = 50\ \Delta/D_1.$$

(Vease *N. del T.*, ¶ 11, pag. 926.)

Trácese la curva preferida, $A_1\ B_1$, prefiriendo hacerlo hacia adelante desde $A_1$, hacia atras desde $B_1$, y en ambas direcciones desde $P_1$.

**165.** Fig. 73. Los puntos en la curva final, $A_1$ $B_1$, pueden determinarse **por simples medidas desde la curva, A B**, así:

Se desea buscar (aprox) la dist $x\,x_1$, entre las dos curvas, $A$ $B$ y $A_1$ $B_1$, medida ‖ con el radio central, $O_1$ $P_1$.

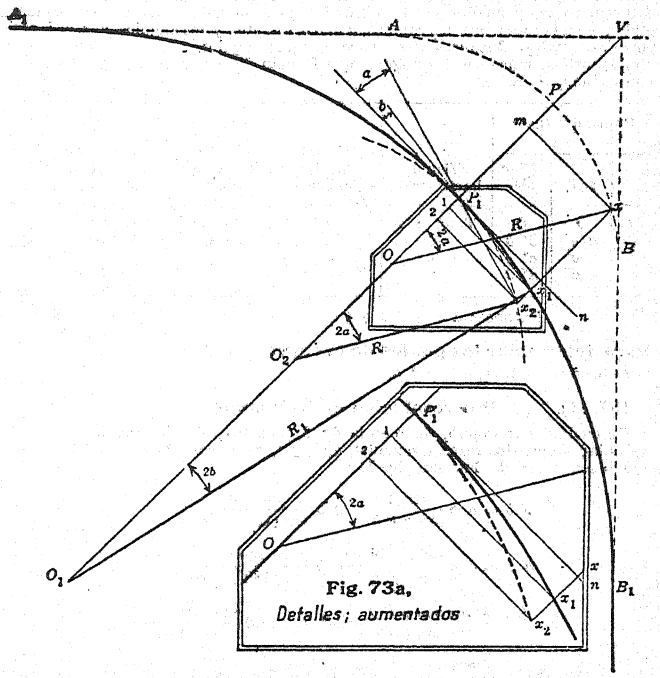

**Fig. 73.**

En la fig. 73 (muy exagerada; vease detalles; fig. 73 *a*), y supongamos que la curva de puntos, $P_1$ $x_2$ represente una curva que tenga el mismo radio, $R$, que la curva, $A$ $B$, pero pasando por el punto medio, $P_1$, de la curva, $A_1$ $B_1$; y sea $x_2\,x_1$ la dist (paralela a $P\,P_1$) de un punto dado, $x_2$ en la curva $P_1\,x_2$, a un punto requerido $x_1$, en la curva $A_1\,B_1$. Trácese $x_1$ 1 y $x_2$ 2, paralelos a la tang, $P_1\,n$, por $P_1$. Entonces:

$$x_2\,x_1 = P_1\,2 - P_1\,1 = P\,m - P_1\,1 = R \text{ senoverso } 2\,a - R_1 \text{ senoverso } 2\,b;$$

$$\text{donde } a = n\,P_1\,x_2, \qquad \text{y } b = n\,P_1\,x_1;$$

y la dist, $x\,x_1$, desde la curva, $A$ $B$, en la misma dirección al punto deseado, $x_1$ en la curva final, $A_1$ $B_1$, es

$$x\,x_1 = x\,x_2 - x_2\,x_1 = P\,P_1 - (R \text{ senoverso } 2\,a - R_1 \text{ senoverso } 2\,b).$$

Este metodo es suficientemente aprox en la práctica, a pesar de que las medidas, dadas por las ecuaciones, son paralelas a $P\,P_1$, en lugar de ser radiales en cualquiera de las dos curvas. A medida que esta divergencia aumenta (con la dist del punto, $x_1$, a $P_1$) la dist, $x\,x_1$, entre las dos curvas, disminuye.

**b. Por Transversales.**

**166.** Fig. 74. Sea $x\ A\ B\ y$, la linea de centro de la carrilera existente. Fíjese un punto, como $a$, sobre una tangente, atrás del punto supuesto de la curva, $A$; y trácese una línea como $a\ b\ c\ d$, seleccionando los puntos transversales, $b$, $c$, $d$, etc., prefieranse puntos (sobre o cerca del afirmado de la via) que la nueva curva deba evitar o tocar, y no demasiado separados para medidas exactas con cadena. Midanse cuidadosamente los rumbos, $a\ b$, $b\ c$, $c\ d$, etc., y los angulos, $\alpha$, $\beta$, $\gamma$, $\delta$, etc., entre los rumbos. Busquense las sumas de estos angulos, como estan en la tabla abajo; dichas sumas son los ángulos que forman dichos rumbos respectivamente con la tang, $A\ V$.

| Punto del Instr. | | | Visual hacia atras. | Visual hacia adelante. | Angulo entre la visual hacia adelante | |
|---|---|---|---|---|---|---|
| | Lat. | Desviación. | | | y hacia atras. | y $A\ V$. |
| $a$ | $O$ | $O$ | Tang $a\ x$ | $b$ | $+\alpha$ | $A = a$ |
| $b$ | $a\ b'$ | $b'\ b$ | $a$ | $c$ | $+\beta$ | $B = A + \beta$ |
| $c$ | $a\ c''$ | $c''\ c$ | $b$ | $d$ | $-\gamma$ | $C = B + (-\gamma)$ |
| $d$ | $a\ d''$ | $d''\ d$ | $c$ | Tang, $d\ y$ | $+\delta$ | $\Delta = C + \delta$ |

Entonces $\Delta = \alpha + \beta + (-\gamma) + \delta$ = suma algebraica.

**Para determinar los puntos de la curva, A y B.**

Se buscan las dists, $a\ A$ y $d\ B$.

**167.** Fig. 74. **1. Por resolucion de triángulos.**

En cualquier triangulo, como en la fig. 9, pag. 107, sean los angulos $A$, $B$ y $C$, y los lados opuestos respectivamente, $a$, $b$, y $c$. Entonces (vease pag. 107, ¶ 20) : $a/b$ = sen $A$/sen $B$. Entonces fig. 74 :

$$F\ b = a\ b\ \frac{\operatorname{sen} a}{\operatorname{sen} a\ F\ b} = a\ b\ \frac{\operatorname{sen}\ a}{\operatorname{sen}\ (180^\circ - B)};$$

$$a\ F = a\ b\ \frac{\operatorname{sen} a\ b\ F}{\operatorname{sen} a\ F\ b} = a\ b\ \frac{\operatorname{sen} \beta}{\operatorname{sen}\ (180^\circ - B)};$$

$$G\ c = F\ c\ \frac{\operatorname{sen} a\ F\ b}{\operatorname{sen} c\ G\ F} = (F\ b + b\ c)\ \frac{\operatorname{sen}\ (180^\circ - B)}{\operatorname{sen}\ (\Delta - \delta)};$$

$$F\ G = F\ c\ \frac{\operatorname{sen} \gamma}{\operatorname{sen}\ (\Delta - \delta)}; \qquad G\ d = G\ c + c\ d;$$

$$V\ d = G\ d\ \frac{\operatorname{sen}\ (\Delta - \delta)}{\operatorname{sen}\ (180^\circ - \Delta)}; \qquad G\ V = G\ d\ \frac{\operatorname{sen}\ \delta}{\operatorname{sen}\ (180^\circ - \Delta)};$$

$$F\ V = G\ V - F\ G.$$

Búsquese $\Delta$ como en el ¶ 166. Entonces :

$$A\ V = V\ B = R\ \text{tang}\ (\Delta/2) = \text{aprox}\ \frac{5730}{D}\ \text{tang}\ (\Delta/2).$$

Entonces :

$$\mathbf{a\ A} = a\ V - A\ V = a\ F + F\ V - A\ V;$$

$$\mathbf{d\ B} = V\ d - V\ B.$$

**168.** Fig. 74. **2. Por Latitudes y Desviaciones.**

*Latitudes* (dists paralelas con una tang como $A\ V$); para buscar la dist $a\ A$ y situacion del punto $A$ :

Lat de $d = a\,d' = a\,b' + b\,c' + c\,d'$
$= a\,b \cos A + b\,c \cos B + c\,d \cos C$;
$a\,A = a\,d'' - d''\,V - V\,A$
$= a\,d'' - d\,d''/\tan \Delta - R \tan (\Delta/2)$.
(Para $d\,d''$, vease abajo. $R$ = radio de la curva existente).

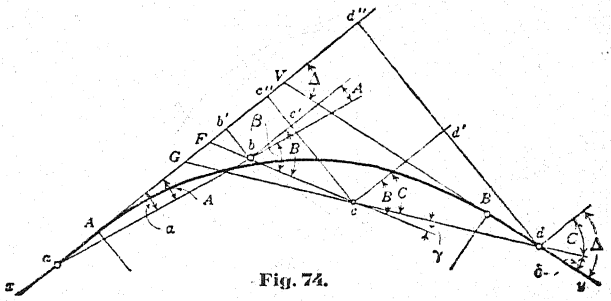

Fig. 74.

*Desviaciones* (dists normales a las latitudes); para buscar la dist $d\,B$ y la situacion del punto, $B$:
Desv de $d = d\,d'' = b\,b' + c\,c' + d\,d'$
$= a\,b \operatorname{sen} A + b\,c \operatorname{sen} B + c\,d \operatorname{sen} C$;
$d\,B = d\,V - V\,B$
$= d\,d''/\operatorname{sen} \Delta - R \tan (\Delta/2)$.

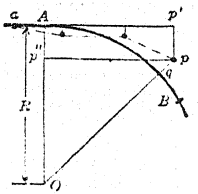

Fig. 75.

**Por puntos de las transversales.**

**169.** Fig. 75. (Para curvas con espirales vease el final de este ¶). Habiendo así encontrado, por medio de la transversal, ¶ ¶ 166-168, Fig. 74, el punto de la curva, $A$, y el punto de la tang $B$, los varios puntos transversales pueden usarse para determinar por simples medidas otros tantos puntos en la curva; asi, Fig. 75: Para encontrar la distancia radial, $p\,q$, de un punto transversal dado, $p$, a la curva, $A\,B$;
Sea $a\,p'$ = lat de $p$ { referido al origen, $a$, de la transversal,
$p'\,p$ = diverg de $p$ { y encontrado como en el ¶ 168.
$R$ = radio, $O\,q$.
Entonces:

$$\text{Tang } A\,O\,p = \frac{p\,p''}{O\,p''} = \frac{a\,p' - a\,A}{R - p'\,p};$$

$$O\,p = \frac{p\,p''}{\operatorname{sen} A\,O\,p} = \frac{a\,p' - a\,A}{\operatorname{sen} A\,O\,p};$$

$$p\,q = R - O\,p.$$

Si, como en la Fig. 75, $R < O\,p$, entonces $p$ debe moverse hacia dentro.
Si $R > O\,p$, entonces $p$ debe moverse hacia afuera.

Fig. 76. Para un punto, $q$, en la porción circular, $B\ B_f$, de una curva espiral, (para $A$, en lo anterior, lease, $A'$; y, para $R - p'p$, lease $R + H - p'p$). Entonces, como arriba, $p\ q = R - O\ p$.

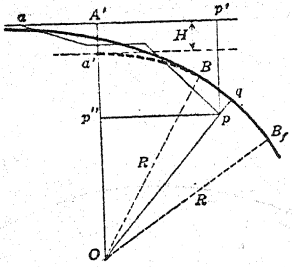

**Fig. 76.**

## Curvas largas, que se desea combinar.

**170.** En curvas muy largas, especialmente donde la carrilera se ha movido mucho fuera de su posicion, algunas veces se hace impracticable situarla satisfactoriamente con una curva simple sencilla.

Entonces se recurre a combinaciones de curvas de otros radios. Como las curvas largas son rara vez agudas, el cambio requerido de agudeza es tambien, muy rara vez, de mas de unos pocos minutos.

El instrumento se pone sobre un punto tan cerca como se pueda al punto medio de la curva, y se corre en cada direccion una curva de prueba, con la agudeza, $D$, de la curva, y se corre en cada direccion una curva de prueba, con la agudeza, $D$, de la curva existente, como se encuentra en las anotaciones, ó planos o como se calcule, o se suponga.

Cuando cualquier curva de prueba comienza a desviarse considerablemente de la carrilera existente, la agudeza se aumenta o disminuye ligeramente, como sea necesario. Esto puede tenerse que hacer varias veces durante el trazado de la curva de prueba.

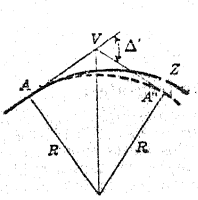

**Fig. 77.**

Fig. 77. Supongase que una de estas curvas de prueba, acercandose a la derecha en la Fig., ha llegado asi a un punto, $A'$, digamos 500 pies (digamos 150 m) desde su origen que es el punto, $A$, de la curva existente, $Z\ A$.

Se desea, determinar el punto $A$, y la agudeza, $D$, de la curva, $A'\ A$, que se unirá tangencialmente a la tangente, $A\ V$, en $A$. Tracese una tang, $A'\ V$, que se une en, $V$, con la tang, $A\ V$, de la curva existente, $Z\ A$. Midase el angulo de interseccion, $\Delta'$, en $V$, y la semitangente, $T = A'\ V = V\ A$.

Entonces, para la agudeza, $D$, de la curva corta, $A'\ A$, que completará la linea, tenemos :

$$R = T \cot (\Delta'/2);\ D = \text{aprox } 5730/R;$$

y $V\ A\ (= T) = A'\ V$, medido desde $V$, da el punto de la curva, $A$.

**171. Cuando se hace de doble vía una vía sencilla existente**, Fig. 78, *y A B a b z* (centros en *O* y en *o*), la agudeza de la curvatura puede reducirse (si da lugar la zona de propiedad) colocando la segunda vía, *y' A' B'*, *B" a' b'*,

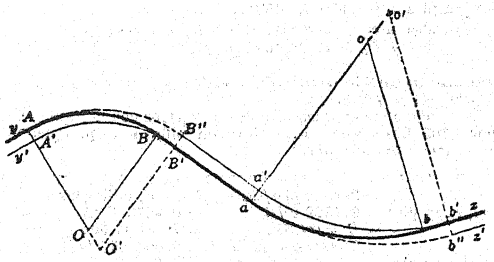

Fig. 78.

*b" z'* (centro en *O'* y *o'*), alternativamente sobre uno y otro lado de la vía sencilla existente, construyendo tambien las curvas nuevas, *A B"* y *a b"* (centros en *O'* y en *o'*), y eventualmente cambiando las curvas antiguas, *A B* y *a b*. (Eng News, 1913, oct 23, p 802.)

## SUPERELEVACION (PERALTE) del carril exterior en las curvas.

(Para curvas de transición, vease ¶ ¶ 194, etc.)

### Teoría.

**172.** Sea *W*, un bloque sin friccion deslizándose hacia adelante, sobre una vía recta, en la cual los dos carriles estan en el mismo nivel, y supongamos que encuentra una curva, con el *peralte*, *e*, como se ve en la Fig 79.

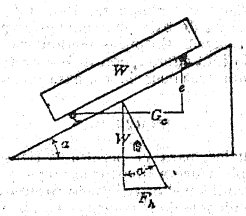

Fig. 79.

**173.** Sobre la curva, su fuerza centrífuga (horizontal), transversal a la vía, es $W\ v^2/R\ g$ (pag 373); donde $W$ = peso del bloque; $v$ = su velocidad, en pies por segundo; $R$ = rad de la curva, en pies; y $g$ = aceleración de la gravedad = 32,2 pies (9,81 m) por segundo.

**174.** La componente horizontal que lo hace descender por el plano es (fuerza centripeta): $F_h = W$ tang $a = W\ e/G_c$; donde $e$ = superelevacion (peralte) en pies, y $G_c$ = dist hor, en pies, entre centros de carril.

(*N. del T.* Puede emplearse el Sistema Métrico, tomando medidas en metros y para aceleracion de la gravedad = 9,81 m.)

**175** *. Con el objeto de que el bloque no se corra lateralmente, debemos de tener estas dos fuerzas iguales; $W\ v^2/R\ g = W\ e/G_c$; de aqui:

Peralto, $e$, en pies $= G_c\ v^2/R_g = 0.03106\ G_c\ v^2/R$ ..... (114)

Para veloc., $V$, en millas por hora, tenemos:

Peralto, $e$, en pies $= 0.06680\ G_c\ V^2/R$ ..... (115)

Aprox, $e$, en pies $= G_c\ D\ v^2$ * *$/5730\ g = G_c\ D\ v^2/184{,}500$

$= G_c\ D\ V^2/85{,}768$ (†) ..... (116)

**176. Con ancho de via** (*standard*). Modelo ( = 4 pies, 8.5 pulgs = 4.708 pies. tenemos, aprox, $G_c = 4.9$ pies, y

(*N. del T.* Cuando se tengan las medidas en metros conviértanse en pies multip. aquellos por 0,305. Los kilometros por hora en millas multip. aquellos, por 0,6214 así pueden usarse estas fórmulas.)

| | Para $v$, pies/seg. | Para $V$, millas/hora. | |
|---|---|---|---|
| Superel, $e$, en pies | $= 0.1522\ v^2/R$ | $= 0.2273\ V^2/R$ | |
| | $= D\ v^2/37{,}652$ | $= D\ V^2/17{,}504$ | |
| | $= 0.000\ 026\ 56\ D\ v^2$ | $= 0.000\ 057\ 2\ D\ V^2$ ..... | (117) |
| Superel, $E$, en pulgs | $= 1.826\ v^2/R$ | $= 3.928\ V^2/R$ | |
| | $= D\ v^2/3{,}137.7$ | $= D\ V^2/1{,}458.6$ | |
| | $= 0.000\ 319\ D\ v^2$ | $= 0.000\ 686\ D\ V^2$ ..... | (118) |

**177. Para otros anchos de via**, como el angulo, $a$, Fig. 1, es independiente del ancho de via, el peralto, $e$, para un radio y velocidad dada, es proporcional al ancho de la via.

**178. Cuerda, $C_0$, cuya media ordenada = peralte.** Comparese ¶ ¶ 159-186. En cualquier arco circular, tenemos aprox:

$$\text{Cuerda} = \sqrt{8\ R \times \text{med ord.}}$$

De aqui (Ec 117) tenemos:

$$C_0 = \sqrt{8\ R \times 0.000\ 057\ D\ V^2} \quad \ldots\ldots\ldots\ldots \quad (119)$$

y, como $R\ D$ = aprox 5730, tenemos aprox:

$$C_0 = 1{,}62\ V = \sqrt{1.219}\ v = 1.1\ v \quad \ldots\ldots\ldots\ldots \quad (120)$$

**179.** Asi, sea la velocidad 40 millas/hora. Para este caso, Ec (120) da $C_0 =$ 64.8 pies. Estirese una cuerda de 64.8 pies, entre dos puntos cualquiera sobre el lado concavo de cualquier carril. Entonces cualquiera que sea la agudeza de la curvatura, la media ord. de esta cuerda, con la cabeza del carril, sera aproximadamente el peralto que dan nuestras ecuaciones, para una velocidad de 40 millas/hor

## Práctica.

**180.** En los trenes actuales, para el peralte se tiene en cuenta, no solamente la posicion de los troles (plataforma que forman ejes y ruedas) transversalmente a la carrilera (¶ 175), sino tambien el **equilibrio de los cuerpos en los carros.** El peralto neutraliza la tendencia de los cuerpos en los carros a oscilar hacia fuera bajo la acción de la fuerza centrifuga.

---

* (Vease *N. del T.*, ¶ 11, pag. 926).

** (*N. del T.* — Con un radio de 5730 pies (aprox) la cuerda unidad de 100 pies (una cadena) subtiende un arco de un grado (1°) o de otro modo $D$ (en grados) $= 5\,730/R$ (vease ¶ 29, pag. 959) y por tanto $1/R = D/5\,730$. Para que una cuerda de 20 metros subtienda un arco de (1°) un grado, es necesario que el radio sea de 1146 m; (vease ¶ 29, pag. 959), asi pues en el sistema métrico $D$ (en grados) $= 1146/R$. Naturalmente $R$ en metros.).

† (*N. del T.* — La fórmula para el peralte en sistema metrico es $e = \dfrac{Gc\ v^2}{9.81\ R}$; por supuesto dando a $Gc$ = ancho via; $v$ = velocidad par seg y $R$ = Radio en metros.)

**181.** Las ecuaciones anteriores estan basadas sobre las **condiciones ideales** de la Fig. 79; pero un carro de ferrocarril, y, todavia mas aun, un tren, es un cuerpo complicado, armado de muchas partes sobre las que obran de diverso modo diferentes fuerzas; y las condiciones son marcadamente distintas de las de la Fig. 79. La friccion, entre la llanta de la rueda y la parte superior de la cabeza del carril, hace que la primera rueda exterior de un carro se balancea hacia afuera y su pestaña ejerce presion contra la cabeza del carril exterior; y la resistencia de ese carril al movimiento hacia adelante de la rueda origina una fuerza centripeta, adicional a la de $F_h$ debida a la gravedad (¶ 174), deficiente en la Fig. 79; y la acción de las dos fuerzas principales, sobre las ruedas siguientes, es complicada por la tracción ejercida sobre ellas por las partes, que le preceden en el tren. Vease ¶ 36, pag 1133. Aun si se pudiera encontrar una fórmula idealmente exacta comprendiendo la velocidad, su utilidad estaria limitada por el hecho de que solo un peralte puede darse en un pedazo de la via; ademas, en la mayoria de los ferrocarriles, los trenes tienen que viajar con notables diferencias de velocidades, no obstante estas ecuaciones son generalmente usadas en la práctica, con modificaciones para ajustarlas a casos especiales.

**182. El valor y detalles del peralte** se determinan generalmente por un criterio individual (¶ ¶ 183 a 187), basado en las condiciones locales, por la naturaleza del tráfico, etc. En vista de la seguridad y para la comodidad de los pasajeros, el peralte se calcula para las velocidades *mayores* posibles; pero esto puede producir un trabajo fuerte para trenes largos y pesados; y, donde un tren se pare sobre una curva aguda, resulta una inclinacion inconveniente para la carga de los carros.

**183.** Es costumbre tomar el peralte de 0.5 a 1.0 pulg (digamos 12 a 25 mm) (en algunos casos 1.25, 1.5 y aun 2 pulgs) (digamos 30 a 50 mm) **por grado de agudeza**; con un limite total maximo de 4 a 6 (y aun 8) pulgs (digamos 10 a 15 y aun 20 cm); la velocidad se reduce donde sea necesario. La Ec (114) da un peralto de 0.5 pulg por grado de agudeza en cerca de 27 millas/hora, 1 pulg en cerca de 38 m/h, y 2 pulgs en cerca de 55 m/h. (1)

**184.** La practica comun (¶ 183) de hacer el peralte proporcional a la agudeza de la curva, descarta el hecho de que **sobre las curvas agudas se disminuyen las grandes velocidades.** (Vease ¶ 187.)

**185. En el F. C. New York Central** (cuatro vias) $E$ max = 6.5 pulgs (162 mm). Para trenes de pasajeros en curvas de mas de 1° de agudeza,

$E$ = 2 pulgs (50 mm) por grado;

para trenes de pasajeros en curvas de 1° de agudeza y mas agudas,

$E$ = 1 pulg (25 mm) por grado + 1.5 pulgs (37 mm);

para trenes de carga,

$E$ = 0.75 pulgs (18 mm) por grado.

Esto da:

| Para agudeza. | 0.25° | 0.50° | 0.75° | 1.00° | 1.25° | 1.50° | 1.75° |
|---|---|---|---|---|---|---|---|
| $E$, pulgs, pasajeros | 1/2 | 1 | 1 1/2 | 2 1/2 | 2 3/4 | 3 | 3 1/4 |
| Carga | 3/16 | 3/8 | 9/16 | 3/4 | 15/16 | 1 1/8 | 1 5/16 |

| Para agudeza. | 2.00° | 3.00° | 4.00° | 5.00° | 6.00° | 8.00° | 10.00° |
|---|---|---|---|---|---|---|---|
| $E$, pulgs, pasajeros | 3 1/2 | 4 1/2 | 5 1/2 | 6 1/2 | 6 1/2 | 6 1/2 | 6 1/2 |
| Carga | 1 1/2 | 2 1/4 | 3 | 3 3/4 | 4 1/2 | 6 | 6 1/2 |

**186. El F. C. Phila. & Reading** hace $E$ o $e$ = media ordenada de la cuerda cuyo largo, $C_0 = 1.466\ V$, es la dist corrida por trenes expresos en un segundo; $E$ max = 8 pulgs (20 cm). Comparense ¶ ¶ 178, 179.

**187. Otras líneas** usan $E$ = 1 pulg (25 mm) por grado, mas una cantidad empezando con 1 pulg para una curva de 1° y disminuyendo 1/8 de pulg (3 mm) en cada grado.

Esto da:

| Para $D$ = | 0 | 1° | 2° | 3° | 4° | 5° | 6° | 8° | 10° |
|---|---|---|---|---|---|---|---|---|---|
| $E$ en pulgs | 0 | 2° | 2 7/8 | 3 3/4 | 4 5/8 | 5 1/2 | 6 3/8 | 8 1/8 | 10 |
| $E$ en mm (aprox) | 0 | 50 | 61 | 93 | 115 | 140 | 160 | 203 | 250 |

(1) *N. del T.* — Esto equivale a un peralte de 12 mm. *por grado de agudeza* (cada grado del val. de D) en cerca de 43 kilometros por hora; 25 mm en cerca de 60 km/h y 50 mm. en cerca de 88 km/h.

Con esto resulta que los recorridos mas rápidos pueden ocurrir en las curvas mas fáciles. Vease ¶ 184.

Para la practica ordinaria, la **Asen Am de Ings F. C.**, Manual de 1915, p. 158, recomienda peralte $E = 0.00066\ D\ V^2$. Compárese nuestra ec (118) ¶ 176; $E$ max = ordinariamente 8 pulgs (20 cm).

**Seccion Transversal.**

**188. En via sencilla el peralte puede hacerse de varios modos :**

| | | |
|---|---|---|
| (1) Subir el carril exterior; | Carril interior permanece en rasante; | Centro de gravedad del carro levantado $e/2$. |
| (2) Bajar el carril interior; | Carril exterior permanece en rasante; | Centro de gravedad del carro levantado $e/2$. |
| (3) Combinacion de (1) y (2); | Linea central permanece en rasante; | Centro de gravedad del carro conserva la elevación. |

**La Asen Am de Ings F.C.**, Manual, 1915, p. 159, recomienda el metodo (1 .

*Plano.* *Dentado.* *En escala.*

**Fig. 80.**

**189. Fig. 80. En doble via**, se usan tres metodos :

**Plano.** Favorable para el desagüe, y para colocar cruceros y cruces de ferrocarril y carreteras.

**Dentado:** Usado generalmente. Requiere desagües cruzados bajo una de las carrileras;

**En escala.** Permite el desagüe sin desagües cruzados.

**Peralte gradual.**

**190.** Donde no se use (¶ ¶ 194) curva de transición, el peralte **generalmente empieza en la tangente,** a una distancia (graduando el peralte) desde cada punto de la curva = 30 a 60 pies (9 a 18 m) por cada pulgada (25 mm) de peralte. La cantidad depende de las velocidades que se supongan y el peralte completo se obtiene cuando se llega a las curvas, pero algunas veces el tercio del peralte se deja para darlo en la misma curva.

**191.** Cualquiera que sea el método adóptado, es un compromiso poco deseable estar forzado por la necesidad a pasar inmediatamente de una tangente a una curva circular, o viceversa. En la tangente la via debe estar a nivel, transversalmente, y el peralte gradual (que requiere el peralte en la tang) solamente se adopta por ser (atendiendo a la seguridad) menos inconveniente que tener la via a nivel transversalmente en la curva.

**192.** Algunas lineas adoptan un **largo fijo** como 120 pies (36 m) para el peralte gradual para todas las curvas. El New York Central usa 120 pies por pulgada (36 m por 25 mm) de peralte y, hasta $E = 3$ pulg (75 mm) y 360 pies (como 110 m) (total) para $E > 3$ pulgs. La Asen Am Ings F. C. en su Manual de 1915, p. 159, recomienda una proporcion de peralte gradual de 1 pulg en $1.75 \times V$ pies; donde $V$ = vel en millas/hora. En doble via, algunos ferrocarriles usan en cada via, un peralte gradual mas largo en el extremo donde los trenes entran a la curva que en el otro extremo.

**193.** El peralte gradual es generalmente **un plano inclinado;** asi, un perfil de cualquier carril es una *linea recta* que forma, en cada extremo, un angulo vertical con el perfil del mismo carril en la tang o en la curva respectivamente. **Teoricamente,** sin curvas de transicion, el perfil del peralte gradual debe ser una curva vertical invertida que consiste en dos curvas verticales de transicion, de radios infinitos en sus extremos. En algunos casos en la práctica esto es solo aproximado,

## CURVAS DE TRANSICIÓN

## O ESPIRALES

**194.** Cuando un tren deja una tangente y entra en una curva circular, la direccion de su movimiento cambia repentinamente. Cuando deja la curva y pasa a una tangente, queda repentinamente aliviado de la compulsion ejercida por los carriles en curva. En cada caso, recibe un choque lateral, que aumenta las resistencias, y que es perjudicial a la via y al material rodante y posiblemente a la carga, ademas desagradable o peligroso para los pasajeros. Análogos efectos se producen cuando un tren pasa directamente de una curva a otra de muy diferente agudeza, o que va en direccion opuesta. Ademas (vease ¶ 191) es imposible distribuir la superelevacion satisfactoriamente donde solo se usa una curva circular.

**195.** Estas dificultades se obvian por medio de las curvas de « transicion » o « espirales » porque, el cambio, entre cada tang y la agudeza completa de la curva, o entre una curva circular y otra, ambos cambios el respectivo a la agudeza y al peralte se hacen exclusivamente en la misma espiral; la agudeza de la curvatura y el peralte aumentan gradualmente desde cero, al comienzo de la espiral (hasta el que corresponde a la curva circular), al extremo de la espiral.

**196. La Asen Am Ings F. C.** (Manual, 1915, p. 133) recomienda el uso de espirales en todas las curvas que requieran un peralte de 2 pulgs (50 *mm*) o mas para la mas alta velocidad permitida.

**197.** Figs 81 *a*, 81 *b*. Asi, supongamos la curva circular $a'\ a\ f'$ que conecta las dos tangs, $A\ a'$ y $a f''\ A\ f$, formando la linea, $A\ a'$, $a f''\ A f$. Esta linea pudiera reemplazarse por la linea, $A\ B\ B f'\ A f$, compuesta de una espiral inicial, $A\ B$, una curva central circular, $B\ B f'$, y una espiral final, $B f'\ A f$. Aqui la curva circular original, $a'\ a f''$, con su centro en $O'$, se mueve hacia dentro a $a\ a'$, con el centro en $O$, conservando su radio original, $R$, pero solamente una porcion central, $B\ B f'$, se conserva como parte de la linea nueva.

En la fig. 81 *a*, la espiral inicial y final son semejantes. Donde, como en la fig. 81 *b*, no sea este el caso, vease ¶ 226.

**198.** En la curva *ideal* de transición, el radio disminuye proporcionalmente con la dist desde el comienzo de la espiral, (*medido a lo largo de la misma espiral*) aumenta. En una curva tal el peralte en cada punto, es el que corresponde a la agudeza en ese punto, a la velocidad que se supone. Esta curva fue descrita por Mr. Ellis Holbrook, en la revista Railroad Gazette, 1880 dec 3, p 639. Fue estudiada por el Prof. A. N. Talbot, en Tecnografia (Universidad de Illinois) n.º 5, 1890-91, y despues detallada por él mismo en el articulo « La Espiral de transicion de ferrocarril », New-York, Eng News Pub Co, 1904. En « La Curva de transicion », New-York, John Wiley & Sons, 1899, el Prof. C. L. Crandall desarrolla métodos exactos para la aplicacion de esta curva en casos de grandes desarrollos. Esta espiral fue recomendada por la Comision de Via de la Asen de Ingo de F. C. y Mantenimiento de Via, Boletin 73, marzo 1906, pp 58, etc.

**199.** Muchas formas de curvas de transicion se han propuesto y trazado. Entre las que hay en uso comun, la eleccion se hace segun la facilidad de calcularla y de trazarla mas que por cualquier diferencia mecánica entre el modo de obrar unas y otras.

### La espiral de 10 cuerdas.

**200.** Buscando la simplificacion de las fórmulas necesarias, la **Asociacion Americana de Ingenieros de ferrocarril** (« Manual », 1915, pag 132) recomienda el uso de una curva, identica practicamente con la espiral ideal descrita. La curva recomendada está subtendida por diez cadenas de espiral iguales (gene-

ralmente menores de 100 pies), y se llama «la espiral de diez cuerdas». En esta curva, la agudeza aumenta con la dist desde el comienzo de la espiral, medida en cadenas de 100 pies y no a lo largo de la curva misma, como en la espiral verdadera. Véase ejemplo, ¶ 233.

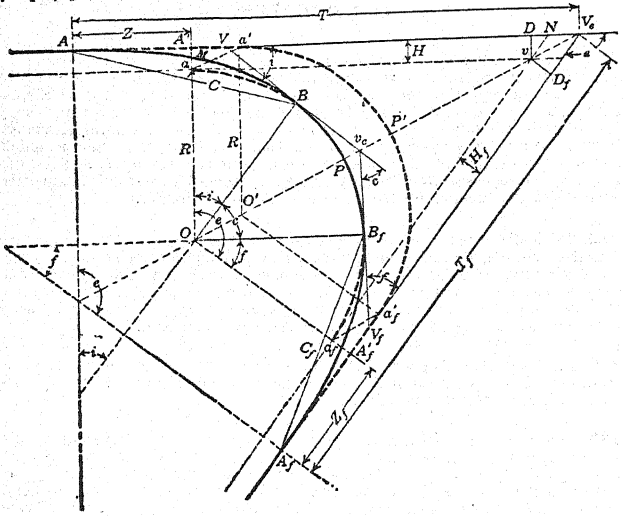

**Fig. 81 a.**

**Propiedades geométricas.** Véase reglas de uso en el campo, ¶ ¶ 231, etc.

## Símbolos.

**201.** Figs 81 *a*, 81 *b*. Sean los puntos, *A*, *B*, *Bf*, *Af*, etc., de cambio designados como sigue (Manual de la Ascn Americana de Ingo de F. C., 1915, p 135).

(*A*) T. E. De tang a espiral (hasta aquí llamado P. de E., punto de espiral);
(*B*) E. C. De espiral a curva circular;
(*Bf*) C. E. De curva circular a espiral;
E. T. De espiral a tangente;
E. E. De — a espiral (de una espiral a la otra).

**202. Lista alfabética de símbolos.** En general las funciones de espiral *final* se distinguen por el índice, subscrito, *f*.

| Figs. | Símbolos. | Significados. |
|---|---|---|
| 81, 82..... | $C$ | = la cuerda, *A B*, en pies, de T. E. a E. C.; |
| | $C_n$ | = la — en pies, de T. E., a cualquier punto *P*, en la espiral; |
| | $c$ | = la cadena espiral usada, en pies; |
| | $c = \Delta_c$. | Vease $\Delta_c$ abajo. |
| 81..... | $D$ | = la agudeza de la curva central circular, *B Bf* = (prácticamente) la agudeza de cualquier espiral en *B* ó *Bf*, donde se une a la curva circular; |
| | $d$ | = la agudeza de la espiral en cualquier punto dado; |

81 $a$.....$E$ = la distancia exterior $P\ V_c$ de la curva entera, $A\ B\ Bf\ Af$, cuando las dos espirales son iguales. Asi definida por la Ascn Am Ingo F. C. Compare ¶ ¶ 238, 239.

$e = \Delta_e$. Vease $\Delta_e$ abajo.

82, 83.....$F$ = el angulo entre la tangente inicial, $A\ V$, y la cuerda, $P'\ P''$, uniendo cualquiera de los dos puntos, dados de la espiral;

83.....$f$ = el angulo, $m\ P'\ P''$, en cualquier punto $P'$ dado de la espiral entre la tang $P'\ m$, en ese punto, y la cuerda, $P'\ P''$, a cualquier otro punto dado, $P''$;

$f = \Delta f$. Vease $\Delta f$ abajo.

81, 82, 84, 86....$H$ = la dist, $A'\ a$, entre la tang, $A\ V$ o $A'\ V_e$, y la tang paralela, $a\ v$, a la curva circular $a\ B$ ($B\ Bf$, prolongada);

= la ordenada del punto, $a$, de la curva circular prolongada referida al T. E. (abscisa = $Z$);

$i = \Delta_i$. Vease $\Delta_i$ abajo.

$k$ = el aumento en agudeza de la espiral por 100 pies de cuerda;

$L$ = la suma, en pies, de los largos de las 10 cadenas de espiral;

$l$ = la suma, en pies, de los largos de la cadena de espiral entre el T. E., en $A$, y cualquier punto dado en la espiral;

$n$ = el número (1, 2, 3..... 10) que indica cualquiera de los 10 puntos de la cadena en la espiral, contando el T. E. como cero;

= el número de cadenas espirales entre el T. E. y cualquier punto dado en la espiral;

$q$ = el número de cadenas de 100 pies entre cualquiera de los dos puntos dados de la espiral, $P'$ y $P''$;

81, 82, 84, 86... $R$ = el radio de la curva circular central;

$S$ = el número de cadenas de 100 pies del T. E. al E. C.;

$s$ = el número de cadenas de 100 pies entre el T. E. y cualquier punto dado de la espiral;

81, 82..... $T_a$, $T_b$ = las semitangs iniciales y finales, $A\ V$ y $V\ B$, de la espiral;

$t_a$, $t_b$ = las semitangs iniciales y finales para cualquier porcion de la espiral;

81, 84..... $T$, $T_f$ = las semitangs iniciales y finales, $A\ V_e$, $V_e\ A\ f$, de la curva entera;

82..... $X$, $Y$ = la abscisa y ordenada del E. C. ($B$), referido al T. E. ($A$);

$x$, $y$ = la abscisa y ordenada de cualquier punto dado de la espiral, referido al T. E. ($A$);

81, 82..... $Z = A\ A'$ = abscisa del punto $a$, de la curva circular prolongada, referida al T. E.; (ordenada = $H$);

81, 82..... $\Delta$ o $\Delta_i$ o $i$. Vease $\Delta_i$ abajo.

81, 86..... $\Delta_c$ o $c$ = angulo central de la curva central circular, $B\ Bf$ *;

81, 84, 86... $\Delta_e$ o $e$ = — — entera, $A\ B\ Bf\ Af$;

81..... $\Delta f$ o $f$ = — de la espiral final, $Bf\ Af$ *;

81, 82..... $\Delta_i$ o $i$ = — — inicial, $A\ B$ *;

83..... $\grave{\upsilon}$ = la abertura o desarrollo de cualquier porcion dada de la espiral empezando en la T. E., ($A$);

= el angulo entre la tang inicial, $A\ V$, y la tang por cualquier punto dado de la espiral;

Vease tambien la prox pagina.

---

* Cuando unicamente la espiral inicial (o final) esté en discusion, es conveniente designar la extension por $\Delta$; pero cuando las espirales iniciales y finales se discuten juntas, puede ser necesario distinguir sus extensiones respectivas, y los indices se usan entonces con o sin la letra, $\Delta$.

81, 82..... $\Theta$ = el ángulo periférico o « deflexion » $V\ A\ B$, en la T. E. $(A)$, entre la tang inicial, $A\ V$, y la cuerda, $A\ B$, de la espiral;
$\theta$ = el ángulo periférico o « deflexion » entre la tang, $A\ V$, en $A$, y la cuerda desde $A$, a cualquier punto dado de la espiral;

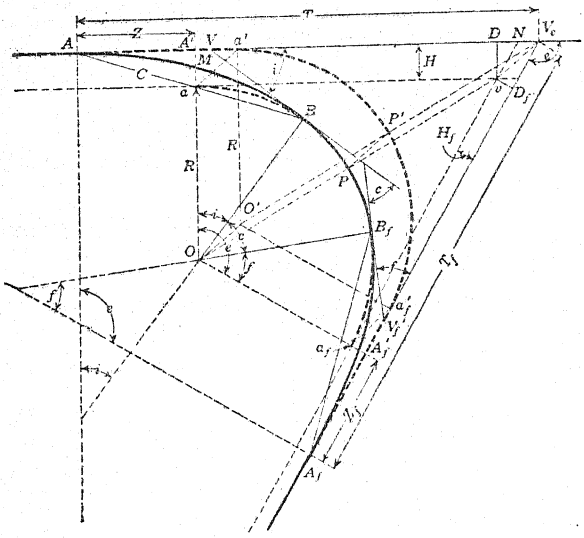

**Fig. 81 b.**

81, 82..... $\Phi$ = el ángulo periférico o « deflexion », $V\ B\ A$, en la E. C., $(B)$, entre la tang final $V\ B$, por la E. C. y la cuerda, $A\ B$;
$\phi$ = el ángulo periférico o « deflexion », en cualquier punto dado de la espiral, entre la tang por ese punto y la cuerda de la T. E.

## Ecuaciones.

**203.** Figs 82, 82'. **Relaciones entre L, I, S, s, c, n y q.**

$L = 100\ S = 10\ c$; $\quad S = 0.01\ L$; $\quad c = 0.1\ L = 10\ S$;
$l = 100\ s = n c$; $\quad n = l/c = 100\ s/c$;
$q = s'' - s' = 0.01\ c\ (n'' - n')$;
$s = 0.01\ l = d/k = 0.01\ c\ n = 0.001\ n\ L$..... (121)

**204. Agudeza, D o d.**

$D = k S = 0.01\ k L = 2\ \Delta/S = 200\ \Delta/L$..... (122)
$d = k\ s = 0.01\ k\ l = 2\ \delta/s = 200\ \delta/l = n\ \Delta/5\ S = 0.01\ k\ c\ n$..... (123)

**205. Proporcion k, del cambio de agudeza.**

$k = D/S = 100\ D/L = d/s = 100\ d/l = 2\ \Delta/S^2 = (\text{aprox})\ 6\ \Theta/S^2 = 2\ \delta/s^2$
$= (\text{aprox})\ 6\ \theta/s^2$..... (124)

Vease tambien ec (133).

**206. Angulo central ó desarrollo $\Delta$ ó $\delta$.**

$$\Delta_e = \Delta + \Delta_c + \Delta f \quad \ldots\ldots (125)$$

$$\Delta = D\,S/2 = D\,L/200 = k\,S^2/2 = k\,L^2/20{,}000 = (10/n)^2\delta = (S/s)^2\delta$$
$$= (L/l)^2\delta = (\text{aprox})\ 1.854\sqrt{D\,H} \quad \ldots\ldots (126)$$

$$\delta = d\,s/2 = d\,l/200 = d^2/2\,k = k\,s^2/2 = k\,l^2/20{,}000 = (n/10)^2\,\Delta$$
$$= (s/S)^2\,\Delta = (l/L)^2\,\Delta \quad \ldots\ldots (127)$$

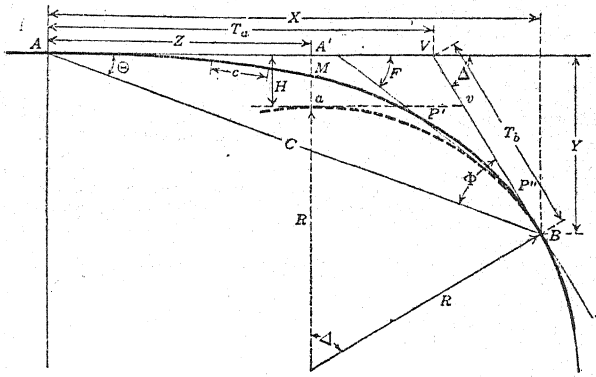

**Fig. 82.**

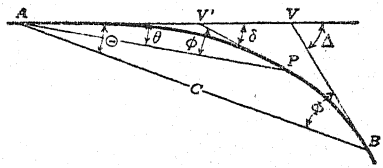

**Fig. 82'.**

**Angulo periferico o deflexion, Θ o θ.**

El angulo entre una tang y una cuerda.

**Para las ecuaciones de uso en el campo,** vease ¶ 231.

**Valor del angulo de deflexion, θ, en T. E., o al empezar (A) la espiral,** entre la tang, $A\ V$, y la cuerda que une $A$ con cualquier punto $P$ de la espiral fig. 82'.

**207.** Sea $\delta$ = la extension de la espiral entre $A$ y el punto dado, $P$, fig. 82'. Entonces :

$$\theta \text{ aprox } * = \delta/3 \quad \ldots\ldots (128)$$

* Grado de aproximacion. Error = 0.00297 $(\delta^\circ)^3$.

| Cuando $\delta$ = | 1° | 2° | 3° | 4° | 5° |
|---|---|---|---|---|---|
| Error = | 2.97 | 23.8 | 80.2 | 190 | 371 segundos. |
| 1000 × error/$\delta$ = | 0.08 | 0.33 | 0.74 | 1.32 | 2.06 |

Para el valor verdadero de $\theta$, tenemos, bastante aprox,

$\delta/3 - \theta$, en segundos, $= 0.00297$ ($\delta$ en grados)$^3$.

Asi, sea $\delta = 30^o$; $\theta$ aprox $= 30^o/3 = 10^o$. Entonces :

$\delta/3 - \theta$, en segundos, $= 0.00297 \times 30^3$

$= 0.00297 \times 27{,}000$

$= 80.19$ segundos,

o, $\theta = (\delta/3) - 0.00297\ (\delta^o)^3 = 10^o - 80.19$ segundos

$= 36{,}000'' - 80{,}19'' = 35{,}919.81'' = 9^o 58' 39.81''$.

Tomando $\theta$ aprox $= \delta/3$, tenemos :

$\theta$ *aprox* en grados $= \delta^o/3 = k^o\ s^2/6 = d^o\ s/6$ ..... (129)

$\theta$ *aprox* en minutos $= 10\ k^o\ s^2 = 10\ d^o\ s$ ..... (130)

Por lo tanto. Figs 81, 82, para el angulo $\Theta = V\ A\ B$, entre la tang $A\ V$, y la cuerda, $A\ B$, desde $A$ al extremo, $B$, de la espiral, tenemos :

$\Theta$ aprox en minutos $= 10\ k^o\ S^2 = 10\ D^o\ S$ ..... (131)

**Valor del angulo de deflexion**, $\theta_1$, en la T. E. ($A$), entre la tang $A\ V$, y la cuerda que une $A$ con el **primer punto de la espiral**, $n = 1$.

**208.** Sea $s_1$, ( $= 0.01\ c$), $\theta_1$ y $\delta_1$, los valores de $s$, de $\theta$ y de $\delta$, respectivamente para el punto $n = 1$, al extremo de la primera de las diez cadenas espirales.

Si $\Delta$ es menor de $45^o$ (como sucede siempre en la práctica), tenemos de la ec (127), para la extension, $\delta_1$, subtendida por la primera cadena espiral : $\delta_1 < 0.45^o$; y, de la ec (128) practicamente :

$\theta_1 = \delta_1/3 = d_1\ s_1/6 = s_1^2\ k/6 = (0.01\ c)^2\ k/6$ ..... (132)

de donde :

$k = 6\ \theta_1/s_1^2 = 6\ \theta_1/(0{,}01\ c)^2$ ..... (133)

De la ecuacion (127), tenemos :

$\delta_1 = (1/10)^2\ \Delta = \Delta/100$ ..... (134)

y

$\delta_1 = \delta_1/3 = \Delta/300$ ..... (135)

De la ecuacion (130), tenemos :

$\theta_1$, en minutos $= 10\ k^o\ (S/10)^2 = k^o\ S^2/10 = D^o\ S/10 = D^o\ S_1$ ..... (136)

**Valores de los angulos de deflexion F y f, entre una tang y la cuerda, P' P''**, uniendo dos puntos cualquiera de la espiral, figs 83 *a* y 83 *b*.

Sea :

$F$ = el ángulo entre la tang inicial, $A\ V$, y la cuerda, $P'\ P''$;

$f$ = el ángulo, en $P'$, entre la tang, $P'\ m$, y la cuerda $P'\ P''$.

**209.** Sea:

$d'$, $d''$ = la agudeza en $P'$ y en $P''$, respectivamente;

$\delta'$ = la extension entre $A$ y $P'$ = el angulo, en $V'$, entre la tang inicial, $A\ V$ por $A$, y la tang $V'\ m$, por $P'$;

$s'$, $s''$ = el número de cadenas de 100 pies entre $A$ y $P'$, y entre $A$ y $P''$, respectivamente;

$q = s'' - s'$ = el número de cadenas de 100 pies entre $P'$ y $P''$.

Se buscan, $F$ y $f$; ($f = F - \delta'$).

**210.** Fig. 83 *a* *. De cualquier punto de la espiral, $P'$, corramos una curva *circular* $P'\ c$, con la agudeza, $d'$ de la espiral en $P'$. Esta curva circular diverge de la tang, $P'\ m$, en $P'$ en la proporcion *constante* de $d'$ grados por cada 100 pies de cuerda; pero la *espiral*, $P'\ P''$, diverge de la misma tang, $P'\ m$, en la proporcion constante en que aumenta en $(d' + k)^o$ por 100 pies de cuerda, donde $k$ = el aumento en agudeza de la espiral por 100 pies de cuerda *. Por tanto, la espiral, $P'\ P''$, diverge de la curva *circular*, $P'\ c$, en la proporcion constante de $k^o$ de aumento por cada 100 pies de cuerda *; pero esta $k$ es tambien la proporcion en que, la espiral $A\ P''$, diverge de la tang inicial, $A\ V$ en $A$. O (como cualquier punto en la espiral puede tomarse como $P'$) supongase a $P'$ tomado en $A$ *. Entonces, en $A$,

---

* En la fig. 83*b*, la proporcion del aumento proporcional $k$ de la agudeza de la curva es *negativo* ; asi, la agudeza *disminuye* de $P'$ hacia $P''$, y la espiral diverge de la curva circular en una proporcion *decreciente* de $(d' - k)^o$ por cada 100 pies de cuerda. Tambien, en la fig. 83*b*, si $P'$ se toma en $A$, entonces $P''$ tambien esta en $A$.

la tang inicial, $A\ V$, la tang por $P'$ (ahora tomado en $A$), y la curva circular (aquí una linea recta; agudeza, $d' = 0°$) coincide, y tenemos (con $P'$ en $A$) : $d' = 0$; y

proporcion de la divergencia de la espiral con la tangente por $A$
= proporcion de la divergencia de la tangente por $P'$ (tomado en $A$)
= proporcion de la divergencia de la espiral de la curva circular empezando en $P'$ (tomado en $A$) = $(d' + k)° = k°$.

**211.** En $q$ cuerdas de 100 pies de $P'$, la curva circular, $P'\ c$, describe una extension de $q\ d'$ grados, y un ángulo periférico o de « deflexion » = mitad de $q\ d'$ ; o bien

$$m\ P'\ c = q\ d'/2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (137)$$

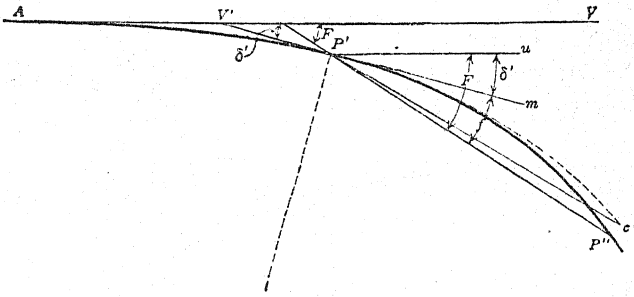

**Fig. 83 a.**

**212.** En la misma distancia, $q$, la espiral aumenta su agudeza, sobre la de la curva circular, $P'\ c$, en $q\ k°$ ; su agudeza *media* aumenta $q\ k°/2$; y su aumento de extension sobre la de la curva circular, es $q\ (q\ k°/2) = q^2\ k°/2$; pero la divergencia, $c\ P'\ P''$, de la *cuerda* espiral, $P'\ P''$, con la cuerda de la curva circular, $P'\ c$, es solamente un tercio de $q^2\ k°/2$ (vease ec 128); o

$$c\ P'\ P'' = q^2\ k/6 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (138)$$

**213.** Ahora :

$$f = F - \delta' = m\ P'\ P'' = m\ P'\ c + c\ P'\ P''$$
$$= q\ d'/2 + q^2\ k/6$$
$$\text{Ec (137)} \quad \text{Ec (138)}$$

$$= \frac{q}{6}\ (2\ d' + d' + q\ k) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (139)$$

$$= \frac{q}{6}\ (2\ d' + d'') \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (140)$$

y

$$F = \delta' + q\ d'/2 + q^2\ k/6 = \delta' + \frac{q}{6}\ (2\ d' + d'') \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (141)$$

**Valor de f entrando $\theta_1$.**

**214.** Sea $m = f/\theta_1$. De la ec (140) y ec (132) tenemos :

$$\left.\begin{aligned} m &= \frac{f}{\theta_1} = q\ \frac{2\ d' + d''}{d_1\ s_1}\ ; \\ \text{o bien } f &= m\ \theta_1 = \theta_1\ q\ \frac{2\ d' + d''}{d_1\ s_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (142)$$

**215.** Así, sea $c = 20$ pies; $k = 2°$.
Entonces, $s_1 = 0.01\ c = 0.2$ y $d_1 = s_1\ k = 0.4°$; $d_1\ s_1 = s_1^2\ k = 0.08$; $\vartheta_1 = d_1\ s_1/6 = 0.0133\ldots$; y, por ejemplo:

| Visuales. | | $q =$ | $d' =$ | $d'' =$ | $m = f/\vartheta_1 =$ | $f =$ |
|---|---|---|---|---|---|---|
| De est. | a est. | $0.01\ c \times (n'' - n')$ | $0.01\ k\ c\ n'$ | $0.01\ k\ c\ n''$ | $q\ \frac{2\ d' + d''}{d_1\ s_1}$ | $m\ \vartheta_1$ |
| 5 | 8 | 0.6 | 2.0 | 3.2 | 54 | 0.72 |
| 8 | 5 | − 0.6 | 3.2 | 2.0 | − 63 | − 0.84 |

Para $\vartheta_1$, vease ec (132).

**216.** Para los valores del coef, $m = f/\vartheta_1$, usado para obtener el angulo de deflexion, $f$, para determinar cualquier punto de la espiral, $P''$, desde cualquier punto del instrumento, $P'$, vease tabla, ¶ 233.

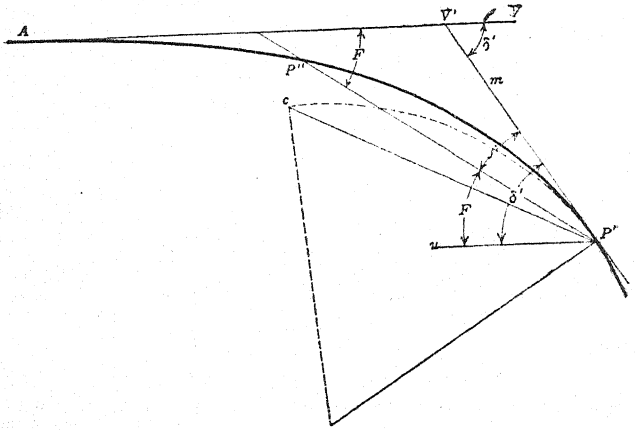

**Fig. 83 b.**

**Valores de los angulos de deflexion $F_a$ y $f_L$** entre una tang y la cuerda $P'\ P''$ ( = 1 cadena espiral) que une dos puntos de cadena *adyacente* de espiral.

**217.** Figs 83. Supongamos los puntos, $P'$ y $P''$, que sean ahora dos puntos *adyacentes* de cadena de espiral, $n$ y $n + 1$. Entonces, de la ec (140) y (123), tenemos (desde ahora $q = S/10$):

$$f_a = \frac{S}{60} \times \frac{2\ n + n + 1}{5\ S}\ \Delta = \frac{3\ n + 1}{300}\ \Delta \quad \ldots\ldots\ldots \quad (143)$$

y, de la ec (127), tenemos:

$$\delta' = \frac{n^2}{100}\ \Delta = \frac{3\ n^2}{300}\ \Delta \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (144)$$

De aqui:

$$F_a\ (= f_a + \delta') = \frac{3\ n^2 + 3\ n + 1}{300}\ \Delta \quad \ldots\ldots\ldots \quad (145)$$

Sea $m_a = 3\,n^2 + 3\,n + 1 = 300\,F_a/\Delta$. Entonces para los nueve puntos, de $n = 0$ a $n = 9$, mirando de $n$ a $n + 1$, o viceversa, tenemos, respectivamente :

| | | | | | |
|---|---|---|---|---|---|
| $n =$ | 0 | 1 | 2 | 3 | 4 |
| $n + 1 =$ | 1 | 2 | 3 | 4 | 5 |
| $m_a = \frac{300}{\Delta} F_a =$ | 1 | 7 | 19 | 37 | 61 |
| $m_a/300 = F_a/\Delta =$ | 0.0033 | 0.0233 | 0.0633 | 0.1233 | 0.2033 |

| | | | | | |
|---|---|---|---|---|---|
| $n =$ | 5 | 6 | 7 | 8 | 9 |
| $n + 1 =$ | 6 | 7 | 8 | 9 | 10 |
| $m_a = \frac{300}{\Delta} F_a =$ | 91 | 127 | 169 | 217 | 271..... (146) |
| $m_a/300 = F_a/\Delta =$ | 0.3033 | 0.4233 | 0.5633 | 0.7233 | 0.9033 |

del cual, y de $F_a = \frac{m_a}{300}\,\Delta$ los varios valores de $F_a$ para los puntos de 10 cadenas.

se encuentran facilmente, para cualquier valor dado de $\Delta$.

**218.** Asi, en estacion $n = 7$, mirando a la estacion $n + 1 = 8$, el angulo, $F_a$, entre la visual 7-8, y la tangente inicial, $A\ V$, es :

$$F_a = \frac{m_a}{300}\,\Delta = \frac{169}{300}\,\Delta = (0.5633.....)\,\Delta.$$

**219.** Figs. 81, 82. **Valor del angulo de deflexion,** $\Theta$ en $A$, entre la tang $A\ V$ y la cuerda $A\ B$. Sean los valores sucesivos de $F_a$, asi encontrados :

$$F_1 = \frac{\Delta}{300}; \qquad F_2 = 7\,\frac{\Delta}{300}; \qquad F_3 = 19\,\frac{\Delta}{300}; \text{ etc.;}$$

y sea $x_1, x_2, x_3$, etc., $y_1, y_2, y_3$, etc., las coordenadas para los puntos $n = 1$, $n = 2$, $n = 3$, ... $n = 10$ (punto $B$). Sea $L$ = la suma de las cadenas de espiral, en pies; $c = L/10$.

Entonces :

$$x_1 = c\,\cos\,F_1\,; \qquad y_1 = c\,\text{sen}\,F_1\,;$$

$$x_2 = c\,(\cos\,F_1 + \cos\,F_2); \qquad y_2 = c\,(\text{sen}\,F_1 + \text{sen}\,F_2) \ldots\ldots \quad (147)$$

etc. as etc.

$$\text{Tan}\,\Theta = \tan\,V\,A\,B = \frac{Y}{X} = \frac{\text{sen}\,F_1 + \text{sen}\,F_2 + \ldots \text{sen}\,F_{10}}{\cos\,F_1 + \cos\,F_2 + \ldots \cos\,F_{10}} \ldots\ldots\ldots \quad (148)$$

De los valores de las funciones de $\Theta$, asi encontrados, se deriva el valor :

$$\left(\frac{\Delta}{3} - \Theta\right)\text{en segundos} = 0.002\ 97\ (\Delta \text{ en grados})^3$$

o bien $\Theta = \Delta/3 - [0.002\ 97\ (\Delta^\circ)^3]$ segundos..... (149)

**Valor del angulo de deflexión,** $\Phi$, en la E. C. ($B$), entre la tan $V\ B$ y la cuerda $A\ B$.

**220.** Figs 81, 82. Necesariamente, $\Delta = \Theta + \Phi$; o bien :

$$\Phi = \Delta - \Theta = \Delta - \left[\frac{\Delta}{3} - (0.002\ 97\ (\Delta \text{ en grados})^3 \text{ segundos }^*)\right].$$

De aqui :

$$\Phi = \frac{2}{3}\Delta + \left(0.002\ 97\ (\Delta \text{ en grados})^3 \text{ segundos }^*\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (150)$$

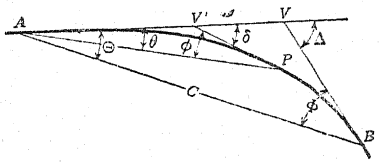

**Fig. 82' (Repetida).**

Practicamente * : $\Phi = 2\ \Delta/3 = 2\ \Theta$ ..... (151)

Similarmente, fig. 82', en cualquier porción, *A P*, de la curva espiral *A P B*, dicha porcion empezando en la T. E. (*A*), tenemos practicamente :

$$\delta = \theta + \Phi;$$
$$\theta = \delta/3;$$
$$\Phi = 2\ \delta/3 = 2\ \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (151')$$

**221. Relaciones entre H, L y Z**, fig. 82.

$$H = \text{aprox}\ \frac{L^2}{24\ R} = \frac{L^2}{24} \cdot \frac{D}{5730} = 0.0727\ S^2/D \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (152)$$

$$L = \sqrt{24\ R\ H} = 4.9\sqrt{R\ H} = 4.9\sqrt{5730\ H/D} = 371\sqrt{H/D} \quad \ldots\ldots \quad (153)$$

$$\Delta = 0.005\ DL \text{ (ec 126)} = 0.005\ D\ 371\sqrt{H/D} \text{ (ec 153); o } \Delta = 1.854\sqrt{DH} \quad (154)$$

**222. Bisecciones en M aproximadas.** Fig. 82. Practicamente :

$$L/2 = A\ M = M\ B = A\ A' = Z = a\ B \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (155)$$

$$A'\ M = M\ a = H/2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (156)$$

o, practicamente, $A'\ a$ divide en dos partes iguales y es dividida por la espiral *A B*, en *M*.

Mas exactamente (Boletin 73, p. 67, 1906 de la Asen Am Ings F. C.) :

$$\frac{L}{2} - Z\left(= \frac{L}{2} - A\ A'\right) = \frac{L^3}{1280\ R^2} = \frac{L^3}{1280}\left(\frac{D}{5730}\right)^2 \quad \ldots\ldots\ldots\ldots \quad (157)$$

**223. Ordenadas.**

$$y = \frac{l^3}{6\ R\ L} = \frac{l^3\ D}{34.380\ L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (158)$$

Multiplicando por $4\ L^2/4\ L^2$

$$y = \frac{4\ L^2\ l^3}{24\ R\ L^3}\text{; y, (ec 152) } y = 4\ H\ (l/L)^3 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (159)$$

---

* Vease * nota, pag 1018.

**224. Otras relaciones.** Fig. 82.

$$C = \sqrt{X^2 + Y^2} = X \sec \Theta \quad (160)$$

$$C = \text{aprox } L\,[\cos 0.3\,\Delta + 0.004 \operatorname{exsec}(3\,\Delta/4)] \quad (161)$$

$$X = C \cos \Theta; \qquad Y = C \operatorname{sen} \Theta \quad (162)$$

$$T_a = C \operatorname{sen} \Phi/\operatorname{sen} \Delta; \qquad T_b = C \operatorname{sen} \Theta/\operatorname{sen} \Delta = Y/\operatorname{sen} \Delta \quad (163)$$

$$t_a = C_n \operatorname{sen} \Phi/\operatorname{sen} \delta; \qquad t_b = C_n \operatorname{sen} \theta/\operatorname{sen} \delta \quad (164)$$

$$Z = X - R \operatorname{sen} \Delta \quad (165)$$

$$H = Y - R \operatorname{senoverso} \Delta \quad (166)$$

**225.** Fig. 81 *a*. Cuando las **dos espirales**, *A B* y *Af Bf*, son **iguales y semejantes**, tenemos :

$$T = a\,v + D\,V_e + A\,A' = (R + H) \operatorname{tang}(\Delta_e/2) + Z \quad (167)$$

Distancia externa, $E = P\,V_e = (R + H) \operatorname{exsec}(\Delta e/2) + H$ (168)

**226.** Cuando, como en la fig. 81 *b*, las **dos espirales**, *A B* y *Af Bf*, son **desemejantes**; sea *a' a* (igual y paralela a *P' P*, $V_e\,v$, $a_f'\,a_f$ y *O' O*) la dist a que la curva circular original *a' a*$_f''$ es movida a *a*$a_f'$; y sea $\alpha$ = el angulo *A' a a'*; $a_f$ = el angulo $A_f' a_f a_f''$.

Entonces, dando la dist movida = *a' a*, y los angulos, $\alpha$ y $a_f$, tenemos :

$$H = a'\,a \cos \alpha; \quad H_f = a_f'\,a_f \cos a_f = a'\,a \cos a_f, \text{ y } H_f/H = \cos a_f/\cos \alpha \quad (169)$$

Dando *H* y $\Delta_e$, tenemos : $\dfrac{A'\,a'}{H}\left(= \dfrac{D\,V_e}{H}\right) = \dfrac{N\,V_e}{H} - \dfrac{N\,D^*}{H}$; o bien :

$$\text{tang } \alpha = \frac{H_f}{H \operatorname{sen} \Delta_e} - \cot \Delta_e^* \quad (170)$$

$$a_f = \Delta_e - \alpha \quad (171)$$

Tenemos, tambien :

$$T\ (= A\,V_e) = A\,A' + a\,v + D\,N\dagger + N\,V_e = Z + R \operatorname{tang}(\Delta_e/2) + H \cot \Delta_e + H_f \operatorname{cosec} \Delta_e \quad (172)$$

Una ecuacion análoga da los valores de la otra semitang, $T_f = A_f\,V_e$.

$Z$ = practicamente $L/2 = 2.45\sqrt{R\,H}$ (vease ec 153) (173)

## Eleccion de la espiral.

**227.** Fig. 82. La eleccion del largo, *L*, de la espiral puede **restringirse por el valor de H**, determinado topograficamente o por otras condiciones. Tenemos entonces (ec 153), para el largo de la espiral :

$$L = \sqrt{24\,R\,H};$$

donde *R* = radio de la curva circular.

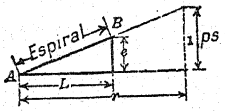

**Fig. 83½.**

**228.** Fig. 83 ½. Donde la espiral elegida no esta asi restringida, el largo, *L*, se **determina por el peralte, e**, en pies (o *E* en pulgs) en la curva circular, y por la relacion, *r*, del peralte gradual por pies de linea (¶ ¶ 190-193); asi (ec 117) :

* Cuando, como en la Figs 81, $\Delta e > 90° < 180°$, *N D* y cot $\Delta e$ son *negativas*.

† Cuando $\Delta e < 90°$, *D H* y *Df Hf* son *negativas*.

$L = e\,r = 0.3273\ V^2\ r/R = 0.1522\ v^2\ r/R = 0.1522\ v^2\ t/R$ ..... (174)
donde $t = r/v$ = tiempo, en segundos, durante el cual la rueda exterior en el peralte gradual, se levanta 1 pie.

La regla de la Ascn Am Ings F. C., ec (175), da $t \leqslant 5.45$ cuando $V = 45$ millas por hora (digamos 70 kilom/hora), y el peralte = 8 pulgs (20 cm) = 2/3 pie.

**229. La Ascn Am Ings F. C.** (Manual, 1915, pag 131-132) recomienda:
En curvas que no limitan la velocidad de los trenes:
$L \leqslant 360\ e_u$; o $L \leqslant 8\ V_u\ e_u$ ..... (175)
En curvas que limitan la velocidad de los trenes:
Cuando $D < 6°$, $L \leqslant 16\ V_s/3$; cuando $D \leqslant 6°$, $L \leqslant 240$ ..... (176)
donde
$L$ = largo de la espiral, en pies;
$V_u$ = velocidad maxima, en millas/hora; $e_u$ = superel, en pies, para $V_u$;
$V_s$ = velocidad en millas/hora calculada para una elevacion de 8 pulgs (como 20 cm).

$$= \sqrt{\frac{8\ R}{3.928}} \text{ (vease ec 118).}$$

Con $V = 45$ millas/hora, y superel, $E$, = 8 pulgs, o $e = 2/3$ pie, cada una de estas reglas da $L \leqslant 240$ pies (digamos 72 ms).

**230. En la práctica**, y con objeto de evitar el uso de sub-cadenas en la espiral puede usarse una longitud aproximada a la $L$, de la espiral, calculada.
Por ejemplo, con $H = 9.6$ pies, curva circular 5° ($R = 1146.3$ pies), tenemos (ec 153):

$$L = \sqrt{24\ R\ H} = 513.9 \text{ pies.}$$

Con $V = 50$ m/h, en una curva de 6° ($R = 955.4$ pies), relacion, $r$, del peralte gradual = 600, tenemos (ec 174):

$$L = r\ 0.3273\ V^2/R = 513.9 \text{ pies.}$$

En cualquiera de los dos casos, pudieramos usar 500 pies (10 cadenas de 50 pies) o 510 pies (10 cadenas de 51 pies) o 525 pies (10 cadenas de 52.5 pies), etc.

## Trazado.

Resultados condensados, para usarlos en el campo.

### Por angulos de deflexión.

**231.** La espiral puede determinarse convenientemente con angulos de «deflexion» desde una tang como si fueramos a determinar una curva circular; pero en las espirales, los incrementos sucesivos, en el angulo de deflexion total marcado desde la tang en un punto dado, aumenta regularmente, en lugar de ser constantes como en las curvas circulares.

**232.** Las derivaciones de las ecuaciones para tales angulos se dan en ¶ ¶ 207 a 220. Los siguientes (para uso en el campo) dan la deflexion necesaria para determinar cualquier punto, en cualquier espiral dada de 10 cuerdas, cuando el instrumento está en cualquier otro punto en la espiral. Asi:

**233.** El largo de cadena espiral, $c$ (largo de espiral, $L = 10\ c$) y el aumento, $k$, de agudeza por 100 pies de cuerda, determinan completamente la espiral. Vease el ejemplo abajo.
Dando $c$ y $k$, **se busca el angulo de deflexion**, $i$, Figs 83 $a$, 83 $b$, necesario para fijar cualquier punto dado, $P''$, desde la tang, $P'\ m$, desde cualquier punto dado, $P'$.

Sea:

$c$ = el largo dado de la cadena espiral en pies;

$k$ = el aumento dado de la agudeza, $d$, por 100 pies de cuerda, en grados;

$n$ = el numero de cadenas espirales entre la T. E. ($A$) y cualquier punto dado de la espiral;

$s_1$, $s'$, $s''$ ( = 0.01 $c\ n$) = el numero de cuerdas de 100 pies entre la T. E. ($A$) y los puntos $n = 1$, $P'$ y $P''$, respectivamente;

$d_1$, $d'$, $d''$ (= $Ks_1$, $Ks'$, $Ks''$ respeetivamente) = a la agudeza de la espiral en los puntos $n = 1$, $P'$ y $P''$ respectivamente;

$q = s'' - s'$ = el número de cuerdas de 100 pies entre $P'$ y $P''$;

$\vartheta_1$ = deflexion de..... { la tang inicial, $A\ V$, } en $A$, a { la cuerda ( = 1 cadena espiral, $c$) de $A$ al primer punto de la espiral donde $n = 1$;

$f$ = deflexion requerida de { la tangente $P'\ m$, } { en cualquier punto dado de la espiral, $P'$, } a { cuerda, $P'\ P''$, de $P'$, a cualquier otro punto de la espiral $P''$;

$m = f/\vartheta_1$ = un coeficiente.

De la ec (132) tenemos $\vartheta_1 = (0.01\ c)^2 k/6$.

De la ec (142) tenemos

$$m\ (= f/\vartheta_1) = q\ \frac{2\ d' + d''}{d_1\ s_1};\ \text{y}\ f = m\vartheta_1.$$

La siguiente tabla da los valores de $m\ (= f/\vartheta_1)$ cuando se mira desde cualquier punto dado de la espiral, $P'$ hacia adelante (Fig. 83 *a*) o hacia atrás (Fig. 83 *b*) a cualquier otro punto $P''$ de la espiral.

**Valores de m** $(= f/\vartheta_1)$ para ángulos de deflexion de tangentes a puntos de cadena. Figs 83 *a*, 83 *b*.

| Punto del instrumento $P'$. | Numero, $n$, del punto requerido, $P''$. | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | T. E. $A$ 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | E. C. $B$ 10 |
| | *m* | *m* | *m* | *m* | *m* | *m* | *m* | *m* | *m* | *m* | *m* |
| 0 $A$ ($T$ E)... | 0 | 1 | 4 | 9 | 16 | 25 | 36 | 49 | 64 | 81 | 100 |

| 2..... | 8 | 5 | 0 | 7 | 16 | 27 | 40 | 55 | 72 | 91 | 112 |
| 3..... | 18 | 14 | 8 | 0 | 10 | 22 | 36 | 52 | 70 | 90 | 112 |
| 4..... | 32 | 27 | 20 | 11 | 0 | 13 | 28 | 45 | 64 | 85 | 108 |
| 5..... | 50 | 44 | 36 | 26 | 14 | 0 | 16 | 34 | 54 | 76 | 100 |
| 6..... | 72 | 65 | 56 | 45 | 32 | 17 | 0 | 19 | 40 | 63 | 88 |
| 7..... | 98 | 90 | 80 | 68 | 54 | 38 | 20 | 0 | 22 | 46 | 72 |
| 8..... | 128 | 119 | 108 | 95 | 80 | 63 | 44 | 23 | 0 | 25 | 52 |
| 9..... | 162 | 152 | 140 | 126 | 110 | 92 | 72 | 50 | 26 | 0 | 28 |
| 10 $B$ ($E$ $C$)... | 200 | 189 | 176 | 161 | 144 | 125 | 104 | 81 | 56 | 29 | 0 |

**Ejemplo. Dando :**

$c$ = largo de la cadena espiral, = 20 pies;

$k$ = aumento de agudeza de la espiral, $d$, por 100 pies de cuerda, = 3°.

Entonces :

Ec (121) Largo, $L$, de la espiral, $A\ B$, en pies, medida a lo largo de las cadenas de espiral = $10\ c = 10 \times 20 = 200$ pies;

Numero, $S$, de cuerdas de 100 pies en $L$ = aprox $0.01\ L = 2$;

Ec (122) Agudeza, $D$, de la espiral en la E. C. ($B$), = aprox $k\ S = 3° \times 2 = 6°$;

Ec (126) Extension, $\Delta$, de la espiral, $A\ B$, = aprox $D\ S/2 = 6° \times 1 = 6°$;

Ec (129) Angulo de deflexion, $\Theta = V\ A\ B$, = aprox $\Delta/3$ = aprox 2°;

Angulo de deflexion, $\Phi = V\ B\ A$, = aprox $2\ \Delta/3$ = aprox 4°.

**Se busca el ángulo de deflexion, f**, de la tangente, $P'\ m$, en el punto $P'$ a otro punto de la espiral, $P''$ :

Aquí ec (132) :

$$\vartheta_1 = (0.01\ c)^2\ k/6 = 0.04 \times 3°/6 = 0.02°;$$

y (de la tabla arriba), fig. 83 *a*, mirando de :

$P'$, $(n = 5)$ a $P''$, $(n = 8)$, $m = 54$.

Por lo tanto, en este caso,

$$f\ (= m\ \mathfrak{d}_1) = 54 \times 0.02^o = 1.08^o.$$

Ademas, fig. 83 *b*, mirando de $P'$, $(n = 8)$ a $P''$, $(n = 5)$ tenemos :

$$f\ (= m\ \mathfrak{d}_1) = 63 \times 0.02^o = 1.26^o.$$

**234. Valores de m, etc., en casos especiales.** Figs. 82, 83.

(*a*) Cuando el punto $P'$ del instrumento esta en la T. E. $(A)$ o punto $n = 0$ (Linea de arriba de la tabla ¶ 233.)

Figs 82, 83 *a*. Cuando se mira (hacia adelante) de $A$ a cualquier otro punto de la espiral $P''$, de numero $n$, la ec (142) se convierte :

$$m = q\ \frac{2\ d' + d''}{d_1\ s_1} = 0.01\ c\ n\ \frac{k\ s''}{0.01\ k\ c.\ 0.01\ c} = n\ \frac{s''}{0.01\ c} = n^2;$$

y $\mathfrak{d}''$ ($\mathfrak{d}$ para el punto $P''$) $= m\ \mathfrak{d}_1 = n^2\ \mathfrak{d}^1$.

Por lo tanto, cuando $P''$ esta en la E. C. $(B$, o $n = 10)$, tenemos $m\ (= n^2) = 100$, y $\Theta\ (= V\ A\ B) = 100\ \mathfrak{d}_1 =$ aprox $\Delta/3$ *.

(*b*) Fig. 83 *b*. Cuando el punto, $P''$, mirado (hacia atras), esta en la T. E. $(A)$ o punto $n = 0$ (Columna en cabezada T. E.).

Cuando mirando de cualquier otro punto, $P'$, de numero $n$, hacia $A$, tenemos, aprox, ec (151'), $\Phi = 2\ \mathfrak{d}$.

Por lo tanto, cuando el punto $P'$ del instrumento, esta en la E. C. $(B$, ó $n = 10)$, tenemos $\Phi\ (= V\ B\ A) = 200\ \mathfrak{d}_1 =$ aprox $2\ \Theta = \frac{2}{3}\ \Delta$ *.

**Por ordenadas desde la tangente inicial, A V.**

**235.** Fig. 82. Las ordenadas, $x$ e $y$ (ecs 147, 158, 159) a cada uno de los puntos en toda la espiral $A\ B$, pueden medirse desde la tang inicial, $A\ V$.

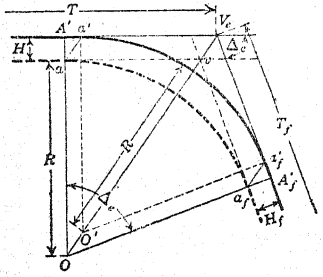

Fig. 84.

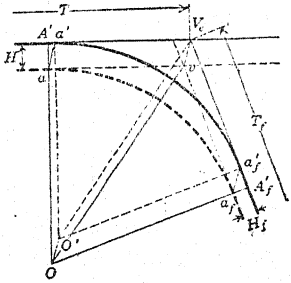

Fig. 85.

O, hacer la ordenada, $A'\ M$, por el punto medio, $M$, de la espiral $= A'\ a/2 = H/2$ (¶ 222), y el resto de las ordenadas proporcionales a los cubos de sus distancias desde $A$ y de $B$ respectivamente, midiendo las ordenadas por la primera mitad de la espiral hacia adentro a angulos rectos desde la tang $A\ V$, y el resto radialmente hacia afuera de la curva circular, $a\ B$.

**Por perpendiculares de la cuerda larga A B.**

**236.** Fig. 82. Sea :

$h$ = la ordenada normal desde la cuerda larga a cualquier punto dado en la espiral;

$H$ = dist entre tangentes paralelas, $A\ V$ y $a\ v$;

$n$ = numero de cadenas espirales entre la T. E. $(A)$ y el punto dado;

$N$ = numero de cadenas de espiral en la espiral.

---

* Vease nota al pie *, p. 1048.

Entonces, **en cualquier espiral** :

$$\frac{h}{H} = 4\,n\,\frac{N^2 - n^2}{N^3} \qquad (177)$$

Esta ecuacion, es bastante aproximada para la espiral de 10 cuerdas de la Asen Am Ings F. C.

**En la espiral de 10 cuerdas**, $N = 10$; asi que :

$$\frac{h}{H} = 4\,n\,\frac{100 - n^2}{1000} = 0.4\,n - 0.004\,n^3 \qquad (178)$$

Por lo tanto tenemos :

Cuando

| $n =$ | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $h/H =$ | 0 | 0.396 | 0.768 | 1.092 | 1.344 | 1.500 | 1.536 | 1.428 | 1.152 | 0.684 | 0 |

$h$ es un maximo ( $= 1.54\ H$) cuando $n = N/\sqrt{3} = 10/1.7321 = 5.77$.

## Insercion de espirales en vias existentes.

Vease tambien ¶ 169.

**237 (a)**. Figs 81, 84, 85. La curva circular original, $a'\,af'$, corrida **sin cambiar de radio**, en una dist dada, $a'\,a$, (igual y paralela a $V_e\,v$ y a $af'\,af$) a una nueva posicion, $a\,af$.

Se buscan las semitangentes, $T$ y $T_f$, a la curva entera, $A\,B\,B_f\,A_f$, fig. 81.

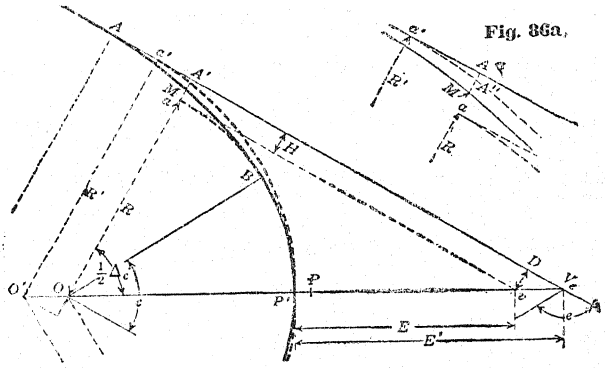

Fig. 86.

(1) Figs 81 $a$, 84. Las dos espirales similares. Corrase, $a\ a$, paralela a la bisectriz comun $O\,v$, de $a'\,af'$ y de $a\,af$ ;

$Tf = T$; $Hf = H$. $R =$ rad de la curva circular.

Aqui $H = H_f = a'\,a \cos(\Delta_e/2)$ ..... (179)

$T = T_f = (R + H)\tan(\Delta_e/2) + Z$ ..... (180)

De las ecs (153 y 157), tenemos :

$$Z = \frac{L}{2} - \frac{L^3}{1280\,R^2} = \text{prácticamente } \frac{\sqrt{24\,R\,H}}{2} = 2.45\,\sqrt{R\,H}.$$

(2) Figs 81 *b*, 85. Las dos espirales desemejantes. Corrase $a'\ a$ (igual y paralela a $V_e\ v$ y á $a_f'\ a_f$), no paralela a la bisectriz $O\ v$ ó, $O'\ V_e$.
$T_f$ y $T$ desiguales $H_f$ y $H$ desiguales.
Para $T$ y $T_f$, vease ec (172).
Para $H$ y $H_f$, vease ec (169).

**238 (b).** Fig. 86. **Conservando el punto medio original**, $P'$ y acortando el radio de $R'$ a $R$. Se cambia la linea de $A\ a'\ P'$ a $A\ B\ P'$. Habiendo determinado (¶ ¶ 227 etc.) la longitud, $L$, y $A'\ a = H = \frac{L^2}{24\ R}$;

Sea:

$\Delta_e$ = ángulo central entero, = 2 arc $a\ P'$ = 2 angulo $a\ O\ P'$;
$A''\ M$ (Fig. 86 *a*) = movida máxima de la linea de centro de la via;
$a'\ A'$ = movida del punto $a'$ de la curva circular, hacia la interseccion, $V_e$; y

| Radio. | Semitang. | Dist ext. | Agudeza. |
|---|---|---|---|
| $R' = O'\ a'$ | $a'\ V_e$ | $E' = P'\ V_e$ | $D'$ de la curva circular existente $a'\ P'$; |
| $R = O\ a$ | $a\ v$ | $E = P'\ v$ | $D$ de la curva circular aguda, $a\ P'$) |

Entonces:

$$E = E' - V_e\ v = E' - H \sec (\Delta_e/2); \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (181)$$

$$R = \frac{E}{\text{ex sec } (\frac{1}{2}\ \Delta_e)}; \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (182)$$

$$D = \frac{E \text{ de una curva de 1.º, de una extension dada, } \Delta_e}{E} \quad \ldots\ldots\ldots\ldots \quad (183)$$

$$a'\ A' = (R' - R - H) \text{ tang } (\Delta_e/2) = a'\ V_e - (R + H) \tan (\Delta_e/2) \ldots\ldots \quad (184)$$

Practicamente (Fig. 86 *a*), $A''\ M = \frac{H}{2} - \frac{7}{8}\left(\frac{a'\ A'}{100}\right)^2 D$ ..... (185)

**239 (c).** Fig. 86. **Con la corrida mínima de la linea.** Corrase el punto medio, $P'$ a $P$, haciendo $P'\ P = H/2$. Entonces:

$$E = E' - H \sec (\Delta_e/2) - H/2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (186)$$

Úsese este nuevo valor de $E$ en Ecs (182) y (183).

# SEÑALES

## GENERALIDADES

**1. El objeto** de las señales de ferrocarril es facilitar el movimiento de trenes, y evitar los choques dandole al maquinista informaciones con respecto a la via o las necesarias instrucciones para seguir o parar. La expresion « señales » se extiende hasta incluir los cambios de agujas, para correr los trenes en diferentes vias segun sea necesario.

**2.** El asunto lo tratamos aqui con poca extension, él en sí y el trazado de vía estan considerablemente relacionados sobre todo donde el tráfico puede ser fuerte. Nos hemos desviado un poco de la nomenclatura acostumbrada y en el modo de tratar el asunto con el propósito de abreviar el artículo, y facilitar su comprension a los que no estan versados con la práctica de señales.

**3. Las divisiones principales** del tema pueden hacerse así; (*a*) manipulacion; (*b*) trasmision (mecanismo); (*c*) señales.

(*a*) *Manipulacion* es la operacion (manual, eléctrica, o neumática) de las palancas u otros medios, que, por « trasmision » (*b*), hacen las señales (*c*).

(*b*) *Trasmision* son los medios (tales como barras, tubos, alambres, etc.) por los cuales la manipulacion (*a*) hace las señales (*c*). Los medios pueden ser mecánicos, eléctricos, o neumáticos.

(*c*) *La señal* es el aparato que el personal de la locomotora observa y del cual directamente recibe sus instrucciones o informacion. La señal puede ser visible (semáforos, discos o luces) o auditivos (campanas o pitos, etc.). En la expresion « señal » puede incluirse tambien la Parada Automática, ¶ 64, que para el tren si el maquinista no atiende a una señal de parada. Estas tres divisiones se tratan aqui en orden invertido, con una division en los « Sistemas » insertada entre « Trasmision » y « Manipulacion ».

**Fig. 1** *Parar*

**Fig. 5** *Aplicar Frenos*

**Fig. 6** *Tren Partido.*

## SEÑALES

**4. Las señales a Mano** se intensifican a menudo de dia con el uso de una bandera, y de noche con faroles. Tres de las principales señales de mano se indican en las Figs 1 a 6. Un movimiento al través de la via con cualquier color u objeto significa « Parar ». Siempre que sea practicable se emplean banderas de colores y faroles, pero los colores no son esenciales.

**5. Hachones** se usan, generalmente, por la noche y en las neblinas; y algunas veces de dia, su humo sirve de señal. Son fuegos de artificio, conocidos como « fuego de color », con un extremo aguzado para enterrarlos en el terreno o en una traviesa. Cuando se encienden dan un resplandor continuo brillante (cinco o diez minutos); aun con viento o lluvia. Indican a un tren que sigue, que delante de él ha pasado un tren por el lugar, solamente unos minutos antes. Pueden arrojarse (encendidos) desde un tren en marcha a la via.

**6. Torpedos** son de tamaño pequeño en forma de cazoleta, se colocan en la cabeza del carril del lado derecho, y detras del tren que se va a proteger. El torpedo explota por las ruedas del primer tren que sigue, produciendo un ruido que el

maquinista seguramente tiene que oir. Se usan mucho durante las neblinas, nevadas, tormentas, etc., cuando las señales de vista no se pueden ver bien. Se usan sobre todo como auxiliar para hacer señales de bandera « atrás », para proteger el tren delantero mientras el abanderado vuelve al tren, o en caso de que el maquinista que sigue no pueda ver el abanderado.

### Señales Fijas.

**7. Los discos** de señales dan su indicacion, de dia tanto como de noche, solamente por medio del color, y no por la forma o posición. Cada disco de señal esta incluido en una caja. Moldeada como una guitarra (de aquí el nombre señal de « guitarra »), provista de un frente de cristal. Para usarla de dia, la señal consiste esencialmente en un disco de color opaco. Si este disco se mira al traves de la cara de cristal, indica « parar » cuando es rojo, o « precaución » * cuando es verde. Para indicar que se « siga », el disco se hace girar a un lado, dejando un fondo blanco que se ve al traves de la cara de cristal. De noche, un disco de cristal de color frente a una lampara indica « parar » o « precaucion »; o bien « seguir » al ser quitados aquellos dejando ver la lampara por un cristal claro.

**8. Semáforos.** Para señales se usa generalmente el tipo semáforo, vease figs 7 a 12, incl. Cada una consistente en un brazo movible o « tablero », de cerca de 4′ (1,20 m) de largo y 10″ (25 cm) de ancho, giratorio y montado en un poste u otro objeto apropiado.

**9. Señal Definitiva.** Una señal definitiva es aquella segun la cual el tren debe parar cuando la señal esta puesta para » parar ». Se coloca generalmente a la entrada de un (« block ») tramo de via, o inmediatamente antes de llegar a un desvío, descarrilador, crucero, puente giratorio, u otro objeto del que se va a proteger. Cuando está horizontal indica « parada », y por la noche la posicion horizontal se indica por un vidrio rojo, que aparece al frente de un farol. Cuando esta inclinado, la señal indica « seguir » y por la noche enseña una luz de algun color que no sea rojo. Vease tambien « Aspectos de las señales », ¶ ¶ 17, 32 y 33.

**10. Señal Distante.** Cuando se instala una señal « Distante » o de « Precaución * », se la coloca a alguna distancia (generalmente a varios millares de pies o centenares de m.) « atras de » (antes de llegar) a la señal « definitiva » a que se refiera y asi indica ademas la posición de la señal definitiva, que puede quizás estar oculta. De este modo se le anticipa al maquinista la informacion con respecto a la señal definitiva y hace posible el recorrido mas rápido y seguro. Las indicaciones de las señales definitivas y distantes simultaneamente siempre corresponden. A menos que el tren esté en la via entre las dos, en cuyo caso la señal distante indica « precaucion » * aunque la señal definitiva pueda estar en la posicion de « seguir ».

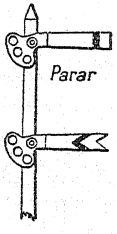

Fig. 7.

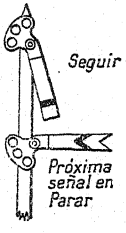

Fig. 8.

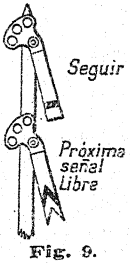

Fig. 9.

**11. Disposición** de las señales. La señal definitiva y la señal distante para el bloque o tramo de via adelante, están usualmente montados en el mismo poste, como en las figs 7, 8 y 9; la de arriba es la señal definitiva, y la de abajo, la señal distante.

---

*"Precaución" es una expresion usada aquí algo vaga, aunque indica su usual o roximado significado; « siga preparado para parar a la próxima señal ».

**12.** Cuando dos o mas señales definitivas, fig. 15, están montadas en el mismo poste, la de arriba (cuando indica libre) relativamente permite movimientos de alta velocidad, o movimientos sobre via recta. La señal de abajo gobierna movimientos mas lentos, o aquellos que van con rumbo para vias laterales.

**13. Señales enanas** son señales de semáforo, pequeñas, cerca de 9″ (como 23 cm) de largo y 3″ (como 8 cm) de ancho. Usualmente colocadas cerca del terreno, y se aplican a los trenes que vayan en contra de la direccion normal del tráfico.

**14. Las señales en conjunto** están formadas de luces y discos, etc., dando frente a direcciones diferentes, y montadas de modo que giren en un eje vertical. Se usan sobre todo en conexión con los cambios.

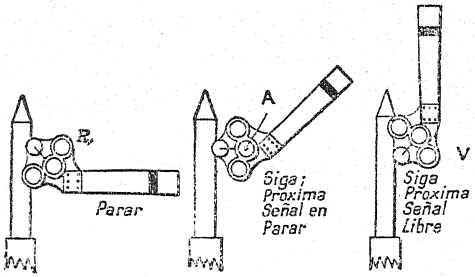

**Fig. 10.** R = *Rojo*.

**Fig. 11.** A = *Amarillo*

**Fig. 12.** V = *Verde*

**15. Señal de tres-posiciones**, figs 10, 11 y 12. Una señal de tres posiciones combina en un semáforo, las indicaciones de una señal definitiva y de una señal de distancia.

**16. Señal de dos luces** son aquellas (generalmente de tres-posiciones) en la cual una segunda ó luz simulada o « marcador », (o luz y semáforo) está debajo de la señal activa. Este marcador muestra rojo, (o « parar ») pero su indicacion es la que predomina cuando la señal activa indica otra cosa. Las ventajas son : que, siendo de color, el marcador ayuda de noche a determinar e identificar la señal activa, y reduce la posibilidad de que se deje de notar la señal propia en el caso de que cualquier luz se haya extinguido.

**17. Indicaciones o aspectos de señales.** Véase también ¶ ¶ 32 y 33. Aunque hay muchas variaciones en la práctica, los posiciones y colores indicados en las figs 10, 11 y 12 son las mas adoptadas. Las indicaciones de *dia* son dadas por la *posicion* del semáforo, y el color del semáforo no es entonces esencial, aunque generalmente es rojo o amarillo en la cara. Las indicaciones de *noche* estan dadas por las luces de color, — como sigue :

| | « Parar. » | « Precaucion *. » | « Seguir. » |
|---|---|---|---|
| | — | — | — |
| Práctica nueva..... | Roja. | Amarilla. | Verde. |
| Práctica antigua..... | Roja. | Verde. | Blanca. |

(El « amarillo », por algunos se llama anaranjado; mientras que el « blanco » luz descolorida tiene generalmente un tinte amarilloso.)

---

*"Precaución" es una expresion usada aquí algo vaga, aunque denota aproximadamente su significado usual; « siga preparado a parar en la señal próxima ».

**18.** Se está generalizando el uso de levantar el brazo al cuadrante de arriba (lado *izquierdo*) en los ferrocarriles eléctricos, tiene la ventaja de colocar la señal en los mismos ángulos como en el conocido sistema antiguo o sea en el cuadrante de abajo (lado derecho), y así queda mas facilmente colocado para ser visible entre los postes del telégrafo y las pértigas de los troles.

**19. Luces de relámpago**, para usarlas de noche. Se estan probando especialmente en el extranjero. El iluminante es generalmente gas acetileno, y cada lámpara esta preparada para lanzar destellos periodicamente (por el estilo de ciertos faros) alumbrando generalmente cerca de 0.1 de segundo y, extinguiendose por serca de 0,3 a 0,9 de segundo. Parecen adecuadas y economicas, y ayudan a distinguir las luces de señales, de otras luces extrañas al ferrocarril, y tambien para establecer diferencias entre diversas clases de señales.

**20. Las señales por luces** que no se usan con semáforo, son economicas en su costo primitivo, y no tienen partes movibles, fuera de las piezas que las ligan, Se usan en vias subterraneas y túneles, donde un semáforo no se puede ver bien; y hasta cierto punto en ferrocarriles eléctricos. Cuando se usan a la luz del dia, cada luz debe estar acompañada de una cubierta u otros medios para evitar que los rayos de sol caigan sobre los lentes, y por una pantalla u otro objeto grande obscuro, para llamar la atencion sobre la señal, y hacerla mas visible reduciendo asi la posibilidad de que se pase por alto. Vease tambien « Señales de dos vias », ¶ 16.

**21.** Se estan haciendo experiencias para combinar las señales de luces y de relámpagos.

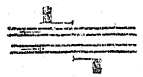

Fig. 13
*Doble via*

Fig. 14

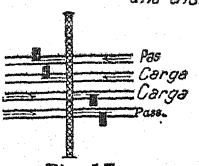

Fig. 17

*Cuatro vias*

**22. Situacion de las señales.** Las señales fijas visibles van colocadas generalmente a la derecha, o directamente sobre la via a que se aplican. Las figs 13 a 17, incl, muestran ciertas disposiciones típicas de señales, seleccionadas de las que trae el « Diccionario de Señales » de la Asen de Señales de F. C.

## MECANISMOS DE TRASMISIÓN

**23.** Las señales y los cambios estan operados convenientemente desde un punto central, como una torre de señal; y deben proveerse de los medios para connectarse a la torre, y para manejarlos desde la misma.

### Operados a mano.

**24. Las conexiones mecánicas** para la manipulacion se hacen generalmente con tubos (usados como barras) ó con alambres.

**25. El tubo** es generalmente de hierro dulce o acero, de una pulgada (25 mm) de diámetro, y como puede obrar lo mismo por tension que por compresion, solamente se necesita un tubo (en general) para cada señal o chucho. Las lineas de tuberia se ponen sobre rolletes soportados en marcos. Cuando hay que darle vueltas rápidas, los extremos del tubo estan conectados por medio de brazos de cigüeña, *B*, fig. 18 (no esta en escala), o por medio de barras encorvadas, *D* que se deslizan entre rolletes :

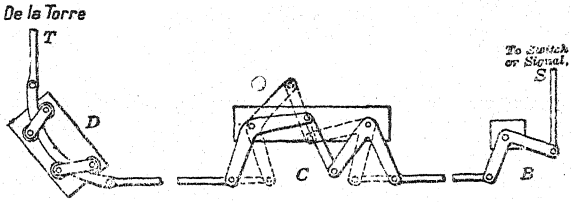

Fig. 18.

**26. Compensadores.** Como los cambios, aun los moderados, de temperatura alteran el largo de la tuberia, y alteran el ajuste, las lineas de tuberia estan divididas en secciones y estan conectadas por medio de « compensadores », *C*, que neutralizan los efectos del cambio de temperatura sin afectar los movimientos de las señales. La fig. 18, representa una linea de tuberia, que arranca de la torre de señal, pasando por una barra de desvio, *D*, un « compensador », *C*, y un brazo de cigüeña, *B*, a un chucho o a una señal *S*. Las lineas de punto indican las posiciones de las partes del compensador cuando la linea de la tuberia se expande por el calor.

## Fuerza.

**27.** La fuerza puede ser aire comprimido llevado por los tubos a los cilindros en que actua sobre los émbolos conectados con las señales o chuchos, y tambien la electricidad conducida por alambres a motores eléctricos (o a solenoides para pequeñas señales). El aire comprimido, o electricidad, que *opera* las señales, esta dirigida generalmente por medio de circuitos eléctricos relativamente ligeros, o, en los aparatos que son todos neumáticos, por presion de aire relativamente baja. En cualquiera de los dos casos la fuerza es aplicada por medio de palancas, etc.

**28.** El uso de sistemas **todo-eléctrico** se está generalizando : tienen la ventaja de que no necesitan planta especial para el aire comprimido; y se eliminan las varias dificultades del aire comprimido.

## SISTEMAS

**29. Intervalo de tiempo.** Con este sistema, se le debe dar un adelanto al tren de 5, 7 ó 10 minutos, antes de que al tren que le siga se le permita continuar, con el objeto de que, si el primer tren pasa inesperadamente, tener tiempo suficiente para permitir al abanderado hacerle señales al tren que le sigue; pero el sistema, en las mejores condiciones está lejos de ser seguro.

**30. Espacio de intervalo o bloque.** Bajo este sistema, el largo de la via está dividido en secciones llamados bloques; de largo adecuado y donde se practica, no se permite que dos trenes lleguen a estar en un mismo bloque al mismo tiempo. El largo del bloque puede variar, desde cerca de una milla (como 1.600 m) o menos hasta 5 ó 10 milles (9 a 16 kiloms) segun la densidad y caracter del tráfico.

**31. Paso permitido.** La expresion paso ó bloque permitido, significa que a un tren se le permite pasar una señal de bloque que indique « parar » con la condicion de que debe correr a una velocidad disminuida de modo que pueda parar en el primer punto que no pueda pasar, con seguridad evidente. Esto permite a un tren operar en un largo de bloque mayor; pero es menos seguro que el bloque absoluto.

Fig. 19

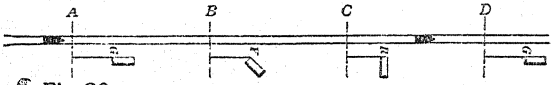

Fig. 20.

**32. Aspectos de señales.** Se aplica frecuentemente a las señales de bloque. Las figs 19 y 20 ilustran, para condiciones dadas en una linea determinada, las posiciones de señales con los sistemas de semáforo respectivamente de « dos posiciones » y « tres posiciones ». *A B*, *B C* y *C D* representan bloques. Bajo cualquier sistema, el tren en el bloque *C D*, está protegido por la señal definitiva en *C*, detrás de él, puesta en « parar »; pero al mismo tiempo, un tren puede entrar en el bloque *B C* en *B*, bajo la señal de « precaución » que está ahi; o un tren puede entrar en el bloque *A B*, en *A*, sin restriccion; la señal, en *A*, indica no solamente « seguir », sino también que la « próxima señal adelante esta franca ».

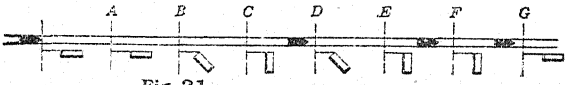

Fig. 21.

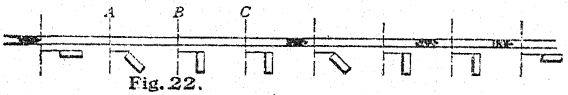

Fig. 22.

**33.** Las figs 21 y 22 ilustran, para condiciones dadas, en una linea dada, las posiciones de semáforo en el sistema de « tres posiciones » bajo los sistemas respectivos « **franco normal** » y « **peligro normal** ». Bajo el sistema « franco normal » la señal que gobierna un bloque, siempre muestra franco cuando el bloque está franco, aunque el tren esté o no proximo a entrar al bloque. Bajo el sistema « peligro normal », la señal permanece en peligro (si el bloque está ocupado o no) hasta que un tren se aproxima a la señal, para entrar en el bloque; y entonces, por supuesto, la señal se franquea solamente si el bloque esta actualmente franco. Estas diferencias se indican en los bloques *A B* y *B C*.

**34. Bloque por telegrafo ó bloque a mano.** En este sistema se estaciona un hombre al final de cada bloque; y, cuando un tren pasa de un bloque al otro, comunica el hecho eléctricamente, a los hombres situados en los otros puntos. Los hombres avisados de este modo, despliegan entonces las señales necesarias.

**35. El teléfono** está sustituyendo mucho al telégrafó para tales señales, y para despachar trenes. Esta usado comunmente en conjuncion con otros sistemas. Vease ¶ 71.

**36. Sistema manual restringido**, o de Cierre y Bloque. Para reducir la posibilidad de un error en la operacion en los sistemas de bloque manual y telegráfico, se pueden instalar, dispositivos que requieren la acción simultanea de ambos hombres en quitar y poner los contactos eléctricos antes de que se pueda poner la señal de « seguir ».

**37. Cierre automático.** Para evitar un acuerdo entre los dos hombres para abrir el bloque cuando aun no está franco, pueden disponerse los « aparatos de vía, o el circuito de vía » (véase ¶ 50) de tal modo que este acuerdo no se pueda practicar mientras que el tren no haya salido del bloque.

**38. Sistema de Pértigas.** Este método es aplicable especialmente a ferrocarriles de vía sencilla. En cada extremo del bloque hay un receptáculo que contiene un número de duelas o barras de metal. Los dos receptáculos estan dispuestos y conectados eléctricamente, de tal modo, que solamente *una* pértiga puede sacarse de los receptáculos; y esta pértiga debe devolverse a uno de los receptáculos antes de que otra pueda sacarse. La pértiga es el permiso del tren para viajar por el bloque, y la lleva el mismo tren. Cuando el tren deja el bloque (en cualquier extremo), la pértiga debe colocarse en el receptáculo de ese extremo ; haciendo otra vez posible sacar una pértiga del receptáculo en cualquier extremo del bloque.

**39. Requisitos especiales.** Pueden establecerse requisitos especiales, para operar las máquinas en bloque permitido « y tomar previsiones para las máquinas « empujadoras » (de servicio) que regresan; pero esto todavía no permite que dos pértigas completas estén fuera del receptáculo al mismo tiempo.

## MANIPULACIÓN

**40.** Las manipulaciones pueden ser lo mismo « *iniciales* » o « *entrelazadas* » o ambas (Vease ¶ 3 *a.*)

**41.** La manipulacion **inicial** puede ser efectuada por *empleados*, o (mecánicamente o por electricidad) por los mismos *trenes.*

**42.** La manipulacion **entrelazada** (parte de la cual puede estar en « Trasmision ») es la de dispositivos automáticos, ideados para evitar operaciones impropias. Esto puede hacerse por movimientos puramente mecánicos, por electricidad o por aire comprimido. Cuando unas cuantas señales y desvios estan operados desde un punto, pueden ocurrir choques de trenes causados por errores de los operadores. Con el propósito de evitar esto, las palancas y barras están agrupadas de tal modo, y provistas de piezas corredizas adicionales, llamados « perros », o con contactos eléctricos trancadores, etc., tales que (en lo posible) las combinaciones o posiciones con las cuales pudieran peligrar los trenes, están evitadas mecánicamente.

**43. Mecánica.** Aquí consideramos el entrelazado mecánico como un ejemplo : Así pues en un cruce de doble via cuando todas las señales indican « parar », cualquier otra señal puede hacerse indicando « seguir », pero, al hacer esto, la barra conectada con su palanca mueve los perros de modo que trancan las palancas de las señales que gobiernan las vias que cruzan por aquella vía. Así, si la señal para un tren rumbo al Oeste es libre, las dos señales para los movimientos rumbo Norte y Sur están por consiguiente trancadas en « parar »; pero la señal para la via rumbo Este queda franca; porque ambos trenes, el de rumbo Este y Oeste pueden pasar por el crucero simultaneamente mientras las vias rumbo Norte y Sur están trancadas en « parar ».

**44.** A la inversa, a los trenes con rumbo Norte y Sur puede darsele señal franca solamente despues que las señales rumbo Este y Oeste hayan sido puestas en « parar » y trancadas en esa posición.

**45.** El principio fundamental, aqui ilustrado por un ejemplo sencillo, se lleva a cabo con gran cuidado.

**46. Desvíos para descarrilar.** Para evitar choques debido a que un maquinista inadvertidamente pase una senal de « parar », se suele emplear un « descarrilador » donde es practicable. Esto consiste generalmente en un medio desvio, que cuando « abre » es suficiente para sacar un tren fuera de los carriles sobre las traviesas; y cuando es para tráfico de pasajeros, puede ser un desvio completo que vaya a un desviadero enterrado en arena, o provisto de otros medios para detener

el tren con un mínimo de daño. Este descarrilador esta entrelazado con los desvíos y señales de modo de evitar que se « cierre » para el recorrido normal, a menos que los otros desvíos y señales referidos estén puestos de tal modo que sea seguro el hacerlo así. El descarrilador produce un efecto muy ventajoso sobre cualquier tendencia del maquinista a riesgos indebidos ó á olvidar una señal puesta en peligro

**47. Bloque Escocés** (Scotchblock). Otros descarriladores comunmente usados en vías laterales de mercancías, etc., consisten en una pieza movible de metal, de tal forma que cuando se coloca sobre el carril, levanta y dirige la pestaña de la rueda por sobre el carril y fuera de la vía.

**48. Cierre de Chuchos,** * fig. 23 (no está en escala y muestra lo esencial solamente). Ademas de la palanca del chucho, generalmente se provee este de una palanca para trancar, que puede forzar un pasador, *A*, por uno o dos agujeros en la barra, *B*, solamente cuandos las puntas del chucho, *C* y *D*, han hecho su movimiento completo en cualquier direccion. Si por una acumulación de basura o de nieve, las puntas del chucho no se han llevado a su lugar, ningun agujero en la barra, *B*, viene frente al pasador, *A*, y el pasador no puede entrar en el agujero; y como la palanca de trancar a su vez se entrelaza con las señales, estas no pueden ser francas. Conectada a la palanca de trancar, hay tambien una barra indicadora.

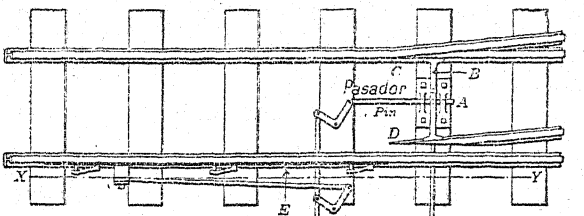

Fig. 23. *Plan*

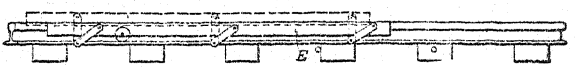

**Fig. 24.** *Sección por X Y.*

**49. Barra indicadora,** *E*, fig. 24, que está conectada de tal modo con la barra de cierre que la barra debe levantarse sobre la cabeza del carril cuando la palanca de trancar se mueve. Esto no se puede hacer si hay ruedas en el chucho. Así resulta practicamente imposible cambiar la posición de un chucho mientras un tren está pasando por él.

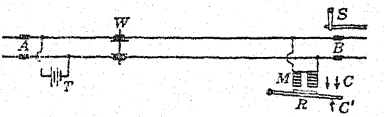

**Fig. 25.**

**50. El circuito de la via** es un recurso que facilita el modo de llevar a cabo muchas operaciones automáticas de señales, y muchas combinaciones ó su equivalente descartando muchas torres de señales, y plantas complejas. El principio fundamental del circuito de la via se ve en la fig. 25, que muestra los dos carriles de una via sencilla en un « bloque » u otra seccion, *A B*. Esta sección está aislada eléctricamente de las secciones adyacentes por mordazas de madera pesada, o de fibra aisladora, indicadas en *A* y *B*.

* Véase *N. del T.*, pag. 858.

En un extremo de la sección, hay una bateria, *T*, uno de cuyos alambres está conectado con un carril, y el otro alambre con el otro carril. En el otro extremo de la sección hay un electro magneto *M*, conectado de modo análogo. La armadura, *R*, de este magneto, lleva uno ó varios contactos, algunos de los cuales, *C*, están hechos, y otros *C'*, se interrumpen cuando la armadura es atraida por el magneto.

**51.** Supongamos que el circuito de la vía, *A B*, esté completo, y supongamos que no haya carros en la vía. Entonces la corriente de la bateria, *T*, obra sobre el magneto, *M*; la armadura es llamada hacia el magneto y el contacto superior *C* queda cerrado, dejando franca la señal *S* en *B*. Pero si un tren o cualquier otro par de ruedas, *W*, está sobre los carriles entre *A* y *B*, la corriente de la bateria, *T*, estará en corto circuito por las ruedas, hacia la bateria, robando de este modo corriente al magneto *M*, y haciendo que su armadura, *R*, caiga, y la señal, *S*, marque « parada ». Tambien, si por accidente o de otro modo el circuito se rompe en alguna parte o si ocurre algun corto circuito, o si la bateria falla, o si cualquier objeto metálico toca ambos carriles entre *A* y *B*, la señal marcará « parar ».

**52. La disposicion** es tal que la corriente, que acciona el magneto, *M*, es suficiente para atraer la armadura, *R*, a pesar de las pérdidas por el balasto, agua, nieve, y hielo, pero siempre el corto circuito total, causado por un par de ruedas. *W*, entre *A* y *B*, hará con seguridad caer la armadura, y poner la señal en « parar ».

**53. Las pérdidas debidas a las corrientes directas** de ferrocarriles eléctricos próximos a la via o el retorno directo de la corriente del mismo ferrocarril eléctrico (cuando se usan los carriles para circuitos de la vía), pudieran cambiar la señal cuando no se debiera cambiar, pero el uso de las corrientes alternas, para hacer señales, evita practicamente tal peligro.

**54. El Relevo**, *M C*, fig. 25, conectado con el circuito de via está hecho generalmente para servir simultaneamente a varios propósitos, por medio de sus varios contactos. Cuando la armadura cae, puede romper varios circuitos y poner varias señales en « parar », y puede tambien formar parte de él:

**55. Entrelazado eléctrico.** Donde se usa la electricidad para el manejo, y se usa electricidad o aire para la fuerza que opera, el chucho* y las palancas de señal simplemente hacen y deshacen los contactos electricos y operan una relativamente pequeña máquina de entrelazado; y son generalmente de menos de un pie de largo. En distintos tipos, las palancas se mueven en sentidos distintos. Pero las características principales son comunes a todos los tipos.

**56. Entrelazado de trenes.** La mera presencia de un tren, en cualquier sección de la via provista de un circuito en la línea, puede arreglarse por medio de su relevo, cortando los circuitos de cualquier señal o señales que guíen esa via. Esto suprime la necesidad de las « barras indicadoras » que son tan toscas en los chuchos.

**57. El entrelazado todo-automático** se ha usado hasta cierto punto y en él las válvulas sustituyen los contactos eléctricos, y los diafragmas ó émbolos sustituyen a los magnetos y armaduras.

## Operación de señales para manejo de trenes.

**58. Las señales automáticas** han demostrado ser muy útiles. Dependen principalmente del « circuito de la via », parrafo 50. Cuando la cabeza del tren entra en un bloque, ó tramo, la señal que ha pasado marca inmediatamente « parar », a cualquier otro tren que pueda venir. Cuando todo el tren haya pasado este bloque, el segundo bloque y la señal detras de él se « borra ». Esto sucesivamente se produce de modo automático y se continua indefinidamente de bloque en bloque, operando señales distantes.

Ademas, la mera presencia de cualquier tren, y aun, de un par de ruedas, en cualquier parte de un bloque de una sección de circuito, conservará (en cualquier señal o señales que gobierne cualquier entrada a tal seccion) la indicacion de « parar ». En la mejor práctica como se indica en el « Entrelazado Electrico », ¶ 55, los circuitos de via están entrelazados, por relevos, etc., con cualquier chucho* o

* Vease *N. del T.*, pág. 858.

cruceros en que estén envueltos. Si un tren ha entrado en un bloque, ningun chucho (1) de desviadero que conecte con ese bloque puede abrirse; é inversamente, una vez que el bloque este despejado, y un chucho (1) de desviadero se abre, todas las señales que vayan a la sección marcarán « parar ».

**59. Via sencilla automática.** Las señales automáticas tales como fueron aplicadas primero en operaciones de via sencilla, permitirian que dos trenes en extremos opuestos de un tramo de via sencilla, dejando sus desviaderos, corrieran uno contra el otro, siendo por supuesto la via sencilla bastante larga para contener un numero de bloques ó secciones. No obstante, no resultaria choque, porque cada tren pone en « parar », no solamente las señales que pasa sino tambien bastantes de las señales *delante* de él, para evitar choque. Pero un tren o el otro eventualmente quizas tendria que retroceder al desviadero que dejó.

**60. Amplitud-permitida.** En este sistema, no obstante, un tren entrando por cualquier extremo de un largo de via sencilla mantendrá en la señal de « parar » *todas* las señales delante de él en ese tramo. Otros trenes pueden seguirlo, como en las lineas corrientes de doble via con señales automáticas.

## MISCELÁNEA

### Seguridad.

**61.** La seguridad debida a las señales de ferrocarril han llegado a un alto grado. Todos los accesorios, hasta donde ha sido posible están dispuestos de tal modo que cualquier falta o descuido hará desplegar la señal de « parar ».

### Indicadores.

**62.** Se usan varios tipos de indicadores, y con varios propósitos, generalmente son modelos en miniatura de señales, o chuchos (1) o vias, e indican a los hombres de señales de patio la condición o posición de los objetos representados, pero, que no pueden ser visibles.

### Otros Métodos.

**63. Métodos nuevos** de gobierno de trenes, por medio de aparatos de señal se han desarrollado, con principios radicalmente diferentes a los expuestos hasta aqui, basados sobre otros principios fundamentales. Estos envuelven en conjunto, varias combinaciones o modificaciones de la parada automática (¶ 64), control de tiempo o velocidad, y señales de casilla. Algunos de estos métodos estan en uso con gran éxito; pero, como esta parte del arte de señales está en estado de transicion, nos abstenemos, por el presente, de discutirla mas en detalle.

**64. Parada automática.** El efecto de la parada automática sobre el motorista, es análoga a la que hace el descarrilador (¶ 46). Si aquel no para antes de llegar a cualquiera de estos dispositivos, se le llama seguramente la atencion y se disciplina; mientras que, de otro modo podria con frecuencia pasar una señal, sin darse cuenta, hasta que el hábito llegue á un grado peligroso. El alto costo de la parada automática y la duda de su seguridad bajo las severas condiciones del tiempo en los ferrocarriles de vapor han demorado su adopción para tal servicio.

**65. Señales « Rompibles ».** Se usan algunas veces en las proximidades de puentes giratorios y en otros puntos particularmente peligrosos. Una señal rompible consiste en un brazo o tabla, que se extiende sobre el paso de un carro en una posicion tal que franquee los trenes cuando marca « via libre »; pero, cuando está puesto en posición de « parar », chocará con alguna parte de la locomotora o del carro. El golpe rompe o desbarata (de aqui su nombre) la señal y deja una marca en la locomotora que sirve para identificar al maquinista culpable.

**66. Señales de tranvias y ferrocarriles eléctricos.** El aumento de tamaño y velocidad del material rodante eléctrico de calle e interurbano ha hecho deseable el cambio de métodos primitivos por aparatos de alta perfección. No obstante, el uso de los carriles para el regreso de la corriente, hace el circuito de señales de via, inseguro ó costoso : por esto se utiliza el paso de la rueda del trole por debajo de un contacto especial colocado sobre el alambre del trole para poner las señales.

(1) Véase *N. del T.*, pág. 838.]

**67.** La fig. 26 representa un tramo de linea de vía sencilla, con una señal y un cruce ó pase en cada cabeza, cuando el tramo está libre de carros, el aparato está « neutral ». Supóngase ahora un carro que este entrando por la izquierda. Pasando bajo el « contacto », en *B*, este carro pone la señal, *E*, en « seguir », y al mismo tiempo poniendo la señal, *F* (en el extremo lejano del tramo) en « parar » avanza un paso o diente una « rueda contadora », en cada señal.

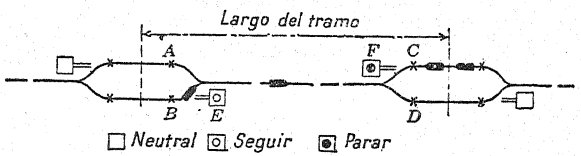

**Fig. 26.**

**68.** Estando la señal *F* en « parar », ningun carro puede entrar en el tramo por la derecha; pero un carro que le sigue, entrando por la izquierda puede entrar en el tramo pasada la señal de « seguir » en *E*, el motorista no obstante, la considera como una señal de precaución y observa que « destella », indicándole que su carro ha sido « contado ». Y asi sucesivamente, con cualquier otro carro que siga, entrando por la izquierda.

**69.** Pero, a medida que cada carro deja el tramo, pasando el contacto, *D*, la rueda contadora en cada señal echa para atras un diente o paso, hasta que el último carro haya dejado el tramo. Las ruedas entonces se han puesto en cero, y ambas señales, *E* y *F*, vuelven automáticamente a ponerse en « neutral ».

**70.** Entre los perfeccionamientos recientes hay aparatos para evitar que aparezcan las indicaciones de « seguir » en ambos extremos de un tramo simultaneamente, aun cuando dos carros, en extremos opuestos del tramo hagan sus contactos respectivos simultaneamente. Hay también aparatos para asegurar la contada exacta aun cuando se hagan movimientos inversos; para evitar trastornos de las ruedas contadoras al desconectar o conectar la corriente motriz; para aplicar el sistema a señales en via sencilla de tramo; y para la extensión del sistema incluyendo movimientos desde un tercer punto : digamos, un desviadero.

**71. Señales seleccionadas.** Estas permiten que un despachador de trenes ponga una señal cualquiera o un gran número de señales, visible ú oibles y asi, ponerse en comunicación con uno o mas jefes de Estación o con el personal de trenes.

**72.** El despachador está provisto de aparatos con los que él puede mandar, por el alambre (que conecta con todas las señales) inducciones eléctricas a intervalos exactos predeterminados o combinaciones de aquellas como en los sistemas de alarmas en los incendios. Cada señal está arreglada de modo diferente para responder solo a una clase dada de induccion ó combinación.

**73.** Si la señal es visible cuando se pone para que marque « parar », esta manda una « indicacion » al despachador de modo que puede este asegurarse que la señal está puesta, y esta se tranca automáticamente en esa posición. Solamente puede ponerse en « libre » con la cooperación del despachador. El conductor de un tren que ha sido parado por la señal, telefonea al despachador; y el despachador, cuando queda satisfecho de que sus instrucciones han sido entendidas, mueve sus aparatos de modo que la señal no quede trancada, permitiendo asi al conductor « borrarla ».

**74. Alarmas en Cruceros de Carreteras.** La alarma en si mismo puede ser o una campana u otro aparato que suene, o luces o señales ú ambas. Las alarmas son generalmente manejadas eléctricamente por medio de circuitos de vía, y varias disposiciones complejas de relevos a menudo entrelazadas unas con otras.

**75.** Una señal cruzada, utilizando la flexibilidad vertical de los carriles, elimina, la mayor parte de las dificultades debidas a los movimientos irregulares del tren, etc., y tiene fuerza propia. El mecanismo es *sensible* « direction sensitiv » y necesita un movimiento de tren en la direccion correcta para dar el alarma y esta termina automáticamente cuando el tren se para.

**76. Uso de señales.** Enero 1, 1911 y 1915, tal como la dá

La Comision de Comercio entre Estados :

(Una « milla de *linea* », o milla de *camino* = a una milla de *carretera*, si está ocupada por una vía, o por dos o mas vias. Una « milla de vía » = una milla de *vía* sencilla. De modo, que hay *dos* « millas de vía « en una » milla de linea » de *doble* vía) (1).

| Clase de señal. | En uso, en 1911, en | | En uso, en 1915, en | |
|---|---|---|---|---|
| | Millas de linea. | Millas de vía. | Millas de linea. | Millas de vía. |

| Número de secciones cerradas | | 29,881 | | 51,690 |

**77. Costo** de señales, antes de 1911, tal como lo da la comisión sobre Relaciones de Operacion de F. C. en Legislacion, 1911, nov. 14, como resultado de las preguntas y repuestas recibidas de los ferrocarriles que operan cerca del 80 0/0 de toda la via en los E. U. equipada con señales de secciones. Tomado de la revista Railway Age Gazette, 11 nov. 1917.

Instalación, por milla de vía;

Automática, $1,146 ($710 por kilometro); No automática, $248 ($154. por kilometro).

Mantenimiento automático por año;

$169 por milla ($105 por km) de vía; $ 69 por paleta de señal.

Los costos de instalación durante 1911 fueron de 10 a 40 0/0 mayores que lo expresado; probablemente es debido a la introducción de mayores perfeccionamientos.

(1) *N. del T.* — Para convertir millas en kilómetros, multipliquense aquéllas par 1,609.

* Substancialmente exacto, á pesar de la discrepancia insignificante entre tablas distintas en los Informes de la comisión de comercio entre Estados.

# ESTACIONES Y PATIOS

**1. Generalidades.** Los patios, estaciones y terminales * consisten en vias adicionales á las vías principales, edificios y varias facilidades, para el movimiento y manejo de locomotoras, carros, mercancias, pasajeros, equipajes, etc. Puede simplemente consistir en una pequeña estacion, un desvío sencillo, un almacén de mercancias; o puede incluir grandes almacenes y estaciones de pasajeros; y docenas de vias, y cubrir un area de 1 ½ kilómetro o más de largo.

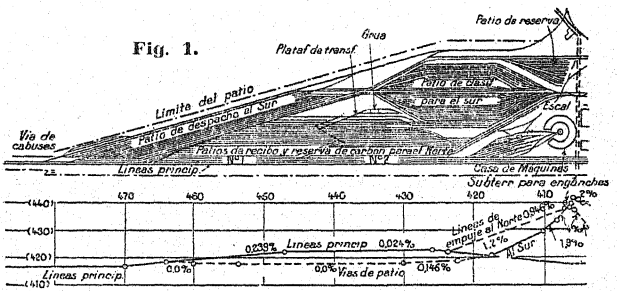
## PATIOS

**2. Definición** (Asen Am Ings F. C.). « Patio. — Un sistema de vias, dentro de límites definidos, provisto para preparar trenes, depositar carros, y otros propósitos, sobre el cual se hacen movimientos no autorizados por itinerarios o por el orden de trenes; sujetos a señales prescritas y reglamentadas. »

**3. Generalidades.** Un patio se compone generalmente de :
(a) un *Patio de Recibo*, ¶ 10, sobre el cual los trenes que vienen de la linea principal, pueden quedarse hasta ser distribuidos;
(b) los *Patios de Servicio*, ¶ 11, en los cuales las locomotoras toman carbon, los carros refrigeradores se proveen de hielo, etc., y el material rodante se repara;
(c) el Patio adecuado para *Separar*, *Sortear*, o *Clasificar*, ¶ 46; y
(d) un *Patio de Entrega*, o *Vias de salida*, ¶ 79, en el cual los trenes *formados* recientemente pueden esperar antes de pasar a la linea principal.

**4. El trazado** del patio, dependerá, en gran parte del carácter, dirección y cantidad de tráfico, del área y forma del terreno disponible, de la proximidad de los materiales varios y demas facilidades, y de otros factores. Los patios grandes

Fig. 1.



deben trazarse teniendo en cuenta una buena información sobre aquellos puntos pertinentes, y despues de considerar cuidadosamente el tráfico futuro y su crecimiento.

**5. Ejemplo.** El patio del F. C. Missouri Pacific en Dupo, Illinois, fig. 1, es una buena muestra del patio ideal corriente para un tráfico bien equilibrado.

**6. Dos direcciones.** Generalmente, en todo caso habrá virtualmente dos patios, uno para cada direccion de tráfico, pero habrá un solo patio de *servicio* utilizable en ambas direcciones.

---

* Véase nota de la llamada entre párrafos 81-82.

Los dos patios pueden ser aproximadamente iguales, o de tamaño muy desigual, esto depende de las cantidades relativas de tráfico en las dos direcciones.

**7. Las Vias de linea principal**, en general, especialmente en patios grandes, deben estar situadas fuera del patio, una a cada lado, si es posible, o ambas sobre el mismo lado si es necesario; para que las facilidades (patios de servicio, etc.) se agrupen cerca del centro del patio.

**8. Conexión con la Via Principal.** El número de chuchos (1) que van directamente de la linea principal debe ser un mínimo, con un crucero si es via doble en un patio pequeño, las lineas distintas de *patio* se conectan solamente *entre sí*. Cualquier chucho (1) debe, donde sea posible, no dar el frente al tráfico, de modo que los trenes de vía principal no entren en ellos, reduciendo asi el riesgo de « precipitarse en un chucho abierto ». El chucho (1) debe tambien estar entrelazado con cualquier señal de la via principal, y tener un descarrilador, pp. 900-2 para evitar que los carros pasen sin querer a la via principal.

**9. Uso.** Los patios de carga se usan (1) para el almacenaje del material rodante que no se usa, (2) para retener los carros mientras se cargan o se descargan, y (3) para la distribución y clasificación de carros, cuando se usan para esto, se llaman comunmente « patios de clasificación » y son probablemente los mas importantes, especialmente en los grandes centros, y no solamente incluyen por lo regular los otros dos tipos, sino que sirven sobre todo para reducir su tamaño. Varios escritores afirman la importancia de considerar un patio como lugar para *manejar* carros, y *no* como lugar para *almacenarlos*.

## Patios de Recibo.

**10.** El patio de recibo debe ser bastante largo para recibir el tren mas largo, y debe tener un número suficiente de vias para recibir todos los trenes que lleguen hasta que puedan manejarse. De ahi la loco de cada tren se saca para el patio de servicio para reponer su carbon, etc., y el tren se empuja al patio adecuado de clasificación.

## Patios de Servicio.

**11.** Los patios de servicio en general deben estar situados en el centro; provistos con vias y otros medios para cambiar los carros del conductor y locomotoras, para quitar y retener los carros en « mal estado », y con vias de tránsito para permitir

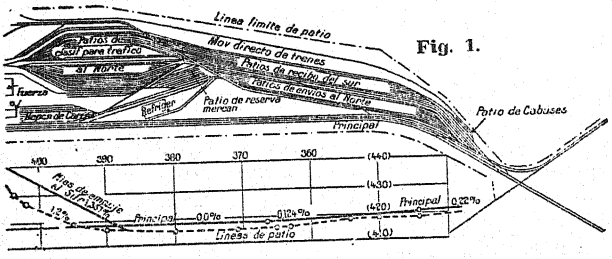


**Fig. 1.**

que los carros y las locos trafiquen libremente alrededor o por los patios. Deben proveerse facilidades; para quitar cenizas de las loco; para tomar agua, carbón y arena; para limpiar, aceitar, para darles alojamiento y hacerles reparaciones menores; para inspeccionar y reparar carros y cajas de chumaceras calientes; para limpiar los coches de pasajeros; para proveer de hielo a los carros refrigeradores; para proveer de agua y alimentar animales vivos; y para otras necesidades que puedan existir.

**12. Los carros averiados** del tipo de tolva o descarga por abajo, y su contenido algunas veces se manejan convenientemente haciéndolos pasar por una via elevada sobre caballetes y descargando su contenido en carretones por debajo de esta via elevada.

---

(1) Véase *N. del T.*, pág. 858.

**13. Vias de Reparación** (Manual 1915 de la Asen Am Ings F. C.). Estas deben tener una capacidad de 15 carros cada una, permitiendo 50 pies (como 15 m) para cada carro alternando las vias con espacios de 16 y 24 pies (4,80 a 7,20 m) de centro a centro. Los patios de reparación deben estar liberalmente equipados con tuberias de agua y aire, con salidas de aire cada 50 pies (15 m). Las vias para reparaciones grandes deben estar bajo techo. Otras especificaciones exigen vias separadas para reparaciones grandes y pequeñas, con el objeto de que los carros que necesiten reparaciones pesadas, levantarlos, etc., no puedan atrasar el trabajo de los otros carros.

**14. Patios de carga y trazado de talleres**, Mr. Walter G. Berg, Ingeniero Jefe del F. C. Lehigh Valley Gaceta de F. C. de marzo 13 á abril 10, urge la importancia de : — un trazado tal que reduzca al mínimo el traslado innecesario de hombres y materiales; la distribucion apropiada de espacios entre los distintos talleres; medios amplios para comunicar y transferir : facilidades entre un departamento y otro para las aglomeraciones; espacio amplio, para salones, pasajes y corredores; buena luz, calefacción, ventilación, servicio sanitario, abasto de agua, protección para incendios, construcciones a prueba de incendio; facilidades para la fuerza motriz : y previsiones necesarias para el aumento o ensanche por (digamos) unos 10 años.

**15. Electricidad :** ésta ha hecho posible la realización de cualquiera disposición de los talleres y de las vias que se deseen, mientras que sin ella, los edificios tenian que agruparse mas o menos, o instalar plantas de fuerza motriz separada.

**16. Una grua movediza elevada**, de suficiente resistencia y espacio para levantar o izar una locomotora entera sobre las otras, evita la necesidad de usar plataformas de transferencia, mesas giratorias, vias de enlace y chuchos (1).

**17. Plataforma de Transferencia**, es una plataforma estrecha, con una via usualmente lo bastante larga para una loco y alijo o ténder. La plataforma corre sobre una via ancha en una fosa a angulo recto con su propia vía y la del taller, y asi transfiere su carga de una via a otra y a la via paralela en el taller. Para vencer el obstáculo ofrecido por la fosa profunda al paso de hombres y materiales, Mr. Henry V. Miller (Eng News, 1909, julio 15) ha patentado una plataforma de transferencia « sin fosa », cuyas ruedas con colgantes en forma de pescuezo de pato, estan por arriba de la misma mesa, « y permiten que su via esté abajo *casi* a nivel con el fondo del espacio sobre el cual rueda ».

**18. Mesas giratorias**, fig. 2. *En general*, la fosa de la mesa giratoria está rodeada por la pared circular, W, la parte superior de la cual se llama parapeto : y el marco consiste en dos alas; cada ala comprende un par de vigas armadas, *G*, con tirantes cruzados apropiados. Las dos alas estan unidas formando una doble viga de contrapeso, continuo sobre el centro, *C*, y el asiento del pivote, *P*.

**19.** *Equilibrio.* Normalmente, al girar la mesa, con su carga viva, se equilibra sobre el pivote central, *P*, al cual se trasmite toda la carga por rolletes cónicos o discos (¶ 39); pero, cuando una locomotora entra o sale de la mesa (y algunos veces cuando gira, véase párrafo 29), la carga descansa *parcialmente tambien sobre el carril circular*, *R*, por medio de ruedas con ejes radiales, colocadas en los extremos de las alas. Las ruedas están alojadas de tal modo que se extienden poca cosa debajo de las pestañas bajas de las vigas.

**20.** *Vigas armadas.* Las vigas *cantilever* (2) para locomotoras modernas pesadas, que requieren mesas giratorias mayores de 75 pies (digamos 22 m), deben ser muy altas; necesitando al mismo tiempo, fosas muy profundas, que pasan algunas veces de 11 pies (3,30 m) Tales fosas son difíciles de desaguar bien. Para reducir las alturas de las vigas se sustituyen algunas veces por vigas (pony) o armadas. Para permitir con seguridad el paso de hombres entre ellas y la loco, a cada lado, las vigas deben estar separadas cuando menos 4,50 m de centro a centro.

**21.** O bien fig. 3, las dos alas, *A* y *B*, son independientes, cada una descansa sobre el centro, *C*, por un extremo, y sobre el circulo de carril, *R*, en el otro extremo. Estas mesas no se inclinan. Al ser sus luces mas cortas, sus vigas y la fosa se hacen mas planas.

**22.** O fig. 4, se usa una viga baja y continua, y está parcialmente soportada por miembros que trabajan en tension, *D*, *D*, desde una torre, *T*, que descansa sobre el centro, *C*.

---

(1) Véase *N. del T.*, pág. 858.
(2) Véase nota ** *N. del T.* al pie de la pág. 458.

**23.** *Largo.* Muchas mesas antiguas varian en su longitud desde 60 a 70 pies (18 a 21 m); pero, de 57 ferrocarriles importantes interrogados por una comision de la Asen Am de Puentes y Edificios de F. C.* en 1912, 54 usaban mesas variando en largos de 75 a 90 pies (23 a 27 m); dos, 30 m; y uno, 31,50 m.

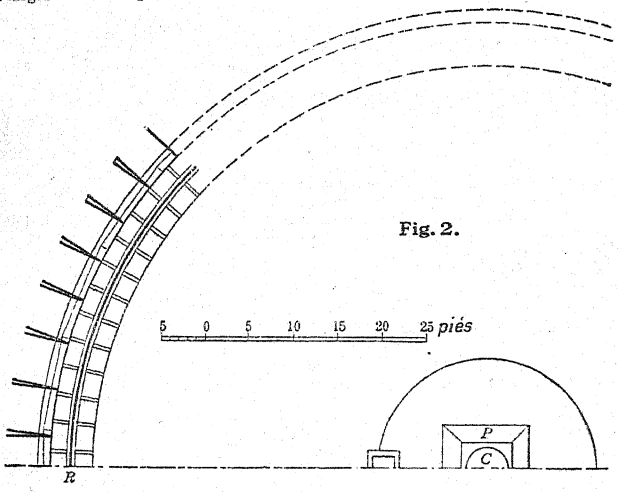

Fig. 2.

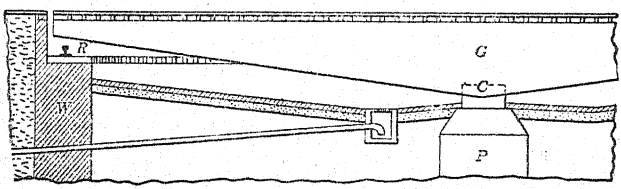

**24.** *Exceso de longitud.* Las mesas giratorias ordinariamente deben considerarse mas largas que la base de ruedas combinadas del ténder y la loco, especialmente donde tienen que « balancear » ténder vacios con sus locos (descansando solamente sobre un pivote central). Comparese figs 5.

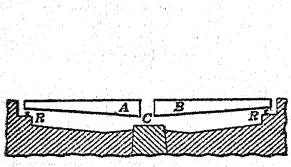

Fig. 3.

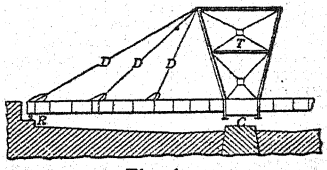

Fig. 4.

* Informe de la Asen Am de Puentes y Edificios de F. C., 1912. A esta comisión que redactó su informe detallado, adoptado en oct. 1912, le estamos agradecidos por muchas de las informaciones y recomendaciones que se dan aquí.

| | Informe pp. | Pesos. | | |
|---|---|---|---|---|
| | | | Ténder. | |
| | | Peso locomotoras kg. | Peso cargados kg. | Peso vacios kg. |
| Mogul Am Loco Co..... | 2 | 84,816½ | 65,226½ | 25,084 |
| Baldwin Mikado..... | 4 | 138,390 | 80,152 | 22,680 |
| Santa Fé Mallet 24 ruedas. | 5 | 279,411 | 106,140 | 47,627 |

y 6, que indican los largos de las mesas necesarias para una loco del tipo « Mogul » (Material Rodante, párrafo 65), con ténder cargado, fig. 5, y vacio, fig. 6.

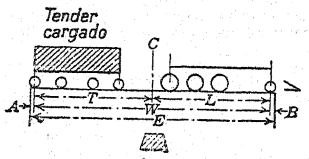

Fig. 5.

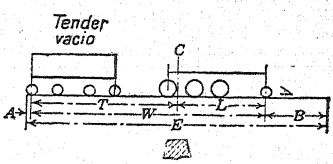

Fig. 6.

**25.** La tabla de arriba indica los pesos y distancias horizontales (con dif de 2 á 3 cm) para este y los otros dos tipos. Los dos primeros son los mas pesados de los tipos hechos por los talleres de la American y Baldwin respectivamente, hasta 1912. La comision * recomienda un largo mínimo de unos 23 m para la práctica ordinaria; y 27,50 m para las máquinas mas pesadas; prefiriendo las mesas ó placas giratorias en forma de Y cuando son de mas de 27,50 m de largo.

**26.** *Mecánica, Momentos y cizallamiento.* Esfuerzos y deflexiones. Cuando una mesa giratoria esta « equilibrada », con o sin carga, el marco debe considerarse como formado por dos *cantilevers* (1) (vigas de pie de amigo), cada una consistiendo de dos vigas paralelas armadas, *G*, los dos cantilevers están conectadas sobre el soporte central. Para este caso, solo una posición de la carga viva es posible. Pero, cuando la carga está colocada de modo que una ala del marco de la mesa descansa en un extremo, sobre el círculo del carril, *R*, y el otro extremo sobre el soporte central, *C*, (como ocurre cuando una loco entra o sale de la mesa), esa ala debe considerarse como una viga simple, y la otra como un cantilever (1), y este es siempre el caso con la mesa que no se inclina, fig. 3. En cada caso, los momentos y cizallamientos, para la carga muerta, para la carga viva, y para ambas combinadas, se buscarán (para distintas posiciones de la carga viva) como indican las pp. 461 a 475; los esfuerzos correspondientes y deflexiones como estan en la pp. 488, etc. y 503 á 504. Para la mesa equilibrada, las deflexiones en el extremo no deben exceder de cerca de 1 ½ cm y no deben llevar la mesa hasta descansar en el círculo del carril, *R*.

**27.** Segun la comision * en la práctica se usan *unidades de esfuerzo* de 1125 kg/cm cuad en tension, y 703 en cizallamiento, cuando se tiene ademas en cuenta el choque (vease vigas armadas pgs 821-2); la comision recomienda 703 y 422 respectivamente cuando no se hace tal prevision; a menos que, en los extremos, los esfuerzos de carga viva deban duplicarse teniendo en cuenta los choques.

**28.** *Carga sobre ruedas.* Al diseñar una mesa giratoria, las locos que puedan usarla, deben estudiarse y el diseño debe basarse sobre *la loco que pueda producir los mayores esfuerzos.* Por razon de su base de rueda corta, las *Cargas de Cooper* (loco + ténder = 14.64 m para todas las clases; vease Especificaciones de Armaduras, p. 818) son inadecuadas para mesas giratorias modernas pesadas; pero sin embargo se

* Informe de la Asen Am de Puentes y Edificios de F C., 1912. A esta comisión in forme detallado, adoptado en oct. 1912) le estamos agradecidos por las muchas informaciones y recomendaciones que nos han suministrado.

usan algunas veces; su separación de ruedas se aumenta con dicho objeto. En la tabla siguiente, las tres loco mas pesadas al distribuir su carga sobre una porción mayor de la luz, producirán, si se coloca sobre un *puente*, aproximadamente los mismos esfuerzos que indica la fórmula mas ligera de Cooper E 50; pero, en una *mesa giratoria* equilibrada (donde cada ala actúa como un cantilever (1) sus largos mayores y pesos producen, en el centro, mayores esfuerzos de cizallamiento y mayores momentos negativos : (2)

| Carga. | Loco lbs. | Ténder lbs. | Base de rueda loco+ténder | Momentos y cizallamiento en en el centro, de la *mesa giratoria*. Momento neg pies-lbs. | Debido a Cooper. | Cizallamiento lbs. |

| Pac.... | 317,000 | 175,700 | 71′ 5⅝″ | 4,650,000 | E 110 | 248,300 |
| Mal.... | 483,000 | 186,400 | 88′ ½″ | 7,228,000 | E 170 | 346,900 |

**29.** *Rotación.* Las mesas pequeñas se hacen girar a mano, para cuyo propósito hay en cada extremo de la mesa una palanca de (2,5 a 3 m) de largo, y a una altura conveniente. Las mesas mas pesadas se hacen girar con fuerza neumática, o con gasolina o maquina de vapor. La fuerza eléctrica se prefiere si se puede conseguir. El aire comprimido se usa cuando hay posibilidad de congelaciones, necesitandose siempre el uso previo de fuerza manual. El motor se coloca algunas veces cerca del centro, *C*, otras cerca de un extremo de cualquier ala, ó, al extremo de una ala ligera a ángulo recto con las alas principales. Con los motores, las mesas por lo regular se giran sin estar en equilibrio, con la carga viva descansando parcialmente sobre el carril circular, *R*. Donde haya que girar mesas corrientes que no están equilibradas y que no se inclinan es costumbre dar a los extremos de las alas y a sus alas peso excesivo para sostener la parte de la carga viva que obra sobre ellos. Entonces las mesas pueden girarse « equilibradas » cuando se viran las loco mas cortas, y « sin estar equilibradas » con loco mas grandes. Las mesas que no se tumban, debido a las grandes palancas que tiene la resistencia en sus soportes extremos, son difíciles de girar, y costosas en su sostenimiento por desgaste de sus soportes.

**30.** Las mesas giratorias se *mantienen en posicion*, para el paso de locos que entren y salgan empleando diversos sistemas como frenos (especialmente donde se usa la fuerza para girarlas); o barras que giran verticalmente sobre una bisagra asegurada a las traviesas de la mesa, y alojando aquella, cuando giran, en una entalladura, ligada a las traviesas entre los carriles de la vía mas próxima; o por pestillos corredizos, que se deslizan en bujes sobre las traviesas de la mesa y en encajes asegurados entre los carriles de las vías mas próximas. Estas últimas se conectan y se mantienen en posicion de cerrarlas por medio de muelles, y se desconectan por medio de una palanca de mano, que puede retirar o desconectar simultaneamente los pestillos en ambos extremos de la mesa. El sistema de cierre está frecuentemente conectado a una señal que indica su posición.

(1) Véase *N. del T.* ** pág. 438.

(2) *N. del T.* — Nos ha parecido más conveniente dejar esta tabla en medidas inglesas. Para tenerlas en sistema métrico recuérdese que las libras se convierten en kilogramos mult por 0,453; pies × 0,305 = metros; pulgs × 0,025 = metros; pies libras × 0,138 = kilogrametros.

**31.** *El cruce de vias radiales adyacentes*, y cerca de la mesa, empleando ranas, etc., se necesita frecuentemente para economizar espacio.

**32.** *Piso.* Ahora se cubre toda la fosa solamente en casos especiales; donde se necesite un paso para parejas de caballo, etc.; o donde el peligro de las congelaciones sea serio. En este último caso puede montarse una estufa sobre las vigas giratorias. Algunas veces se pone un tubo de vapor alrededor de la fosa, junto al carril, circular *R* (fig. 2). Cuando se usa el piso, éste está soportado por vigas ligeras armadas y radiales. Comunmente la mesa se hace lo bastante ancha para que quepa un *pasillo* en uno o ambos lados; el pasillo se sostiene sobre traviesas de largo extra, colocadas a intervalos; y se le pone algunas veces un pasamanos. Con frecuencia se provee con una á dos alas adicionales ligeras a angulo recto con las alas principales para llevar el motor o la estufa, etc., o para otros propósitos; formando todo una especie de cruz. Para darle rigidez, los extremos de las cuatro alas pueden conectarse por medio de riostras.

**33.** *Altura del carril.* La mesa se colloca por lo regular a tal altura que cuando esté sin carga sus carriles esten $^{3}/_{4}$ pulgs (como 2 cm) sobre los carriles de las vias mas cerca, de modo que deje $^{1}/_{4}$ pulg (6 mm) de espacio entre el carril circular y las ruedas de los extremos de la mesa cuando los extremos de las alas cedan ½ pulg (12 mm) bajo una carga equilibrada. La parte superior de los carriles de la mesa deben quedar parejos con los de las carrileras mas próximas al extremo por el cual una loco pueda entrar ó salir de la mesa. Se han empleado muelles de acero para amortiguar los choques ocasionados por las locomotoras que entran y salen.

**34.** *Los cimientos* de ambos, el del asiento ó descanso central y pared circular son usualmente de concreto; y por supuesto que deben construirse con cuidado (especialmente el asiento central) en vista del servicio fuerte a que están sometidos. El asiento central comunmente se cubre con un sillar. Cuando el fondo de roca no es accesible se meten pilotes debajo del asiento central, bajo el carril circular y bajo la pared del parapeto. Los que van bajo el asiento central son generalmente cuadrados, y de 4 a 7 o pilotes por lado cubriendo un area de 3,6 × 3,6 á 5 × 5 ms.

**35.** *La pared del circulo* es por lo regular de concreto (rara vez de madera), con remate de madera para soportar los extremos de las carrileras de las vías, y traviesas radiales de madera para soportar el carril circular. Cuando los carriles de las vias o el carril circular descansan directamente sobre el concreto, este último puede romperse con facilidad. La pared circular es generalmente de (1,8 a 2,1 m) en su mayor *ancho*, y la pared del parapeto de 0,5 a 0,6 m. Debido a su forma circular actúa como si fuera un arco horizontal.

**36.** *Un nicho* se deja en la pared circular en algun punto, conveniente de acceso al extremo de la mesa, para inspección, etc.

**37.** *Mesas giratorias de madera.* Se usan algunas veces, por motivos de economia, especialmente para uso provisional. En ciertos casos se hacen sin rolletes ó discos en el centro y entonces, al girar descansan sobre las ruedas del extremo ó sobre una serie de ruedas dispuestas en un círculo no distante del centro. En el último caso, la carga viva descansa parcialmente sobre las ruedas del extremo cuando entra ó sale de la mesa. Generalmente se necesitan dos hombres con un mecanismo de cigüeña para hacerlas girar. La economia hecha así, en el costo primitivo, puede hacer mayor el costo de reparacion ó sostenimiento.

**38.** *Fosa de desagüe.* Es siempre muy importante sobre todo con las fosas profundas que son necesarias para las locomotoras modernas pesadas. El agua en las fosas oxida las chumaceras y obliga a parar los trabajos para levantar con gatos para poder limpiar y aceitar. El agua congelándose en la fosa, puede paralizar completamente las operaciones. Donde el fondo de la fosa sea demasiado bajo para efectuar un desagüe conveniente, puede hacerse menos profunda por medio de uno u otro de los sistemas mencionados en ¶ ¶ 20-22.

**39.** Figs 7 y 8. * El centro es en síntesis una caja de acero circular, la tapa de la cual (que lleva los marcos) descansa sobre ella generalmente por medio de rolletes

* Informe de la Asca Am de Puentes y Edificios de F. C. 1912. A esta comisión con su informe detallado, adoptado en oct, 1912, le estamos agradecidos por muchas de las informaciones y recomendaciones que damos aquí.

cónicos, collar de bolas, o discos, de acero endurecido; *los rolletes cónicos*, fig. 7, son los que más se usan. Las mesas mejor hechas, están sostenidos en su lugar en general y radialmente por » anilos vivos (*live-rings*) que los rodean en su parte interior y parte exterior, y separados de ellos por collares de bolas o arandelas sin fricción. Los rolletes cónicos son comunmente de 17 a 30 cm de largo, y de 10 a 20 cm de diám en su extremo mayor. Generalmente descansan, arriba y abajo sobre *placas de via* anulares y delgadas relativamente, las que, cuando se gastan pueden cambiarse, dejando la caja y la tapa intacta. El trazado del centro se deja a menudo a juicio del fabrciante.

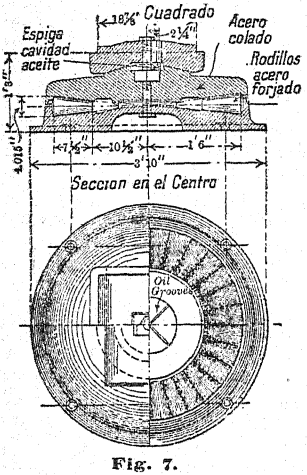

Fig. 7.

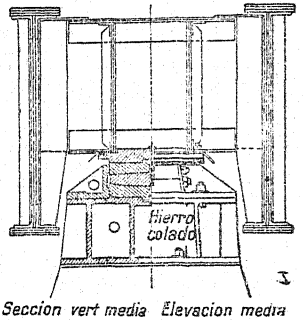

Fig. 8.

(18 7/8" = 47,94 cm; 2 1/4" = 5,71 cm; 1'3" = 38,12 cm; 4,015" = 10,31 cm; 7 ½" = 19,05 cm; 10 ½" = 26,67 cm; 1'6" = 45,74 cm.)

**40.** No obstante el uso con éxito de los *centros de disco*, fig. 8, en puentes giratorios, donde soportan cargas mas pesadas, no son aun de uso comun para las mesas giratorias. La comision * recomienda que sean estudiados seriamente.

**41.** Centros « Hydraulicos » (se usa aceite o glicerina en lugar de agua debido al temor de que se congele) se han indicado. Serían de fácil ajuste en su altura.

**42.** Los centros ó espigas son *muy importantes*. Deben usarse los mejores que puedan obtenerse. Tres cuartas partes de los F. C. usan rolletes cónicos o chumaceras de bolas, de tipos fijados por los manufactureros. Muchas de las dificultades anteriores con las chumaceras de rolletes, parece que se han debido al diseño defectuoso y a su tamaño pequeño, con el consiguiente descuido en su mantenimiento.

**43.** *El mecanismo debe aceitarse* cuando menos anualmente, y *anegarlo* tan a menudo como sea necesario, ó cuando la mesa se pone dura para girarla. Los marcos, o bastidores, etc., deben pintarse con frecuencia. *Para facilitar la inspección*, reparaciones, etc., la mesa se puede levantar con gatos; estos descansan sobre dos asientos de concreto, colocados diametralmente y levantados por medio de grampas de acero, remachadas á la mesa.

---

* Informe de la Asen Am de Puentes y Edificios de F. C. 1912. A esta comisión con su informe detallado, adoptado en oct, 1912, le estamos agradecidos por muchas de la informaciones y recomendaciones que se dan aquí.

**44.** El costo de las mesas giratorias varía mucho con muchos factores, pero los siguientes pueden tomarse como aproximados. Costo de la cubierta de acero de la *mesa giratoria completa*, con tractor, incluyendo fosa, etc., $100 por pie lineal; mesas giratorias continuas $150. Mesas giratorias de madera pueden costar tan solo como $15 o $20 por pie (30,5 cm) lineal. *Fosa*, forrada, incluyendo cimiento (del estribo central desde $0,50 a $1.30 por pie cuadrado ($5,4 a $14,00 por métro cuad); *pavimentado* solamente a menudo se omite), desde $1,70 á $2,7 por m cuadrado.

**45.** Triangulos de via. Véase desvios, ¶ ¶ 18, 19, pag. 900.

## Patios de clasificación.

**46.** El objecto principal del patio de clasificacion es recibir, desde uno ó mas puntos ó lineas, como *A*, *B*, *C*, *D*, etc., trenes en cada uno de los cuales, puede haber carros para cualquiera ó todos los otros puntos ó lineas, como *M*, *N*, *O*, *P*, etc., y así disponer los carros para preparar trenes nuevos, cuyos carros pueden ir directamente (ó con un mínimo de maniobras) a sus destinos respectivos, *M*, *N*, *O*, *P*.

**47.** Otros trabajos de menor importancia son la reclasificación similar (ó «Transferencia») del *contenido* de los carros, y las renovaciones generales y reparaciones.
